an index, which indicates upon a dial the degree of separation of the rollers corresponding to the thickness of the leather then passing between them, and enabling the operator to assort the strips.

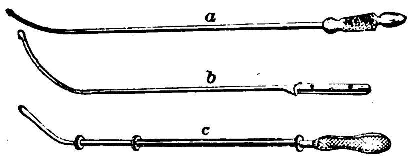
Sough. 1. (*Civil Engineering.*) A small drain at the foot of an embankment, to convey the surface water from it into a side drain.

2. (*Mining.*) *a.* An *adit* or *day level* for carrying off water.

b. The entrance to a mine.

Sound. (*Surgical.*) (Fr. *Sonde*, a canula or director.) A long instrument (*a b*, Fig. 5319), usually of metal and partaking of the nature of a probe. Used especially in making explorations in the bladder in search of stone. It is inserted through the

Fig. 5319.



Sounds.

urethra, and a peculiar click is heard when it comes in contact with stone.

c is Skene's uterine sound. The end of the probe being in contact with the fundus, the section having a button on the end is projected telescopically until it comes in contact with the cervix, and the distance from the button to the end of the sound is the length of the womb.

Leaden sounds are used to follow the curved path of a glancing ball. See PROBE.

Sonde de Anel; a silver stylet with awl-point, used in probing the lachrymal passages.

Sonde de Belloc; an instrument for plugging the nasal fossæ in cases of hemorrhage. A curved silver canula, open at both ends, and furnished with a button, to which the epistaxis plug is attached, and with which the posterior nostril is stopped.

Sonde Brisée; a probe in two sections, which screw together. It is blunt at one end, and has an eye at the other, so as to be used as a probe or seton needle.

Sonde à Conducteur; a guide for a catheter. It is introduced in company with a catheter of small size, open at the beak. The catheter being withdrawn, leaving the Sonde in position, the latter acts as a director in introducing a larger catheter.

Sonde de Saforest; a small nasal probe, or crooked canal, for throwing injections.

Sonde, or *Pincers of Hunter;* a silver canula, containing a wire, which is fenestrated, and has a pair of scoops which spring apart as they emerge from the beak of the canula, and by retraction clasp calculi in the urethra.

Sound-board. 1. (*Music.*) The upper surface board of a *wind-chest* in an organ.

It is pierced with channels, which communicate with the ducts below the respective pipes of the organ. These channels are guarded by spring valves, which are depressed by their appropriate keys on the *manual*, allowing air to escape from the wind-chest to the particular pipe or pipes as the keys are moved. The valves play between thin bars of wood, which divide the under surface of the *sound-board* into a series of parallel partitioned spaces.

On the upper side of the *sound-board* are grooves pierced with holes, which are commanded by the register slides of the respective stops. As the slide is pulled to open the holes, the communication is permitted to the pipes of a given stop, when the valve is depressed by the key of the manual. When more than one slide is opened, the opening of a given valve by the key admits air to so many pipes, which sound the corresponding notes according to their pitch and quality. See SOUNDING-BOARD.

2. A canopy over a pulpit, to direct the sound toward the audience.

3. (*Carpentry.*) Deadening. A partition or an additional division between two apartments, to prevent the propagation of sound from one to the other.

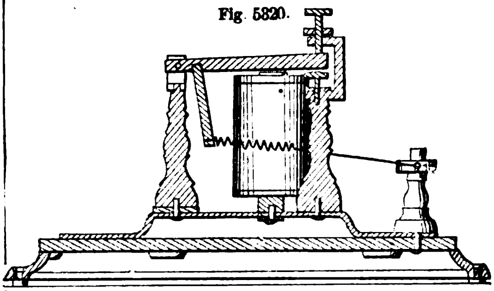
Sound-board'ing. (*Building.*) Short boards disposed transversely between the joists, in order to hold the pugging, which is designed to prevent the transmission of sound.

Sound-bow. That part of the bell on which the clapper strikes. The sound-bow is the point of greatest thickness, and is considered as unity in stating the proportions of the bell.

Sound-bow in thickness	1
Diameter at the mouth	15
Diameter at the shoulder	7.5

Sound'er. A device used in telegraphy in lieu of a register, the communications being read by sound alone. It consists of an electro-magnet with an armature having a lever attached thereto. The movement of the armature as it is attracted by the electro-magnet or withdrawn by a spring being lim-

Fig. 5320.



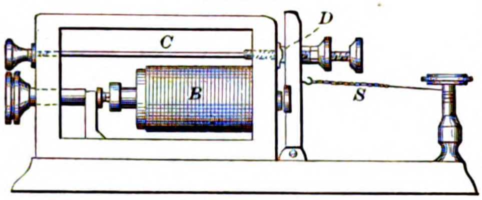
Sounder.

ited by two stops, between which the end of the lever plays and by the striking of which the sound is produced. In Fig. 5320, the posts which support the armature lever and the contact screws are mounted upon a bridge-plate supported at its ends upon an insulator-board, so as to give greater resonance to the blow of the armature.

Sound'er-mag'net. (*Telegraphy.*) The magnet which operates the sounder in the receiving apparatus. In Fig. 5321, the coil *B* is inclosed in a metallic box, the ends of which are maintained in a state of tension by means of a screw-rod *C*, which carries the anvil *D* on its end, the object being to increase the sonorousness of the vibrations caused by the pivoted sounder striking the anvil, and which are propagated through the box. *S* is the spring which draws back the sounder after each impulse of the magnet.

Sound'ing-ap'pa-ra'tus. (*Nautical.*) The

Fig. 5321.



Sounder-Magnet.

tackle or apparatus employed by mariners for ascertaining the depth of water and for bringing up specimens of bottom. The depth and the character of the ground, when on soundings, generally enables the navigator to ascertain approximately the distance from land and the position of his ship.

The lead and line are still in universal use. The former is elongated, has an eye at one end to receive the line, and a cavity, which is partially filled with an *arming* (tallow), at the other, to which the ground, especially if it be sand, shells, or fine gravel, adheres when the lead strikes the ground.

The common *hand-lead* for sounding weighs from 7 to 11 pounds, and is used with 20 fathoms of line.

The leadsman stands in the channels and casts the lead forward. The line is marked to fathoms below 5, and at 7, 10, 13, 17, 20 fathoms; the numbers between are called *deeps*, being estimated by the *dip* of the line. Thus: *by the mark, twain; by the deep*, 6. When great accuracy is required, the line is marked to fathoms and feet, and the leadsman is required to call out the sounding to the nearest foot. See Marks and Deeps, page 1401.

The *deep-sea lead* weighs 25 or 30 pounds, and has a much longer line, marked every 10 fathoms. The lead is dropped from the forepart of the vessel; the line being carried outside of the rigging from the after-part, where it is held.

For the deepest soundings the ship is hove to, and carefully constructed apparatus is used.

"A deeper sea than that of Sardinia has never been sounded, measuring, as it does, according to Posidonius, about 1,000 fathoms." — Strabo, Book I. Chap. 3.

The *catapirater* of the ancients differed in no respect from our sounding-lead and line. Its use is mentioned by Herodotus, St. Paul, and others.

Previous to some 25 years ago few attempts had been made to obtain bottom at depths beyond 200 to 300 fathoms.

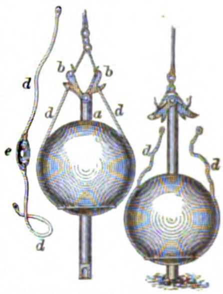
In 1849, the United States schooner "Taney" was fitted out for the purpose of looking up a number of the rocks, shoals, and "vigias" which had long disfigured the charts of the Atlantic Ocean, and for ascertaining, if practicable, its depth; for this purpose she was provided with a large quantity of wire, to be used in lieu of sounding line; this was to be cut when bottom had been reached, involving the loss of the wire and sinker. A number of unsuccessful casts were made, the materials and methods employed proving unreliable.

In 1851, the United States brig "Dolphin" was fitted out for the same objects, under the command of Lieutenant (now Admiral) S. Phillips Lee, twine being furnished in lieu of wire; after numerous experiments it was found that by sounding from a boat and taking proper precautions, bottom could be obtained with reasonable certainty at depths exceeding 3,000 fathoms; a line of soundings was run from near the middle of the Atlantic to the Cape de Verde Islands, thence to the coast of South America, and thence again to the United States, the greatest depth attained at which bottom was reached being 3,825 fathoms to the southward and eastward of Bermuda. One, two, or sometimes even three 32-pounder shot were used as sinkers, and when bottom had been reached, the boat, anchored thereby, was used for testing currents at and below the surface.

A subsequent cruise in 1852-53, when the vessel was provided with the sounding-apparatus then just invented by passed midshipman J. M. Brooke, United States Navy, confirmed the results previously obtained.

This consists of a rod *a*, having pivoted horns *b b* at its upper end, to which the sounding-line *c* is secured. Two wires *d d* extend from the horns, around the shot or lead, which is perforated for the reception of the rod, and are secured to a washer *e* beneath it. On striking bottom, the rod is thrown up, releasing the wires from the shot and enabling the rod to be drawn up by itself. A small Stellwagen cup may be attached for procuring specimens of bottom. This was the first device by which specimens of bottom from great depths — 2,000 fathoms or more — were secured. These were found to consist principally of minute infusorial shells, which were then supposed to be denizens of the upper regions of the sea, and had sunk to the bottom after death. The latest researches, however, prove the existence of low forms of animal life at the greatest depths which have yet been reached.

Fig. 5322.



Brooke's Sounding-Apparatus.

Reference has been made in various works to a sounding of 7,706 fathoms, said to have been obtained by Captain Denham of H. M. S. "Herald," off the river Plate; there can be little doubt, however, that when this amount of line had been run out the ship was miles to leeward of the sinker (a 9-pound lead), and no subsequent sounding in any part of the world leads us to infer that the ocean anywhere attains nearly this enormous depth.

The latter cruise of the "Dolphin" and soundings subsequently made by other vessels established the existence of a plateau extending from Newfoundland to the coast of Ireland, having a nearly uniform depth of somewhat over 2,000 fathoms; upon this the transatlantic cables have been laid.

A similar investigation is now being made of the bed of the North Pacific. The United States steamer "Tuscarora," Commander Belknap, has ascertained that the depth of water gradually increases with a gentle slope from a point 115 miles west of San Diego, California, in 1,915 fathoms, to a point 400 miles east of Honolulu, where it reaches 3,054 fathoms: at the shore ends of this line the soundings are more irregular, indicating the presence of submarine mountain-ranges.

The Pacific will also form the cruising-ground of the "Challenger," which vessel, being provided with ample apparatus, not only for sounding, but for obtaining specimens of bottom, and having fully demonstrated the practicability of procuring living organisms at depths exceeding 2,500 fathoms, will no doubt throw much light on the sea depths and their inhabitants.

The British admiralty now employs a cast-iron sinker, weighing 3 cwt. (for soundings of 2,000 fathoms and upward), through which is passed a valved tube for bringing up specimens; the weight is detached on reaching the bottom, but it is now proposed to raise it; in either case steam is employed for hauling in the line. In making a sounding of 2,000 fathoms, some 35 minutes is required for the descent, and 45 minutes in hauling in. The line employed is $\frac{7}{8}$ inches in circumference, and will bear $\frac{1}{2}$ ton weight.

Sir William Thomson proposes the use of steel wire. With this, using a 30-pound lead, he states that he obtained bottom in the Bay of Biscay at 2,700 fathoms.

In the sounding-apparatus of Professor Trowbridge, the coil of line is inclosed in a hollow cylindrical case, which is connected with the lead, and unwinds from the center as the latter descends, avoiding the friction of the water and securing a uniform and rapid rate of descent. The time of descent proper to any given depth may be ascertained by experiment and tabulated, so that the time which elapses between heaving the lead and its striking the bottom becomes a measure of the depth. In order to ascertain the precise instant when the lead touches bottom, a fine insulated wire is connected with the lead, and also with an alarm or chronoscope, and a battery in the boat from which the observation is made. The impact of the lead on the bottom completes an electric current, and the time of descent is thus ascertained.

Professor Trowbridge has also employed a pair of Saxton's current meters in connection with the tube containing the line. This instrument consists of a delicately pivoted helix, which is turned by the action of the water, and registers the number of revolutions made on a series of dials. Two of these helices are employed, turning in opposite directions for the purpose of eliminating any error which might occur from the twisting of the line or other similar cause. Arrangements are provided for disconnecting the registering apparatus when the lead reaches bottom.

The helix of Massey, such as that employed in his patent log, has also been used, but owing to its want of delicacy does not give as satisfactory results as those of Saxton's current meter.

In sounding at extreme depths, it is not expected to recover the plummet, but arrangements are made for detaching the registering apparatus or the devices for obtaining specimens of bottom, which may then be hauled up with comparative ease and safety.

It has been proposed to dispense with the sounding-line altogether, and employ a buoyant self-registering apparatus, which is detached from the plummet when the latter strikes bottom. Hollow spheres of glass have been proposed for this purpose. It is said that these have been made capable of resisting a crushing force of seven tons to the square inch, corresponding to the pressure at a depth of about six miles. In connection with these it has been proposed to employ a pressure-gage, registering the maximum hydrostatic pressure to which the apparatus has been subjected.

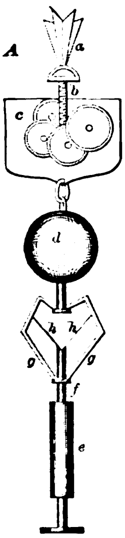
It has also been proposed to ascertain depths by a method founded on the compressibility of water. The unreliability of these latter modes of sounding, and the practical difficulties

in carrying them into execution, have precluded their use, so that they may be looked upon as little more than ingenious theoretical devices.

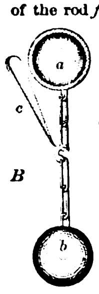
An instrument invented by Messrs. S. E. and G. L. Morse, of New York, and termed by them the bathometer, is designed for measuring the depth without the aid of a sounding-line. It consists of a buoy attached to a sinking weight, from which it is disconnected on reaching bottom, and containing a graduated meter tube, into which mercury is forced by the compression of water or other fluid consequent upon the pressure at a great depth. The buoy is provided with a rod, to which reflectors are attached, rendering it visible for a considerable distance on arriving at the surface.

Other expedients have been proposed for dispensing with the line required in making deep-sea soundings by causing a float to be detached from the sinker when bottom is reached, the depth being registered by an apparatus which rises with the float, or inferred from the length of time occupied by the float in descending and again ascending to the surface.

Fig. 5323.



A (Fig. 5323) is a device of the former kind, proposed by a writer in the English "Nautical Magazine" in 1832. It consists of a set of spiral vanes *a*, which, during the descent of the apparatus through the water, turn an endless screw *b* operating registering-wheels on the plate *c*; from this is suspended a hollow ball *d*. The sounding-lead *e* is placed on a rod *f*, having pivoted or easily detachable arms *g g*, which rest on the flanged bottom of a stem projecting from the lower part of the ball *d*. On striking bottom, struts *h h* at top of the rod *f* throw the arms *g g* outward, detaching the float, which, with the attached registering apparatus, rises to the surface.

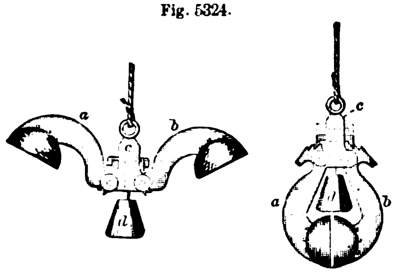


Sounding-Apparatus.

B is a device proposed in 1833, in which a registering apparatus is dispensed with. Two balls, one (*a*) hollow, the other (*b*) solid, are connected by links and by a flattened arm *c* attached to one of the links fastened to the lower ball, and having a hook which catches in one of the upper links. During the descent of the apparatus the action of the water on the flat surface of the arm *c* would cause it to project upwardly, tending to hold the two balls together, but on striking bottom the arm falls, the float is detached and rises to the surface. The time elapsing between the moment of its being cast overboard and its reappearance, the exact rates of ascent and descent being of course previously determined, affords a measure of the depth. Should it not, however, be found for several weeks, or perhaps months, having perhaps drifted many hundred miles in the mean time, the candid mind must admit that the depth derived from calculations based on the above data would be slightly in excess of the truth. We are inclined to think that most persons who have seen a cast of say 2,000 to 4,000 fathoms made at sea would never expect to see the float again, unless it became detached at a comparatively short distance beneath the surface.

The device (Fig. 5324) was invented by M. Toselli, an Italian engineer officer. It consists of two arms *a b*, having hemispherical cups at their ends and pivoted to the support *c*, to which the sounding-line is attached. A cross-head at the upper end of a stem, to which the weight *d* is attached, engages the ends of the arms, keeping them apart until bottom is reached, when they are released by the upward movement of the weight, and come together, securing some of the bottom between them: when lifted from the ground the weight again falls, the branches of the cross-head engaging notches in the upper ends of the arms, and holding the cups together.

Fig. 5324.



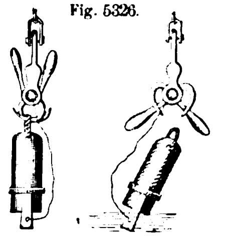
Toselli's Sounding-Apparatus.

For bringing up specimens from moderate depths, the ordinary STELLWAGEN CUP (which see) is very efficient; but for greater distances, devices which more certainly prevent the surrounding water from washing out the mud or other substance are preferred. One of these, invented by Dr. Wallich, was employed on the "Bulldog"; it consisted of two hemispherical cups, upon which the sinker rested during its descent; these were kept apart during the descent of the sinker, but were caused to close together when bottom was struck, inclosing and protecting the matter which they had scooped up, the lead being at the same time detached (Fig. 5325).

The "hydra" of Captain Shortland is now generally used in the British service. It consists of a strong tube with upwardly opening valves, which admit the mud or sand composing the bottom when the sinker strikes, but are closed by gravity during the upward movement.

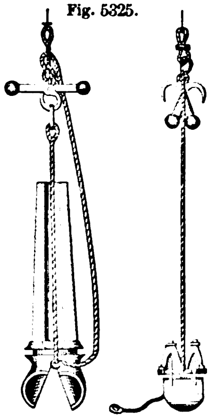
Fig. 5326 is an apparatus employed at one time in the British navy; the weight of the sinker suspended from the weighted jaws holds them together until bottom is reached, when the sinker capsizes, the jaws fall over, and it becomes detached, allowing a wedge-shaped specimen cup to be withdrawn, for the purpose of bringing up a portion of the ground.

Fig. 5326.



British Navy Apparatus.

Fig. 5325.



"Bulldog" Apparatus.

An apparatus devised by Commander Belknap, United States Navy, consists of two cylinders, the upper of which slides within the other; the lower has a cup at its lower end which penetrates the ground when bottom is reached; the upper cylinder then telescopes into the lower, forming a protecting cover to the specimen. Upwardly opening valves permit the water to pass freely through during the descent of the lead, and close when the line is hauled in.

Sound'ing-board. (*Music.*) A thin board over which the strings of a piano, violin, guitar, etc., are stretched, and which propagates and enhances the sound. It is made of the best pine, free from knots and flaws. It is cut in a particular direction of the grain. See also SOUND-BOARD.

Sound'ing-bot'tle. A vessel employed for drawing up water from considerable depths in the sea, for examination and analysis. It frequently contains a thermometer for ascertaining sub-surface temperatures. See Fig. 5327.

A usual form is of wood, and has upwardly opening valves at top and bottom. It is bent on to the sounding-line above the lead, the water passing freely through during the descent, but being prevented from escaping during the upward movement by the valves, which close by gravity. See THERMOMETER.

Sound'ing-lead. (*Nautical.*) The weight used at the end of a line in sounding. See next article. See also SOUNDING.

Sound'ing-line. (*Nautical.*) The line which holds the sounding-lead.

The *hand*-lead weighs from 7 to 11 pounds, and has a line of 20 fathoms.

The ordinary *deep-sea* lead weighs 25 to 30 pounds, and has a length of 200 fathoms. See SOUNDING.

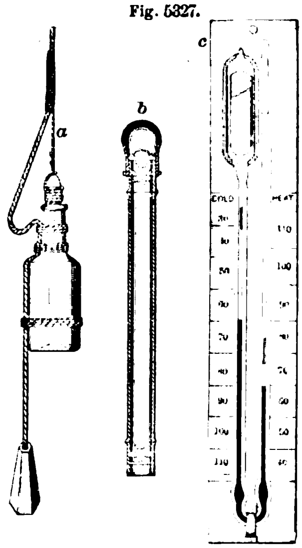
Sound'ing-post. (*Music.*) A post set beneath the bridge of a violin, violoncello, etc., for propagating the sound to the body of the instrument.

Sound'ing-rod. (*Nautical.*) A graduated iron rod, used for ascertaining the depth of water in the well on board ship.

Sound'ing-ther-mom'e-ter. A thermometer for registering temperature at great depths in the sea.

c (Fig. 5327) represents an instrument of this class. It is a bent thermometer, with a large bulb at one end and a small elongated bulb at the other. The large bulb contains a mixture of creosote and water; the small one contains compressed air, below which there is a little creosote and water; the bend of the tube is filled with mercury, which bears a small steel rod on either surface, capable of sustaining itself in the tube by friction until moved by the mercury. When heated, the expansion of the liquid in the large bulb drives the mercury down in that tube and up in the other, both ends marking the degree of heat on the reversed scales. When the thermometer is sunk in deep water, the index moves back and registers the lowest temperature on the side of "cold." To prevent compression of the larger bulb, it is surrounded by a stronger vessel, partly filled with alcohol, which transmits the temperature to the inclosed bulb.

Fig. 5327.



Water-Bottles and Thermometer.

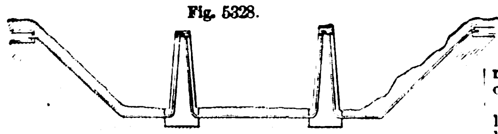
Sou'ple. (*Husbandry.*) That part of the flail which is beaten upon the grain. It is joined by the *hooding* to the *hand-staff.*

Sour'ing. A part of the process of bleaching in which the goods, having been previously placed in a solution of chloride of lime, are exposed to a dilute solution of sulphuric acid, which sets free the chlorine and whitens the cloth. It also neutralizes the alkalies, which have been used in previous treatment of the cloth.

Sour-ket'tle. A vessel used in souring bleached cloth.

Sou'ter-a-zi'ci. (*Hydraulic Engineering.*) The Turks introduced into Europe a mode of crossing ravines by a series of siphons, which consisted of earthen pipes deriving their supply from an upper reservoir, thence descending a hillside, running along part of a valley, and mounting into an intermediate reservoir, supported upon piers of masonry at a rather lower level than the first reservoir. From this second

Fig. 5328.



Souterazici.

source of supply, pipes were conducted down the opposite side of the pier, again along the valley, and successively into a third, or more, reservoirs, at gradually decreasing elevations, and so on to the opposite side of the valley. Their object seems to have been to save the outlay necessary for the construction of masonry bridges; and it is stated that it was intended to diminish the chances of rupture in the earthenware pipes of which the siphons were formed.

A large work of this description is erected upon the ruins of one of the great bridge aqueducts of ancient Constantinople, and which was destroyed during one of the sieges of the city.

Sow. (*Founding.*) The main trough (or the body of metal contained therein) leading from the tap-hole of a cupola or smelting-furnace, and from which ramify the passages leading to the separate molds in casting; or to the shallow ditches in the floor which receive the *pigs* of cast-metal.

Sow'er. Among the ancient Egyptians the modes of seeding were various. It was common to sow on the mud left by the retiring Nile as he receded within his banks, — Osiris retiring from the lap of Isis, according to the mythology of that great and learned nation. The seed was then tramped in by driving goats or sheep over the soil, as we see by paintings in tombs near the pyramids. The more usual practice, however, was to cover it by the plow or hoe. A painting in a pyramid at Memphis shows the sower carrying a basket and sowing broadcast in advance of the plow.

The Hebrews sowed grain broadcast. Sometimes from a basket, probably, as in Egypt, and sometimes from a pocket made by a fold of the garment. This was a common receptacle for things to be carried, such as a measure of wheat or a lamb.

"Good measure, pressed down, and shaken together, and running over, shall men give into your bosom." — Luke vi. 38.

"He shall gather the lambs with his arm, and carry them in his bosom." — Isaiah xl. 11.

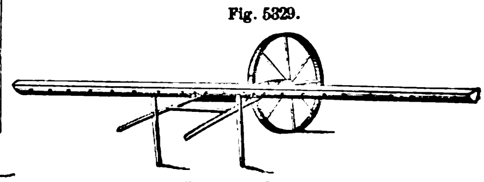
In Ohio it is common to use a two-bushel bag; the bag-string is tied to one lower corner, the bag carried over the right shoulder and under the left arm; the left hand holds the mouth open, so that the right hand may be readily reached into it to gather a handful of seed, — a cast for each step of the right foot.

"Doth the plowman plow all day to sow? doth he open and break the clods of his ground? When he hath made plain the face thereof, doth he not cast abroad the fitches, and scatter the cummin, and cast in the principal wheat and the appointed barley and the rye in their place?" — Isaiah xxviii. 24, 25.

Seed in ancient Greece was sown by hand and covered with a rake. — THEOPHRASTUS, 371 B. C.

One form of broadcast sower consists of a long hopper, provided at bottom with small openings, through which the seed passes. The openings are adjustable in size by means of a register plate, and are fed to the openings by a perforated plate above, which is reciprocated by a lever. The hopper may be 10 or 12 feet long, and is slung by a strap over the back of the

Fig. 5329.



Broadcast Sower.

neck, leaving one hand free to steady the hopper, while the other operates the trigger.

The same device is mounted on a barrow, and the feeding-lever operated by a trigger, cam, or other device put in motion by the wheel.

In Rogers' broadcast sower, operated by hand, the seed passes from a bag fixed upon the shoulder of the person sowing, to a revolving scatterer connected with the bag, and rotated alternately in opposite directions by a strap worked by a reciprocating rod, the seed being thrown out by centrifugal force. See BROADCAST SOWER; FERTILIZER SOWER, SEED-SOWER; DRILL, etc.

Sow'ing-ma-chine'. (*Husbandry.*) See SOWER; DRILL; PLANTER; GRAIN-DRILL.

Space. (*Printing.*) A thin piece of type-metal, shorter than a type, and used to separate the letters in a word or words in a line, so as to *justify* the line.

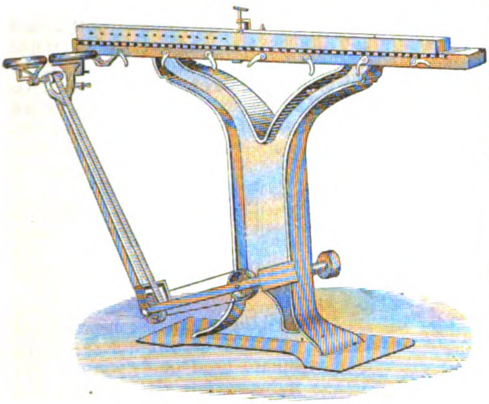
A *lead* separates the lines where the matter is *displayed.*

Space-line. (*Printing.*) A thin strip of metal, not so high as the type, used to separate and display the lines. A *lead.*

Space-rule. (*Printing.*) Fine rules of the hight of the type, of any length, and used for setting up tabular matter, etc.

Spac′ing and Bor′ing Ma-chine′. (*Wood-working.*) A machine for boring blind-stiles, sashes, etc., at accurately equal distances. The work is se-

Fig. 5330.



Blind-Stile Spacing and Boring Machine.

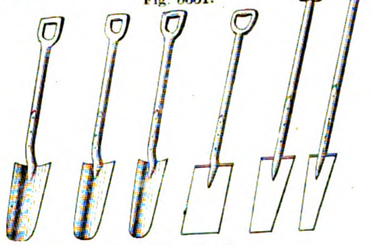
cured to the table by a thumb-screw. At the front edge of the table is a strip having notches and spaces at equal distances apart, the notches serving to retain the bit in proper position while boring.

The bit is attached to a jointed frame pivoted on the driving-shaft, so that a continuous rotary motion is imparted at whatever part of the stile it is applied. The operator grasps the handle and commences boring at either end.

Spad′dle. (*Husbandry.*) A small spade. A *spud.*

Spade. 1. (*Husbandry.*) A square-bladed digging implement, in which two hands and one foot are engaged.

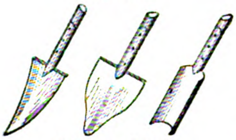
Fig. 5331.



Draining-Spades.

Spades for ditching assume many forms, especially in England, where the blade is made to correspond to the shape of the cross-section of the ditch. This is all very well to a certain extent, but all such ditches may be made by machines drawn by horse-power, either as plows or excavators. Where the ground admits, the team may be hitched to the machine; in wet soil the machine may be drawn by a rope from a capstan moved by a horse walking in a circle See CAPSTAN.

Fig. 5332.

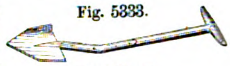


Ditching-Spades.

In the United States, ditches too large for the ditching-plow are made by the usual spade and shovel, or in some cases — and this will move more soil for the same money than any other mode — the ground is plowed and then moved away by the scraper. It may be finished by the shovel. This plowing and scraping does not give the symmetrical, steep bank so much coveted, but is a vast saving of manual labor.

The turf-spade is adapted for cutting sods, one upturned edge severing the sod while the blade cuts the roots. The use of turf in many parts of the British Islands is common, for fuel and for filling in the walls of shelters. The business of getting the winter supply of turf for fuel interests millions in that country, and probably some others with which we are not so well acquainted. It is stacked and thatched after having been cut, dried, and carted. It makes a good hot fire, something like peat, which it resembles in appearance and constituents.

Fig. 5333.



Turf-Spade.

The thistle-digger is a pronged tool, intended to catch the root below the crown, and then pry out the plant. The iron portion of the tool has a foot-tread, and a prong which rests on the ground to form a fulcrum; a blade cuts the root if the fork fail to withdraw the plant.

Fig. 5334.

Thistle-Digger.

The spade, as a digging instrument, does not seem to have been known in ancient Egypt. Its place was supplied by a heavy hoe. (See HOE.) Shovels are illustrated in ancient Egyptian paintings in connection with the moving of grain and gold-washing.

The ancient Greek spade had two cross-pieces for the foot, so as to dig right or left handed. The modern Irish spade has a single cross-bar for use with the right foot. It has a very long curved blade, and a long handle, with or without a bow, for a hand-hold.

The Japanese spade has a wooden handle, and a blade shod with iron.

The Roman *pala* or spade was shod with iron, and had a cross-bar for the foot in digging; this enabled it to be driven farther into the ground than when the foot rested on the blade. The same tool, called *vanga,* is yet used in Italy.

The spades of the Feejees, when first discovered, were poles of

Fig. 5335.

Ancient Greek Spade.

Fig. 5336.

Irish Spade.

Fig. 5337.

Japanese Spade.

the mangrove-tree, slanted off at the end, to form a sort of chisel. A group of three or four men, each with such a tool, stood in a circle, and with repeated strokes loosened a circular piece of earth of about 2 feet surface diameter; the spades were then used as levers to raise the mass, which was then broken up by boys.

The Maori implement of New Zealand was substantially similar. Digging with a sharp hand-spike. The same of Tahiti.

2. (*Seal-engraving.*) A soft iron tool, 3 or 4 inches long, and with the end filed to an angle of 45° and charged with diamond-powder. It is used to dress

Fig. 5338.

Rice's Spade-Bayonet.

off irregularities from the rounded surface of a cameo figure.

3. (*Nautical.*) A cutting implement used in flensing the whale. A *blubber-spade.*

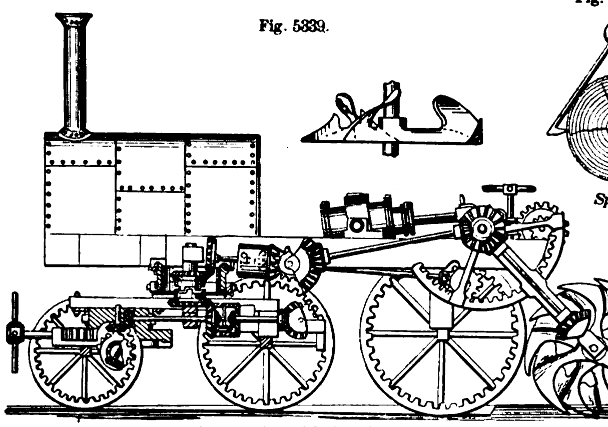
Spade-bay'o-net. (*Military.*) A broad-bladed bayonet, which may be used in digging shelter-holes or rifle-pits. A TROWEL-BAYONET (which see).

Spade-han'dle. (*Machinery.*) A pin held at both ends by the forked ends of a connecting rod.

Spa'der. A DIGGING-MACHINE (which see).

In the locomotive-spader (Fig. 5339), the crank-shaft of the engine is connected by gearing with each pair of wheels. Equalizing gears between the axles permit each wheel to adopt its proper speed in turning curves. The front truck-wheels and the driving-wheels at the rear have clutches by which they may be thrown in or out of connection with the engine. The spades also may be uncoupled and elevated when required. The sharp-pointed spades enter the ground nearly vertically, like a pick, and have wings which lift and turn over the clod after the manner of a plow's mold-board. They rotate in the direction in which the machine moves, and assist the draft of the wheels.

Fig. 5339.



Locomotive with Spading-Apparatus.

Spad'ing-ma-chine'. See DIGGING-MACHINE, pages 702, 703.

Spa-droon'. A light cut-and-thrust sword.

Spake-net. (*Nautical.*) A crab-net.

Spald'ing-knife. One used in splitting codfish.

Spale. 1. (*Shipbuilding.*) A strengthening cross-timber.

2. A lath. A *pale.*

Spall. (*Masonry.*) A chip of stone, removed by the hammer.

Spall'ing. 1. (*Mining.*) Breaking by a hammer the ore previous to *cobbing.* It follows the operation of the heavier hammer, called *ragging.* The *spalling* is for the purpose of removing portions of gangue and valueless rock. The subsequent *cobbing* is for the reduction of the blocks of ore to a smaller size.

2. (*Masonry.*) Reducing irregular blocks of stone to an approximately level surface by oblique blows of a stone hammer, which detaches flakes of stone from the mass.

Spall'ing-ham'mer. (*Masonry.*) An axe-formed, heavy hammer, used in rough-dressing stones.

Span. 1. (*Architecture.*) The chord or reach of an arch. The distance between *imposts* at the *springings* of the arch.

2. (*Nautical.*) *a.* A rope secured at both ends to an object, the purchase being hooked into the bight.

For hoisting in boats they are fitted with a hook at each end; on the bight is either a traveling thimble or a thimble strapped at the center, into which the purchase is hooked.

b. A leader for running rigging, which is conducted through a thimble at each end of the span, which is secured to the stay by a lanyard at the bight. The main-braces are thus spanned to the mizzen rigging to keep them clear of the boat davits.

c. To *span the booms* is to confine them by lashings.

d. The *span of the shrouds* is the length of the shrouds from the *dead-eyes* on one side over the mast-head to the dead-eyes on the other side of the ship.

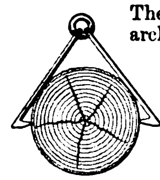
Span-beam. (*Mining.*) The horizontal beam into which the upper pivot of the axis of the whin is journaled.

Span-block. (*Nautical.*) One attached to each end of a span or length of rope which lies across a cap and hangs down at each side.

Span'cel. (*Manege.*) A hobble.

Span-dogs. A pair of dogs linked together and used to grapple timber, the fangs of the extended ends being driven into the log.

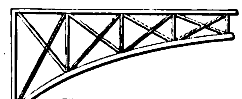
Fig. 5340.



Span-Dogs.

Span'drel. (*Architecture.*) *a.* The space over the haunch of an arch and between it and the out-scribing rectangle; between the extrados of an arch and the square head or drip-stone over it.

Fig. 5341.



Timber-Spandrel.

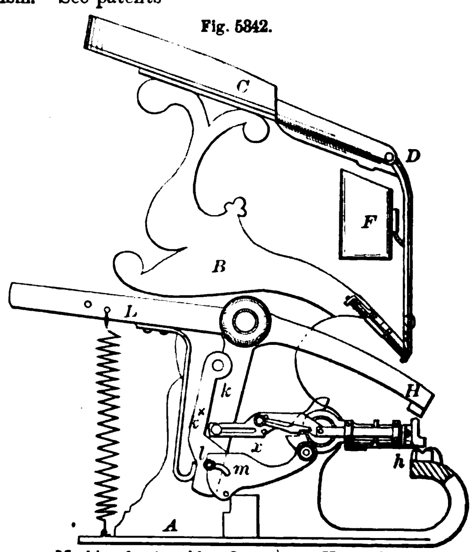
b. The space between the outer moldings of two arches and the string-course above them.

When timber arches support a roadway, the spandrels contain upright posts with diagonal stays. The posts transmit the load to the arch.

Span'drel-wall. (*Masonry.*) One built on the extrados of an arch.

Span'gling-ma-chine'. A machine for setting and securing the clasps or *spangles* by which the wires and tapes of hoop-skirts are secured together. The spangles are placed in a hopper, and automatically take their place in line in an inclined feeding-chute, which leads them to the clinching mechanism. See patents —

Fig. 5842.



Machine for Attaching Spangles to Hoop-Skirts.

No. 35,666.	Beck	June 24, 1862.
No. 36,877.	DeForest	Nov. 4, 1862.
No. 37,124.	Baird	Dec. 9, 1862.
No. 37,992.	Wilmot	Mar. 24, 1863.
No. 50,728.	Olmstead	Oct. 31, 1865.
No. 54,939.	Neumann	May 23, 1866.
No. 64,543.	Komp	May 7, 1867.
No. 71,492.	Jenkinson	Nov. 26, 1867.
No. 79,810.	Carter	July 14, 1868.

In Fig. 5342, the frame *A* carries a standard *B*, supporting the inclined trough *C*, into which a quantity of the spangles are placed. These slide down by gravity, and on reaching the throat of the spangle-guide *D*, those which are not in proper position for fixing are arrested, not being able to pass between the side of the guide and a projecting rib, which acts as a separator, and are dropped into a receptacle *F*. The others continue to slide down the channel of the guide until reaching its lower extremity, where a sliding-gate is provided to arrest them.

The lever *L* is rocked by a treadle, and has a lower branch *k* carrying a rocking arm k^x, provided with a pin *l*, which enters a slot in the lever *m*, establishing a loose connection between the two, and serving, when the end *L* of the lever is depressed, to lift the spangle-carrier *h* up to the mouth of the spangle-guide, where, the sliding-gate being opened by the same movement, a spangle is fed into the spring-jaw of the spangle-carrier, which is reciprocated by a slotted piece *x* engaged by a pin on the arm *k*. The opposite movement of the lever brings down the spangle-carrier upon a horn, where the skirt is held, and forces the spangle through the tap, while by a farther movement the carrier is drawn out of the way, while the hammer *H* falls and clinches the spangle.

Span'ish Bur'ton. (*Nautical.*) A *single* Spanish burton has three single blocks or two single blocks and a hook in the bight of one of the running parts. See Fig. 996, page 413. See also PULLEY, page 1819.

A *double* Spanish burton has one double and two single blocks.

Span'ish Stripes. (*Fabric.*) A kind of woolen fabric.

Span'ish Tu-ta'ni-a. An alloy composed of 24 parts tin, 2 antimony, and 1 steel.

Span'ish White. Finely powdered and levigated chalk, used as a pigment.

Span'ish Wind'lass. (*Nautical.*) One turned by a rope with a rolling hitch and a handspike in the bight.

Spank'er. (*Nautical.*) A four-cornered, *fore-and-aft* sail, whose *head* is extended by a *gaff*, and

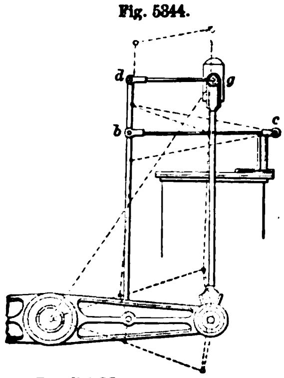
Fig. 5343.

Spanners.

its foot by a *boom* or a *sheet*. Sometimes called a *gaff-sail*, fore or main. Specifically, the *trysail* on the mizzen-mast. A *driver*.

Span'ner. 1. A fireman's wrench by which he fastens or unfastens the couplings of the hose. The curve follows the shape of the coupling, and the eye is caught over the stud on the collar, so as to wrench it fast or loose it, as the case may be.

Fig. 5344.



Parallel Motion for Side-Lever Engines.

Another form of spanner has merely jaws which fit upon nuts or faceted collars. See MONKEY-WRENCH, Fig. 3214, page 1473. See also WRENCH.

2. (*Steam-engine.*) A bar used in the parallel motion of the side-lever marine-engine. *b c*, *radius-rod*; *d g*, *spanner*. See PARALLEL MOTION, Fig. 3549, page 1631.

Span-piece. (*Carpentry.*) The collar-beam of a roof.

Span-roof. (*Building.*) One having two inclined sides.

Span-saw. A frame-saw.

Span-shack'le. (*Shipbuilding.*) *a.* A large bolt driven through the forecastle and spar-deck beams and forelocked before each beam with a large square or triangular shackle at the head for receiving the end of the davit.

b. A bolt driven through a deck-beam, and having a shackle for securing a boat, boom, or anchor.

Spar. 1. (*Nautical.*) A long, wooden beam, generally rounded, and used for supporting the sails of vessels. It assumes various functions and names, as a *mast*, *yard*, *boom*, *gaff*, *sprit*, etc.

2. In hoisting machinery, *spars* form the *masts* and *jibs* of derricks, and the elevated inclined timbers which form *sheers* for masting and dismasting vessels.

3. In building, *spars* are used as *rafters*, as *scaffold-poles*, as *ledgers* to rest on the *putlogs*.

A common rafter is sometimes called a *span*.

4. A pole lashed to a disabled carriage as a substitute for a wheel.

5. (*Mining.*) An earthy, lustrous mineral, which is often associated with ores, such as lead, copper, and tin, forming the gangue or matrix of the ore. It is known among miners by its characteristic color, as *white* spar, *black* spar, etc.

The word has many interesting mineralogical significations, such as *fluor spar*, a beautiful, crystalline fluoride of lime, the double-refracting *Iceland spar*, etc., etc.

Spar'a-ble. A cast-iron nail driven into soles of boots and shoes, and so called from its resemblance in shape to a *sparrow-bill*.

Spar'a-drap. (*Pharmacy.*) An adhesive plaster spread upon linen or paper.

Spar-a-dra'pi-er. (*Pharmacy.*) A machine for spreading plasters. It is a table with two raised pieces, movable and furnished with points by which the cloth may be stretched, and a spatula for spreading the composition.

Spar-deck. (*Nautical.*) Originally one of a temporary character, consisting of spars supported on beams. Now, the upper deck, with an open waist, or flush-deck. The term is somewhat loosely applied.

Spare An'chor. (*Nautical.*) A supplementary anchor, the size of the bower.

Spare Gear. (*Machinery.*) Extra parts carried in steamers to replace any portions of the machinery which may be broken or injured at sea.

The following is a list of tools and spare gear for a naval tender, and may serve as an illustration: —

LIST OF TOOLS AND SPARE ARTICLES FOR ENGINES (WITH SCREW-PROPELLERS) OF 450 HORSE-POWER.

Engineers' Tools.

	No.
Brushes, for boiler-tubes, to every 100 horse-power	20.
Drifts, short and long, to every 100 horse-power	1 each.
Fire-irons	12
Mandrels, to every 100 horse-power	1 each.
Scrapers, circular and forked, to every 100 horse-power	5 each.
Spanners and wrenches, of sorts	24
Stocks, taps, and dies, from ¼ to 1¼ inch	1 set.

Spare Gear.

Air-pump side-rods, with straps and brasses complete (if so fitted)	2
Air-pump rod	1
Air-pump cross-head (if so fitted)	1
Bars, furnace	½ set.

	No.
Bearers	3
Boiler-plates	6 cwt.
Bolts and nuts for engines, properly assorted	120
Cylinder-lid	1
Cylinder cross-head (if so fitted)	1
Ferrules for boiler-tubes, to every 100 horse-power	50
Piston and rod	1
Propeller and shaft complete	1
Rod, connecting, with strap and brasses complete	1
Rod feed-pump (if so fitted)	1
Rod bilge-pump (if so fitted)	1
Rod-slide	1
Screws, packing, for slides, complete for one engine	1 set.
Springs for each piston (if so fitted)	1 set.
Springs for other parts of engines, for one engine	1 set.
Tubes, boiler, to every 100 horse-power	10
Tubes, glass, for barometers	2
Valve, foot, without seat	1
Washers, iron	100

The term is equally applicable to the parts of any machine which may be duplicated.

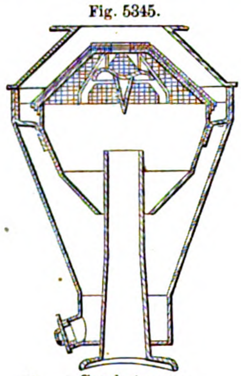
Spare Sail. (*Nautical.*) A duplicate of any of a ship's sails, reserved for use in case one already bent is carried away or is unbent for repairs.

Spar′ger. A sprinkler; usually a cup with a perforated lid, or a pipe with a perforated nozzle. Used for damping paper, clothes, etc.

Spark-ar-rest′er. A device placed upon the chimney of a locomotive or a portable engine, to prevent the passage of sparks from the chimney. Also called a *spark-consumer*. It has usually a wire cage to prevent the passage of sparks, but, in order to prevent impairing the draft, it is usual to depend upon catching the sparks after the first rebound and collecting them in some place out of the danger of being again carried away by the draft.

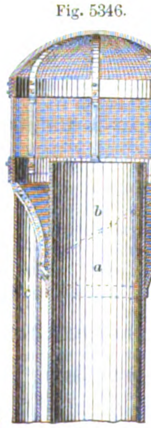
In Fig. 5345, the inner casing forms a hood over the pipe, and is covered with wire gauze, below which is suspended a conical deflector, by which the sparks are directed downward into the inner casing, from whence they pass into the reservoir below through the annular opening between the pipe and the casing.

Fig. 5345.



Spark-Arrester.

Fig. 5346.



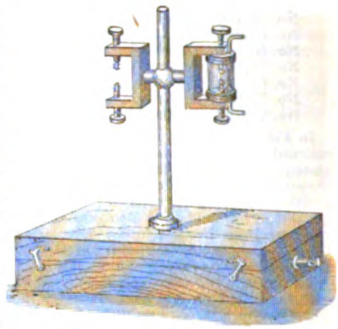
Spark-Arrester.

Fig 5346 is a view of a chimney-cap designed for portable engines for thrashing, where there is danger of communicating fire. The draft carries the smoke and sparks directly upward through the pipe *a* against the fine wire-netting, whose meshes are too small to allow sparks to pass. They rebound to the inclined conveyor *b*, and gravitate through the cinder-pipe *c* to a receptacle on the ground.

Spark-con-dens′er. 1. (*Electricity.*) An instrument having a glass cage in which a spark may be passed between the battery connections. It is used for burning metals or obtaining the spectra of gases, and is designed to isolate the atmosphere in which the experiment is conducted, so as to eliminate accidental disturbing causes; also to enable the experiment to take place in an atmosphere of any required condensation or tenuity.

2. (*Railway.*) A means of carrying away sparks from a locomotive chimney to a chamber where they are extinguished. A pipe from the locomotive over the top of each car to the rear has been proposed.

Fig. 5347.



Spark-Condenser.

Spar-piece. (*Carpentry.*) The collar-beam of a roof. A *span-piece*.

Spar′row-bill. *Sparable.* A shoe-brad.

Spat′ter-dash. A leather legging for equestrians.

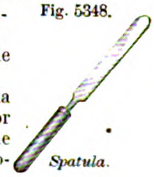
Spat′tle. (*Pottery.*) A tool for mottling a molded article with coloring matter.

Spat′tling-ma-chine′. (*Pottery.*) One for sprinkling earthenware with glaze, or colored slip, to make party-colored ware.

The liquid glaze contained in a trough is pumped up into an upper chamber, from which it is drawn from a faucet and falls through sieves, which divide it so that it falls in spray upon the ware which is passed underneath. This is performed in a *bonnet* to save waste, and the superfluous liquor is collected by a trough in the bonnet and returned to the reservoir.

Spat′u-la. 1. A knife with a broad, thin, flexible blade, used by druggists, color-compounders, painters, etc., for spreading plasters and working pigments.

Fig. 5348.



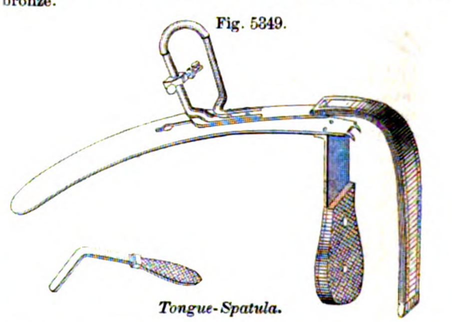
Spatula.

For some purposes spatulas are made of wood. See also PALETTE-KNIFE.

2. (*Surgical.*) The tongue-spatula is a flat instrument (angular or straight) for depressing the tongue and keeping it out of the way, in operations about the throat or larynx.

An ancient Egyptian spatula of iron has been found at Sakkarah. It is one of the few implements of iron which have withstood the rust of centuries These instruments were usually of bronze.

Fig. 5349.



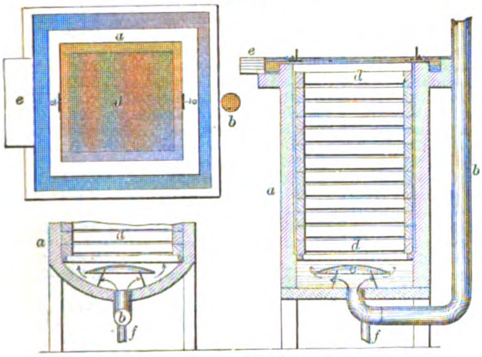
Tongue-Spatula.

Spatulas of copper and bronze were found in 1819 in a house in Pompeii. They were somewhat of the halbert shape. Cauteries were found at the same place and time.

Spawn-hatch′er. An apparatus for preserving and developing the spawn of fish.

Holton's (Fig. 5350) is more particularly designed for winter hatching. It consists of an upright box *a*, preferably about 2 feet in diameter and 2 to 4 feet high, into which a gentle flow of water is admitted at bottom through a pipe *b*; a deflecting plate *c* just over the pipe opening moderates and distributes the flow; *d d* are a series of trays with wire-gauze bottoms, on which the spawn is evenly distributed, and they are lowered one by one by means of attached straps into the case *a*; the water ascends through the meshed bottoms of the trays, finally

Fig. 5350.



Spawn-Hatcher.

overflowing into a channel surrounding the upper end of the case, and is discharged by a trough *e*.

The bottom of the box is segmental, or hopper-shaped, and is provided with a pipe *f* and valve for withdrawing any sedimentary deposits which may accumulate.

Speak'ing-trum'pet. A conical, flaring-mouthed tube employed for intensifying the sound of the human voice, as in giving commands or hailing ships at sea, by firemen, etc.

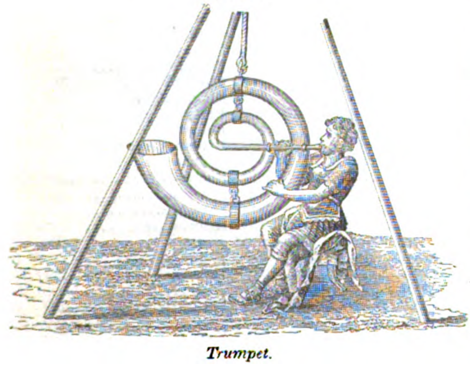
The speaking-trumpet was used by Alexander the Great, 235 B. C. Tradition long reported that the hights of the Caucasus, reaching from the Caspian to the Euxine, were occupied by the armies of Iskender (Alexander), the dread Doolkarnein or Two-Horned, so called from his being the conqueror of East and West. The illusion was said to have been caused by enormous trumpets, placed on the marvelous series of ramparts known in fable as the Wall of Gog and Magog, and craftily disposed so as to sound when the wind blew in certain directions. See Leigh Hunt's poem, "The Trumpets of Doolkarnein."

It is claimed by the modern school that the great horn, described in an old manuscript in the Vatican Library as having been used by Alexander the Great to assemble his army, at a distance of 100 stadia or 8 Italian miles, was not really a *speaking*-trumpet, as it is not expressly stated that he spoke through it. We prefer the tradition as it stands, for Alexander was well acquainted with Egypt, and the blast of trumpets was not unknown there.

Morland, who was born in 1625, and died in poverty in 1695, is believed to have given the speaking-trumpet its present form, though his claims are warmly contested by Kircher. Morland's pamphlet of 8 pages was published in 1671. His first trumpet was made of glass. The next was of brass; 4½ feet long, 12 inches in diameter at the large end and 2 inches at the small end, which had a mouth-piece constructed like a bellows to move with the lips. With this he rendered his voice distinct at a distance of half a mile. His third trumpet was curved, made of copper, and had a length of 16 feet 8 inches; 19 inches diameter at the flaring end, and 2 inches at the smaller. It rendered his speech audible at 1¼ miles. One of his largest carried the voice a distance of 2 or 3 miles at sea.

Fig. 5351 is an illustration of a spiral trumpet, described in Père Kircher's work, and pictured in Père Bonanni's curious work, "Descrizione Degl' Istromenti Armonici," Roma, 1776. It is designed rather for augmenting the voice than for musical

Fig. 5351.



Trumpet.

effects. It is intended to be elliptical in cross-section, and it is claimed to have been suggested by the shape of the exterior aural canals of various animals. Father Kircher takes occasion in this connection to mock the conclusions of Baptista Porta and Cornelius Agrippa that a sound might be made and then imprisoned in a tube by shutting up both ends, and then letting it out as required. A very remarkable instance of this was afterward cited in the veracious history of Baron Munchausen, whose tunes became frozen in his trumpet on a bitter cold day, and afterward issued when the instrument and its contents were thawed by the warmth of the tavern fire.

Speak'ing-tube. A pipe for conveying the voice from one apartment or floor to another.

Spear. 1. (*Weapon.*) A very ancient instrument of war, consisting of a blade on the end of a long shaft. It still survives among savage nations, and under the name of *lance* is used by cavalry among those comparatively civilized.

The spear of antiquity was sometimes provided with the *amentum* or thong for throwing.

Herodotus distinguishes the nationality of some of the nations in the army of Xerxes by describing the peculiar ornaments on the ends of their spear-shafts.

For a dissertation on the spears of the ancients, see article "Hasta," in Smith's "Dictionary of Greek and Roman Antiquities." The spear was the principal weapon of the Macedonian phalanx. The lance was introduced from Tartary into Poland, and thence found its way into the army of Frederick the Great, and into the Austrian service, where its name (*ulan*, from Turkish *oglân*, a youth) indicates its derivation. See LANCE

2. A *fish-gig*.

3. The long transverse pieces fixed transversely to the beam or body of a *cheval de frise* are called *spears*.

4. (*Mining.*) A pump-rod.

Spear-nail. One with a spear-shaped point.

Spe-cif'ic Grav'i-ty. The relative weight of a ponderable substance compared with another which is taken as a standard. For solids and liquids, *water*, and, for gases, *air*, are universally adopted as the standards. It took a long time to find out that air really was a ponderable substance.

The specific gravity of a body is ascertained by weighing the body in air, and then in water. Subtract the weight in water from the weight in air, and divide the weight in air by the difference. The quotient is the specific gravity required. The bulk of the object must agree with that of the standard of comparison if the result is to be stated in relative terms. See SPECIFIC-GRAVITY BALANCE.

In obtaining the specific gravity of fluids, a bottle is obtained, whose capacity is 1,000 grains of distilled water. This is filled with water, and balanced on the scales. The water is then removed and the fluid substituted, and the bottle and contents again weighed. The weight of the fluid divided by the weight of the water gives the specific gravity required.

Archimedes invented the plan for determining specific gravity by displacement of water. He also enunciated the doctrine of the "center of gravity."

Alhazen the Saracen, A. D. 1100, improved upon the hydrometer, which had been in use in Alexandria 600 years previously. See HYDROMETER.

Abu-r-Raihan of Kharizim, about A. D. 1000, compiled a table of specific gravities, which is quoted by Al-Khâzinî in his "Book of the Balance of Wisdom," translated from the Arabic by Chev. Khanikoff, consul-general of Russia, at Tabriz, Persia It was in reference to this table that Al Khâzinî uttered his pious hope that, "in the day of judgment, the All-Merciful will take pity on the soul of Abu-r-Raihân, because he was the first of the race of men to construct a table of specific gravities." The table is recorded in connection with the modern data on pages 84, 85 of the "Journal of the American Oriental Society," Vol. VI., New Haven, 1860. See also page 212, article BALANCE.

Al-Khâzinî states that when a body is weighed in air and afterward in the water-bowl, the beam of the balance rises in proportion to the weight of the water which is displaced, which is equal to the entire weight of the body weighed.

The "Balance of Wisdom," as the instrument is called by its describer, in the fanciful style common in the literature of that day, was a turned brass tube with closed ends, and so weighted as to float upright in a liquid. Graduations on the side were marked above and below a line that was termed the equator of equilibrium, to which line the instrument sank when plunged in the liquid — water of a certain description — which formed the unit of calculation. It is, as to this feature, a hydrometer, such as described by Synesius, and is credited by Al Khâzinî to Archimedes.

The conical instrument of Abu-r-Raihan is described by Al Khâzini, and has a conical body, a narrow vertical neck, and a curved spout leading from the latter, by which the water dis-

placed by a solid body was conducted to the bowl of a balance, by which it was weighed.

Al Khàzinî says in his book, of the eminent teacher 'Abû-Hâtim 'al-Muzaffar Bin 'Ismâil of 'Isfazâr, who was adapting the specific-gravity balance to the determination of the specific gravity of metal by graduations on the beam calculated for liquids of immersion of different densities: "He passed away, to meet the mercy of the Supreme God, before perfecting it, and reducing all his views on the subject to writing."

The first person *in Europe* to make a tabular statement of computations in this line was Athanasius Kircher, 1602-80; after him Galileo, 1657; Boyle (born in 1627). The calculations of the latter of the specific gravity of mercury—13.76 and 13.357—are both less exact than those of the scientific Arab in the retinue of Mahmoud of Ghuzna, A. D. 1000; he made it 13.56. The modern figure is 13.557.

The following table gives the *specific* gravity of a number of gaseous, liquid, and solid substances. See also Clark's "Constants of Nature," Smithsonian Institution Collections, December, 1873.

Gases, Air = 1.

Hydrogen	0.069	Oxygen	1.106
Marsh gas	0.559	Sulphuretted hydrogen	1.191
Steam	0.623	Nitrous oxide	1.527
Carbonic oxide	0.968	Carbonic acid	1.529
Nitrogen	0.971	Sulphurous acid	2.247
Olefiant gas	0.978	Chlorine	2.47
Nitric oxide	1.939		

Non-Metallic, Solid, Elementary Substances, Water = 1.

Boron	2.68	Iodine	4.948
Bromine	2.98 - 2.99	Phosphorus, common	1.826
Carbon, diamond	3.529 - 3.550	Selenium	4.760 - 4.808
Carbon, graphite	2.105 - 2.585	Silicon	2.004 - 2.493
Carbon, from gas-works	1.885	Sulphur, roll	1.868 - 2.000
Carbon, charcoal, variable from 0.280 for that from soft wood freshly burned in the stick, to 1.573 for oak charcoal, pulverized and compressed.		Sulphur, flowers	1.913 - 2.086

Metals, etc.

Aluminium, cast	2.50	Molybdenum	8.49 - 8.60
Aluminium, hammered	2.67	Nickel	7.807 - 9.261
Arsenic	5.763	Nickel wire	8.88
Barium	4.00	Osmium	21.40
Bismuth	9.67 - 9.83	Palladium	10.923 - 12.148
Cadmium	8.54 - 8.67	Platinum, cast	19.5
Calcium	1.55 - 1.8	Platinum, hammered	20.3
Cerium	5.5	Platinum wire	21.0 - 21.7
Chromium	6.81 - 7.3	Platinum sponge	21.47
Cobalt	8.48 - 8.95	Potassium	0.865
Columbium or Niobium	6.0 - 7.37	Rhodium	11.0 - 11.2
Copper, cast	8.78 - 8.83	Rubidium	1.52
Copper, rolled	8.88 - 8.95	Ruthenium	11.0 - 11.4
Copper wire	8.93 - 8.95	Silver	10.362 - 10.575
Glucinium	2.1	Sodium	0.972
Gold	19.2 - 19.4	Steel, cast	7.802 - 7.825
Indium	7.362	Steel, blister	7.720
Iridium	21.78 - 21.83	Steel, puddled	7.640 - 7.707
Iron, pure	7.83	Strontium	2.4 - 2.58
Iron, cast	6.928 - 7.330	Tantalum	10.08 - 10.78
Iron, bar	7.658 - 7.760	Tellurium	6.115 - 6.343
Iron, rolled plate	7.570 - 7.732	Thallium	11.777 - 11.900
Iron, hammered	7.868	Thorium	7.657 - 7.795
Iron wire	7.6 - 7.83	Tin	7.278 - 7.304
Lead	11.07 - 11.445	Tungsten	17.6 - 19.261
Magnesium	1.69 - 2.04	Uranium	18.33 - 18.40
Manganese	8.01	Vanadium	5.5
Mercury	13.568	Zinc	6.861 - 7.21

Alloys.

Brass		Brass wire	8.214
Copper, 84; zinc, 16.	8.832	Bronze gun-metal	8.700
Copper, 67; zinc, 33.	7.820	Gold, English standard, 22 carats fine	18.888
Brass plate	8.380		

Ores.

Copper, compact vitreous	4.129	Iron, brown hematite	3.789 - 4.029
Copper, Cornish	5.452	Iron, specular	4.934 - 5.218
Copper, pyrites	4.080 - 4.344	Iron, sparry	3.64 - 3.81
Iron, chromate	4.057	Iron, ironstone	2.952 - 3.863
Iron, pyrites	4.789	Lead, carbonate	6.00 - 7.20
Iron, magnetic	4.2 - 4.9	Lead, sulphide (Galena)	7.22
Iron, red hematite	4.740 - 5.005	Tin, Cornish	5.8 - 6.45
		Zinc, calamine	3.525

Stones and Mineral Substances.

Agate	2.348 - 2.637
Alabaster	2.611 - 2.876
Amethyst	2.750
Asbestus	0.680 - 0.993
Asbestus, starry	3.073
Barytes	4.00 - 4.865
Basalt	2.421 - 3.000
Beryl	2.723 - 3.549
Brick	1.367 - 1.900
Brick, fire	2.201
Brick-work in mortar	1.600 - 2.000
Brick-work in cement	1.800
Carnelian	2.597 - 2.630
Cement, Portland	1.300
Cement, Roman	1.560
Chalcedony	2.586 - 2.664
Chalk	1.520 - 2.784
Chrysolite	2.782 - 3.489
Clay	1.93 - 2.16
Coal, anthracite	1.436 - 1.640
Coal, cannel	1.238 - 1.318
Coal, Cumberland, Md.	1.355
Coal, Newcastle	1.270
Coal, Welsh	1.315
Coke	1.000
Corundum	3.710 - 3.981
Cryolite	2.692 - 3.077
Diamond, Oriental	3.521 - 3.550
Diamond, Brazilian	3.444
Dolomite	2.800
Earth	2.194

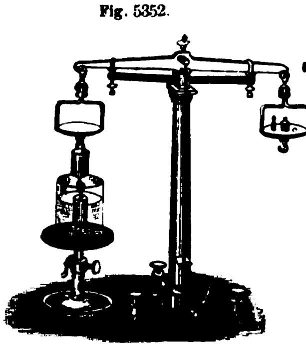
Spe-cif'ic-grav'i-ty Bal'ance. For determining specific gravities. The arrangement (Fig. 5352) illustrates the principle discovered by Archimedes, that every body immersed in a liquid loses a part of its weight equal to the weight of the liquid displaced. See page 2255.

From one of the scale-pans of an accurate balance is suspended a hollow cylinder of copper, and beneath this a solid cylinder of the same metal precisely equal in volume to the interior of the upper cylinder. These are balanced by weights in the other scale-pan, and the solid copper cylinder is then immersed in a vessel of pure water. This disturbs the equilibrium of the scale, which is again restored by pouring water in the upper cylinder. The quantity required is exactly equal to that displaced by the lower cylinder, and its weight divided into that of the latter gives the specific gravity of the copper.

In the case of liquids, a body not liable to be attacked by the liquid is suspended from one of the scale-pans. The body is weighed first in the liquid to be examined, and afterward in water. The weight in water divided into the weight in the other

Fig. 5352.



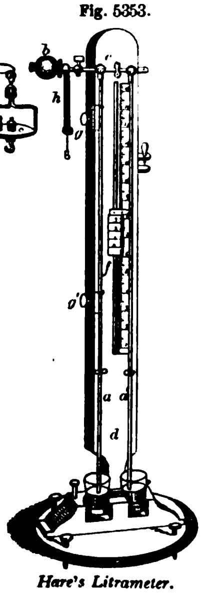
Specific-Gravity Balance.

liquid gives the specific gravity of the latter. See "Mohr's Specific Gravity Balance," pages 39, 40, "Griffin's Chemical Handicraft."

Spe-cif'ic-grav'i-ty In'stru-ment. Professor Hare's litrameter, for ascertaining the relative density of liquids, is shown in Fig. 5353.

Two equal glass tubes *a a'* communicate with each other and with an elastic bag *b* by means of a pipe *c* terminating in a cock, to which the mouth of the bag is tied. The tubes are both attached to an upright standard *d*, provided with a graduated scale *e*, divided into 220 parts, which may be read to tenths by a vernier *f*. Two indexes *g g'* on the tube *a* correspond respectively to the graduations 100 and 200 on the scale. One of the tubes *a'* being immersed in a vessel of water, and the other *a* in a vessel containing the liquid to be tested, the bulb *b* is compressed, partially forcing out the air contained in the tubes. On releasing the bulb the fluids ascend in the tubes. If the fluid to be tested is heavier than water, the expulsion of the air is so regulated that it shall stand a little above the level of the lower index; the cups are then removed, and sufficient air admitted to the tubes by a valve arrangement *h* to reduce its level exactly to that of the lower index *g*; the columns in the two tubes are now supported by the excess of atmospheric pressure over that of the air in the upper parts of the tubes, which, of course, is precisely equal in both. The vernier then, being adjusted to the level of the water in the tube *a'*, indicates the specific gravity of the other liquid. If a liquid lighter than water is to be examined, its level is brought to the hight of the upper index, and the reading of the scale halved.

Fig. 5353.



Hare's Litrameter.

Spe-cif'ic-grav'i-ty Beads. Small spherical bodies of known weight in proportion to their bulk, used for determining the specific gravity of liquids. A form of hydrometer.

Just as a farmer's wife tests the strength of lye for making soap, considering it of the right strength when a fresh hen's egg floats as large as a quarter-dollar above the surface of the liquid.

Spe-cif'ic Heat. The amount of heat required to raise the temperature of a certain weight (as a pound or kilogramme, of a substance) a definite amount, as 1° Cent. or 1° Fah. Water is taken as the standard of comparison; the Centigrade degree and kilogramme being universally adopted on the Continent of Europe, while the avoirdupois pound and degree of Fahrenheit are in common use in England and the United States, though the Continental system is that generally employed by scientific men.

Spe-cil'i-um. (*Surgical.*) An instrument for examining wounds, fistulas, and for passing setons. A *probe*. It is usually of silver, and is terminated by a spherical button.

Speck-block. (*Nautical.*) One used in *flensing* or stripping the blubber off a whale. Through it the *speck-fall*, a purchase, is rove, the blocks being made fast to the *blubber-guy*.

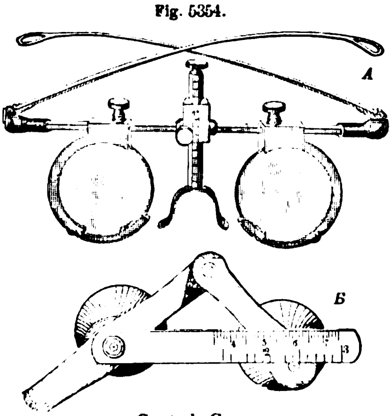
Speck-falls. (*Nautical.*) The ropes of the speck-block for getting blubber aboard.

Spec'ta-cle-fur'nace. (*Metal-working.*) A furnace with two tap-holes, one above the other.

Spec'ta-cle-gage. A device for determining the proper distance apart at which the glasses should be placed to exactly suit each individual case.

In *A* two glasses are fixed in spring-holders, which slide on a square graduated rod, and may be held by set-screws. These

Fig. 5354.



Spectacle-Gages.

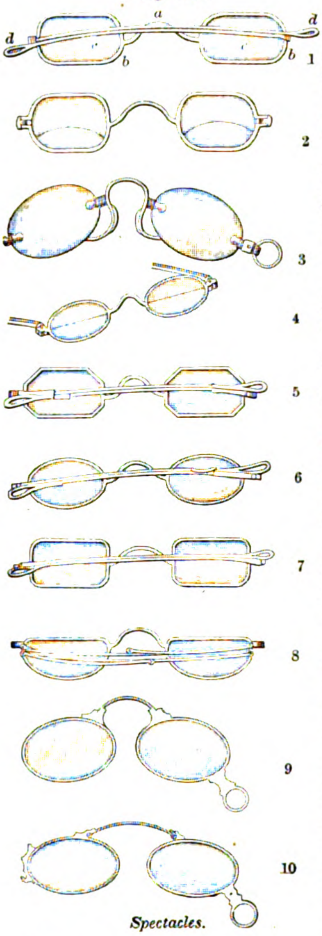
are moved inward or outward, until an object is distinctly seen by both eyes through the centers of the glasses; being then fixed by the set-screws, the distance is read off on the graduated rod; their hight is adjusted by a central sliding nose-piece.

In *B* the object is viewed through a pair of goggles, having minute perforations, and attached to two jointed arms; the distance between the two visual axes is indicated on a scale.

Spec'ta-cles. A pair of lenses in a frame to assist failing or imperfect sight.

In Fig. 5355, 1, the different parts are shown: —

Fig. 5355.



Spectacles.

a, *bridge*.
b, *eye* or *bow*.
c, *glass* or *lens*.
d, *side* or *temple*.

2 has segments of different foci; their line of junction is curved.

3, the metallic portions are riveted to the lenses.

4 has semi-lenses of different convexities; their line of junction straight.

5 has octagonal lenses.

6, oval.

7, oblong.

8, pulpit spectacles, to allow a reader to look over them more readily.

9, *spring eye-glasses*.

10, folding eye-glasses.

Strabismus spectacles have a small central opening to aid in curing the defect by exercising the muscle which brings the eyes into the normal position.

Spectacles with glasses of different refractive powers are made for those whose eyes have unequal foci.

An *astigmatic* glass is adapted for an eye which has different refractive powers at different parts of its cornea or lens.

In other spectacles each glass is made up of two half-lenses of different powers or characters, — one for reading, the other for ordinary use in walking or conversation.

Goggles are short tubes which exclude much light from the eye, especially lateral rays.

Wire-gauze spectacles are used to exclude dust and cinders.

Colored spectacles are used to temper the light, in mercy to weak eyes.

For *weak eyelids* spectacles are used which prop the upper eyelid.

The sides of spectacles are known as *single* or *turn-pin*; the latter having a jointed extension piece.

Spectacles are also known by other names indicative of color of lens, optical character, nature of lens, etc., as *green*, *blue*, *neutral tint*, *smoke* color; *double concave*, *double convex*, *periscopic*, *pebble*.

Periscopic glasses were invented by the eccentric Dr. Wollaston. The glasses are concavo-convex, and facilitate oblique vision.

Spectacles are said to be of Asiatic origin, and are of great antiquity in China. A spectacle lens was discovered in the Stabian Street at Pompeii in 1854. Alhazen appears to have referred to them. Roger Bacon, in his "Opus Major," writes: "This instrument, a plano-convex glass or large segment of a sphere, is useful to old men and to those who have weak eyes, for they may see the smallest letters sufficiently magnified." Bacon was born at Ilchester, in Somersetshire, in 1214, the year before the signing of Magna Charta; was educated at Oxford, then studied in Paris, where he took his degree, which was subsequently confirmed by the Oxford University; in 1240 he took the vows of a Franciscan at Oxford. His talents and originality caused him to be suspected by his brethren, and he was imprisoned in 1268, and closely confined for ten years. He returned to Oxford, and died in 1292. The claim to the invention of spectacles, asserted in behalf of Alexander de Spina, a monk of Pisa, who died in 1313, is believed to be anticipated by this date of Bacon's.

Fig. 5356 is from the tapestry of Nancy, of the latter part of the fifteenth century, and represents a scribe with spectacles on nose, and with all his apparatus of writing, — pen, penknife portable case, book, and paper.

Fig. 5356.

Scribe with Spectacles (Tapestry of Nancy, France).

Chaucer and Lydgate refer to spectacles. John Baret, of Bury St. Edmunds, left by will, in 1463, to one of the monks, his ivory tablets and a pair of silver-gilt spectacles.

"I this morning did buy me a pair of green spectacles, to see whether they would help my eyes or no." — PEPYS' *Diary*, 1666.

Feeling encouraged: —

"Bought me two new pair of spectacles of Turlington, who, it seems, is famous for them." — PEPYS' *Diary*, 1667.

"The residents in Sikkim [says Hooker], in the Himalayas, seek protection for their eyes from the glare of the newly fallen snow, some with veils, others with shades of brown paper, or of hair from the yaks' tails, whilst a few have spectacles of woven hair; and the Lepchas loosened their pigtails, and combed their long hair over their eyes and faces."

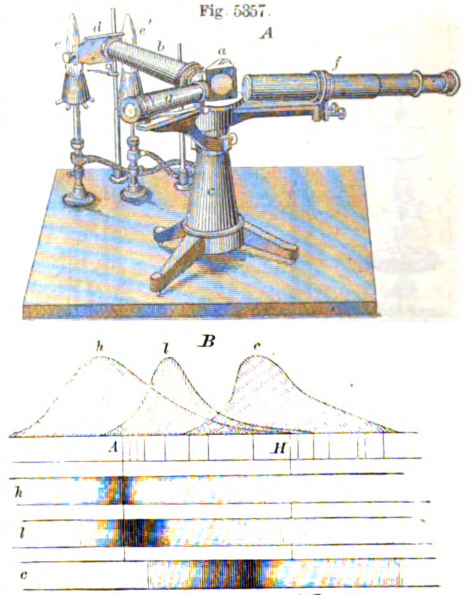
Cohn, an oculist of Breslau, has made an estimate of the number of workmen in metal who have been injured in the eye by minute pieces of metal. Among 1,283 workmen, he found that 90 per cent had suffered thus to some extent, and 40 per cent had been under medical treatment therefor; 59 were permanently injured, and 21 had lost the use of one eye. He introduced mica spectacles with great success. The frame is made to fit around the eye, like goggles.

Spec-trom'e-ter. (*Optics.*) An instrument described by Valz in "Comptes Rendus," Vol. LVII. pp. 69, 141, for viewing the spectrum by direct vision, and so arranged as to reduce the dispersion of the rays as little as possible.

Spec'tro-scope. An instrument for viewing the spectra formed by the solar rays and by those of other bodies in an incandescent condition.

Newton, 1675, determined the fact that the solar light was composed of six different and unequally refrangible colors. (See PRISM.) He also found that these colors, which combined to form white light, could not be farther separated by undergoing a second refraction. In 1781, Scheele, who discovered the fact that light exercises a chemical action upon chloride of silver, found that the compound was blackened most toward the violet

Fig. 5357.

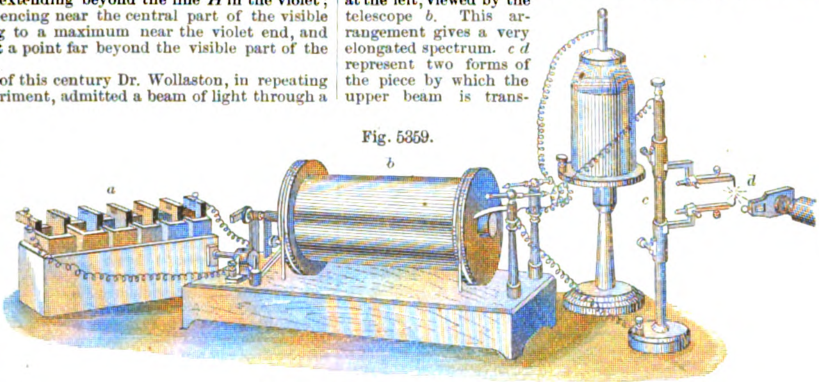


Steinheil's Spectroscope and Spectrum.

end of the spectrum. Subsequent researches have shown that the solar spectrum is apparently composed of three parts, which are, throughout a portion of their extent, superimposed one upon the other (*E*, Fig. 5357); thus the part *h* exhibits the maximum *heating* effect; the part *l* is that which produces light; and the part *c* exerts the greatest *chemical* or actinic action. The curves indicate the respective maxima and minima of heat, light, and actinic force respectively; the first being greatest at a point entirely without the visible end of the spectrum; the second commencing just beyond the line *A* near the end of the red, and extending beyond the line *H* in the violet; and the third commencing near the central part of the visible spectrum, increasing to a maximum near the violet end, and only disappearing at a point far beyond the visible part of the spectrum.

At the beginning of this century Dr. Wollaston, in repeating the Newtonian experiment, admitted a beam of light through a very narrow slit instead of a round hole, and detected a number of black lines in the spectrum; and in 1814, Fraunhofer, pursuing the investigation, had discovered and located 576 of these lines. He also observed that these were uniformly the same in light received directly from the sun and reflected from the planets, and that light from the self-luminous fixed stars contained black lines differing from those of the solar light. He thence concluded that these variations were due to causes existing outside of our atmosphere, — a conclusion which has been since amply confirmed.

Fig. 5359.



Spectroscopic Apparatus and Battery.

Melville, in 1752, noticed the yellow flame due to sodia; and in 1822 Sir John Herschel remarked that "the colors contributed by different objects to flame afford in many instances a ready and neat way of detecting extremely minute quantities of them."

Mr. Fox Talbot, in 1834, distinguishes the difference between the red lines produced by the flames of strontia and lithia, and in 1845 Professor W. A. Miller experimented upon the spectra of the alkaline earth metals.

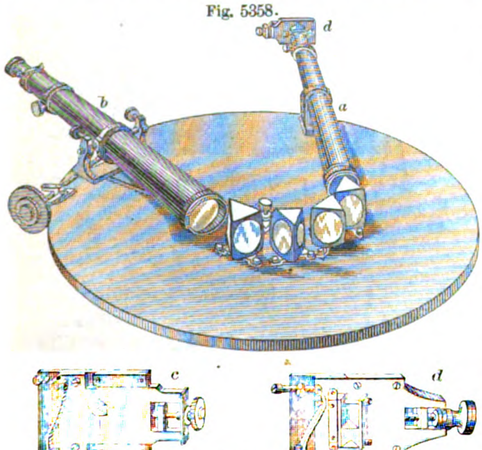
Professor Bunsen, however, so far advanced the subject that he, in conjunction with Kirchoff, may be almost said to have invented spectrum analysis as it now exists.

Through its instrumentality Bunsen discovered, in 1860, the new metals cæsium and rubidium; Crookes, in 1861, discovered thallium; and in 1864 Reich and Richter discovered indium.

In Fig. 5357, *A* represents the improved spectroscope of Steinheil. It consists of a stand *c* carrying the flint-glass prism *a*, having a refracting angle of 60°. The stand has two arms, one of which carries the telescope *f*, and the other the tube *g*, containing a lens in the end nearest the prism, and at the other end a scale which can be seen through the telescope by reflection from the surface of the prism.

The light *e* is admitted to the tube *f* through an adjustable slit in the piece *d*, the upper part only of which is open; the light *e'* is reflected from a prism within the piece *d* below the slit, so that the spectra of the two lights appear one above the other in the telescope *f*, the scale in the tube *g* being illuminated when required by a lamp in front of it; the adjustments consist in properly focusing the telescope and so arranging the tubes *b g* and the lights that their spectra and the micrometer scale are all distinct in the same field.

Fig. 5358.



Kirchoff's Spectroscope.

In Fig. 5358, the arrangement used by Kirchoff, a train of four prisms is employed; the rays passing through the slit in *d* are rendered parallel by a lens in the tube *a*, and, being decomposed successively by the prisms, are, on emerging from that at the left, viewed by the telescope *b*. This arrangement gives a very elongated spectrum. *c d* represent two forms of the piece by which the upper beam is transmitted and the lower reflected through the tube *a*. The width of the slit may be varied by means of screws.

Fig. 5359 shows the apparatus employed for volatilizing the metals in order to obtain their spectra; it consists essentially of a voltaic battery *a*, induction coil *b*, and a stand *c* having adjustable arms, carrying the points between which the substance *d* is held while being subjected to the action of the current. The luminous image of the burning metal is transmitted through a slit and tube to the prism and viewed by a telescope.

Faraday ascertained that the electric spark is but the effect of the combustion of minute particles of the terminals and the air or other matter through which it passes from one to the other.

The spectroscope has already given us an insight of the elements present in the sun and some of the fixed stars, and of the nature of the components of other heavenly bodies, as the nebulæ and comets.

It has also been employed to determine the exact moment proper for adding the spiegeleisen and for stopping the conversion in the Bessemer steel process. See pages 277, 613.

It is as yet comparatively in its infancy, and will no doubt some day be of great service in practical metallurgy, as it has already been in qualitative chemical analysis.

Mr. Norman Lockyer has successfully used the spectroscope as a means of quantitative analysis for testing alloys in the British mint. His apparatus consists of an electric lamp, in the lower carbon of which a recess is made to receive the alloy to be vaporized. The spectrum is thrown on a screen in a closed box and is photographed, admitting of ready comparison with the previously photographed spectra of other alloys containing known proportions of the metals. By means of a delicate scale attached to the instrument, the coincidence or variation of the lines in the different spectra, arranged one above the other, is determined, the relative length, strength, and position of these lines indicating the proportion of each metal contained in the alloy.

Huggins has applied spectroscopic observation to the determining of the proper motion of the heavenly bodies, by observing the displacement of the spectral lines.

Spec′u-lum. 1. (*Surgical.*) An instrument for dilating certain passages of the body, in order to enable examinations or access of instruments for operation.

Speculums are known by their construction, as *bivalve*, *four-bladed valve*, etc., or by the part of the body to which they are applicable, as —

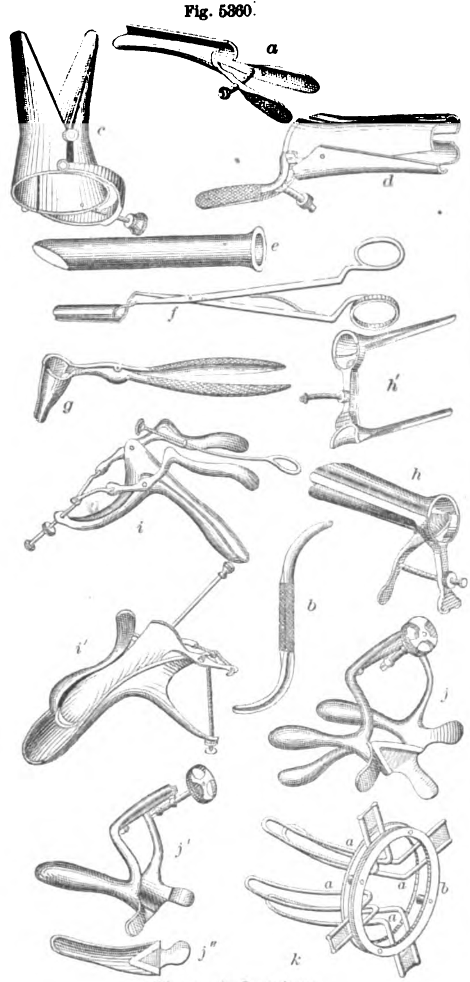
Anal,	Eye,	Nasal,	Vaginal,
Ear,	Mouth,	Rectum,	Uterine, etc.

Some of these names are synonyms, and, besides, there is another class of instruments known as *dilators*, and still another set of names ending in -scope, as *otoscope*, *laryngoscope*, *metroscope*, *rhinoscope*, etc.

a is a two-valved speculum, the parts hinged together and having a set-screw to maintain distention without the aid of an assistant. It is shown in Pitney's patent of 1841. *b* is a speculum of a favorite form found in the same patent.

c is Webber's magnifying bivalve ear-speculum.
d is a four-valve speculum.
e is a glass-mirror speculum.
f is Elliott's intra-uterine speculum.

Fig. 5360.



Tiemann's Speculums.

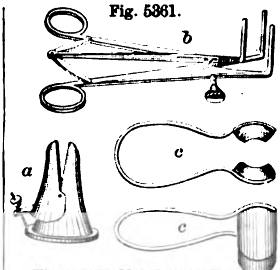
g is Kramar's bivalve ear-speculum.
h h', closed and open views of the Storer vaginal speculum.
i i', Nott's duck-bill speculum.
j j' j'', Bozeman's speculum, three views.

Bivalvular and trivalvular speculums are shown in Plaet XVII., "Magazyn oste Wapen Huys der Chirurgyns door Dr. Johannes Scultetus," Doordrecht, 1658.

k, Knaffl's speculum. It consists of a number of bent movable fingers a a a a, whose outer ends are passed between two connected rings b. In use, the fingers a a a a are slid close together and introduced into the canal, and then each pushed outwardly by the finger of the operator. The pressure of the walls of the canal on their inner extremities causes them to bind between the two rings, and retains them in expanded position.

In Fig. 5361, a is Robert and Collins' nasal speculum.
b, Elsberg's nasal speculum.
c c, Thudichum's nasal speculum.
In Fig. 5362, d is Simrock's otoscope, with lens.
e, Spier's self-sustaining ear-speculum.
f, Whitehead's mouth-gag (showing cleft palate). See STAPHYLOGRAPHIC INSTRUMENT.
Fig. 5363 shows instruments for distending the eyelids during examinations and operations.

Fig. 5361.



Tiemann's Nasal Speculum.

Fig. 5362.

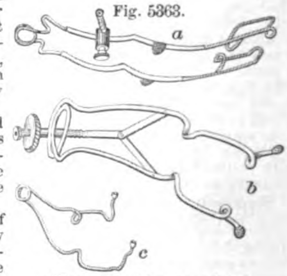
Speculums.

a (Fig. 5363), Graefe's eye-speculum.
b, Noyes' eye-speculum.
c, Hart's eye-speculum.

2. (*Optics.*) A metallic, concave mirror.

These were known to the ancients, and were probably used for lighting the sacred fires. The construction of the mirrors of Archimedes is not accurately known. It need not be doubted that he fired some of the vessels of Marcellus, who was then besieging Syracuse. The wonder is not that an arrangement of burning mirrors, so called, should be able to effect this, for this has been clearly proved by Buffon and others, but the wonder arises from our mis-preconceptions of the condition and talents of the men of former times. Kircher went to the historic spot and tried an arrangement of plane mirrors, which convinced him the account was entirely probable.

Fig. 5363.



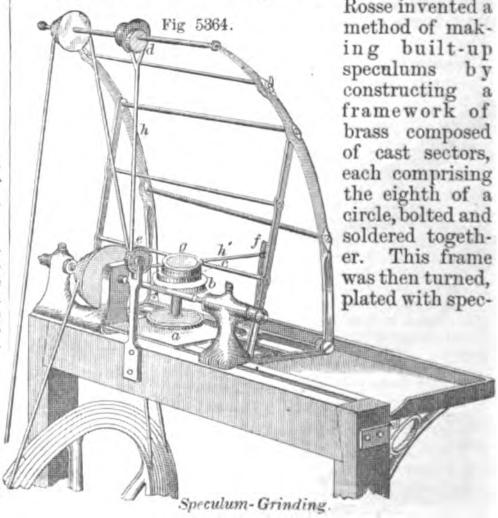
Tiemann's Eye-Speculums.

The ancients also used lens and glass spheres filled with water to collect and concentrate the rays of the sun. See LENS.

During the siege of Byzantium by the navy of Vitalian, the same defense was made by the besieged, and with the same result, for Zonaras informs us the ships were actually consumed. See MIRROR. Also page 410.

Spec'u-lums, Cast'ing and Grind'ing. Lord Rosse invented a method of making built-up speculums by constructing a framework of brass composed of cast sectors, each comprising the eighth of a circle, bolted and soldered together. This frame was then turned, plated with spec-

Fig 5364.



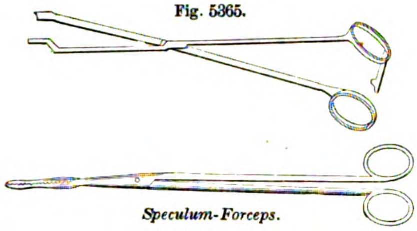
Speculum-Grinding.

ulum-metal, a number of the plates having their joining edges accurately fitted together and soldered with an alloy of zinc and copper having exactly the same expansibility as speculum-metal. The face was then polished.

Fig. 5364 illustrates an apparatus for grinding and polishing speculums of small size. It is attached to an ordinary foot-lathe, and operated by the movement of its treadle. The cast-iron frame *a* is secured back of the lathe-bearers, and carries a vertical mandrel, to the top of which the chuck *b* is fixed. The edge of the chuck is cut as a worm-wheel, to which a slow rotary motion is given by a screw mounted between the mandrel and the puppet-head of the lathe. The speculum *c* is cemented to this chuck, and as it rotates the polisher *g* is caused to traverse back and forth across its face by means of an eccentric *d* carrying a cord *h* attached to one side of a ring inclosing the polisher and passing under a guide-pulley *e*, and a cord *h'* connected to the opposite side of the ring and to the spring *f*.

Spec'u-lum-for'ceps. (*Surgical.*) Long, slender forceps, used for dressing wounds or operating on parts not accessible except through speculums.

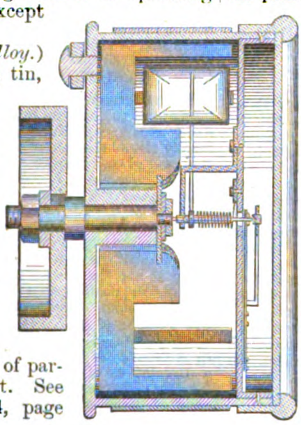
Fig. 5365.



Speculum-Forceps.

Spec'u-lum-met'al. (*Alloy.*) Lord Rosse's: copper, 126.4; tin, 58.9.

Another formula: copper, 7; tin, 4; zinc, 3. Or, copper, 6; tin, 2; arsenic, 1. Or, antimony, 1; tin, 1. See ALLOY, page 63.



Speech. Of a wheel. The hub with the spokes, without the fellies and tire.

Speed-cones. (*Machinery.*) The double cone-pulleys, used for varying and adjusting the velocity ratio communicated between a pair of parallel shafts by means of a belt. See CONE-PULLEY, *C*, Fig. 1424, page 610.

Speed'er. (*Cotton-manufacture.*) A machine invented by Mason as a substitute for the *bobbin and fly frame*, by which *slivers* of cotton from the *carding-machine* are slightly twisted, and thereby converted into *rovings*.

The sliver is *drawn* between rollers, as in the *bobbin and fly frame*, but the bobbins are arranged horizontally and rotated by rollers on which they revolve. Being rotated by their peripheries, their rate of winding is constant, and the *copping* rail is dispensed with. The *twist*, which is given in the *bobbin and fly frame* by the rotation of the spindle and flyer, is given in the *speeder* by an endless belt, which rapidly rotates the guiding tubes of the sliver as it comes from the drawing rollers.

The bobbin is made into a cop with conical ends, as in the other machine, each successive layer being shortened, as its diameter increases, so that each shall have the same length of yarn.

Speed-gage. A velocimeter.

English patent No. 2,692 of 1855 is for a speed-indicator for locomotives or railway-trains, and consists of a governor driven by a cord from an axle of the engine or car. As the balls rise with increased speed, they actuate a lever and that a piston which elevates a colored liquid in a graduated glass tube. The hight of the liquid is therefore the measure of the speed.

See also English patent No. 2,141 of 1860 and 581 of 1867.

A different idea is involved in those indicators which have a dial on which are inscribed all the stations, switches, crossings, etc., of a journey, and a pointer, which is driven by a wheel of the car, and indicates to the engineer or conductor the position of the train on the line. See English patents Nos. 11,619 of 1847, 890 of 1858.

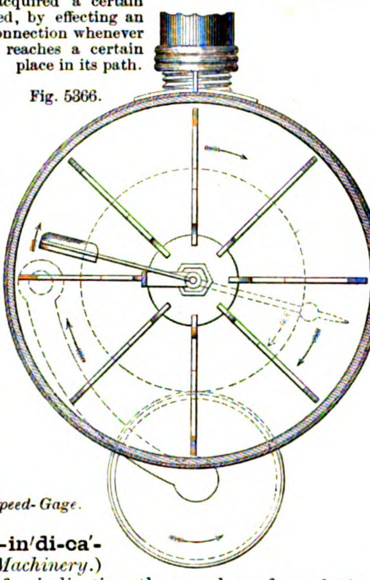
The marine velocimeter is a registering-log. See LOG. See also English patent 8,645 of 1840.

English patent 2,892 of 1856 is to indicate the position of a hoisting-cage in a mining-shaft.

Osborne's speed-gage is for the purpose of determining the rate of speed at which shafting or wheels are rotating. It has an index-hand or pointer, a graduated dial, a current-receiver, and retarding-spring with a current-generator, whereby the force of the current produced in any fluid acted upon by the generator can be indicated upon the dial, which may be so graduated as to express the number of revolutions which the generator makes per second or minute, whereby the trouble of counting and rating the speed by time is avoided. It is applicable for determining the speed of printing-presses, spinning and grinding machinery, paper-mills, centrifugal machines, and shafting; for determining the proper cutting speed of lathes and planers. It is also applicable to the determination of the speed of steam and other land carriages, of marine engines, and of the belting of machinery generally.

It may be made to give an indication or alarm, whenever a shaft has acquired a certain rate of speed, by effecting an electrical connection whenever the pointer reaches a certain place in its path.

Fig. 5366.



Osborne's Speed-Gage.

Speed-in'di-ca'-tor. 1. (*Machinery.*) A device for indicating the number of revolutions made by a shaft in a given time.

In Fig. 5367, the spindle carries a worm, engaging an interior system of gearing, which moves the hands of two dials, one of which registers single revolutions up to one hundred, while the other indicates the hundreds up to one thousand.

The point of the spindle is gently pressed centrally against the end of the shaft, causing the spindle to rotate therewith; the time that it is held in contact with the shaft is noted by a watch, and an inspection of the dials shows the number of revolutions made. See SPEED-GAGE; SPEED-RECORDER.

Fig. 5367.

Speed-Indicator.

2. (*Nautical.*) A log consisting of a spiral vane turned by the passing water, and registering its revolutions. See VELOCIMETER; LOG.

Speed-meas'ur-er. An instrument invented by Mr. Carey, for meas-

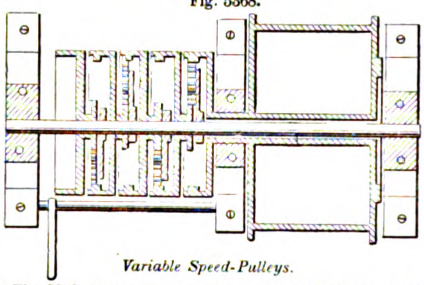
uring the number of revolutions made by the wheel of a carriage. It is secured by straps to one of the spokes near the hub, and has clock-work mechanism for registering the number of revolutions. See ODOMETER; SPEED-GAGE; SPEED-RECORDER.

Speed-mul′ti-pli′er. (*Gearing.*) An arrangement of gearing by which pinions are driven from larger wheels, the pinion-shafts carrying large wheels, and so on. It is seen in the motion work beneath the dial of a watch, by which the motion of the center arbor is geared up to drive the minute-hand and seconds-hand. It is the inverse of the watch-movement proper, in which the relatively slow-moving wheel, which receives the first impulse of the spring, becomes the quicker motions of the wheels in the direction of the escapement.

This *gearing-up* or *gearing-down*, or *speed-multiplying* or *decreasing*, is found in many kinds of machinery.

Fig. 5368 is an arrangement of gearing within a series of pulleys, upon which the driving-belt may be shifted to increase the power or speed of the drum. See also Nos. 73,424, 75,677, 81,248.

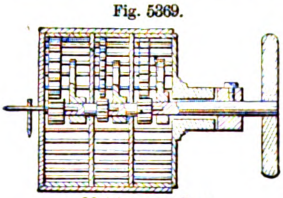
Fig. 5368.



Variable Speed-Pulleys.

In Fig. 5369, the motive shaft has arms which carry spur-wheels engaging the inner gear of the drum, and a pinion which is fast to the second shaft, having similar arms and spur-wheels engaging a pinion on the third shaft. This may be extended as far as desired; the proportion between the planet-wheels and their pinions regulates the increase of speed gained.

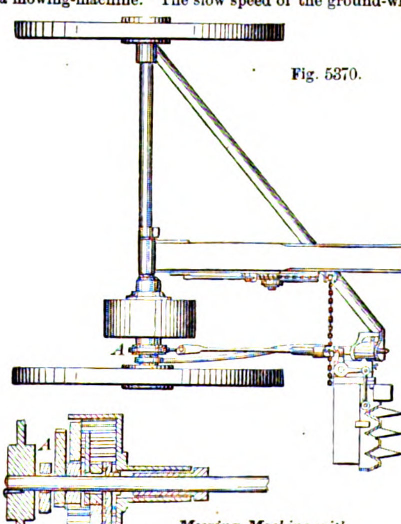
Fig. 5369.



Multiplying Gear.

Fig. 5370 shows the application of the principle to a mowing-machine. The slow speed of the ground-wheels is geared up to give a rapid reciprocation to the cutter-bar. The pinion to which the cam *A* is attached terminates a system of speed-multiplying gear mounted upon the main axle; from this gearing motion is communicated to the cutter through the medium of a yoke surrounding the cam, a pitman-rod, crank-lever, etc.

Fig. 5370.



Mowing-Machine with Speed-Multiplying Movement.

Speed-pul′ley. (*Machinery.*) A cone-pulley. One having several faces of varying diameter, so as to give different rates of revolution.

Fig. 5371.

Speed-Pulley.

Speed-re-cord′er. A contrivance for recording the speed of a carriage, railway-car, vessel, or the revolutions or pulsations of a machine. The record is made up of the progress in a given time; in the case of vehicles of any kind, it is made up of distance and time. An *odometer* or other *velocimeter* usually has a train of wheels similar to those of a GAS-METER or ARITHMOMETER (which see), the reading being taken of the number of revolutions, for instance, within the space since the last reading was had. Such a machine is, after all, a mere *counter*, and does not fulfill the conditions of a *speed-recorder*.

Some of the cab-odometers combine the factors of distance and time, so that when the cab is moving a record is made by a train of wheel and pointers of the distance traveled; and when the cab is at rest, while still hired, a time-measurer is set in motion, which keeps a record of the period of rest. This does not yet fulfill the conditions of the problem, as it is but a double register, and the result is derived from the sum of the two, they not being contemporaneous in action. Cab-odometers are to be found in English patents —

No. 14,176, of 1852.	No. 1,035, of 1863.
No. 2,131, of 1856.	No. 2,082, of 1863.
No. 883, of 1857.	No. 1,217, of 1864.
No. 2,894, of 1857.	No. 2,354, of 1868.

An instrument to be applied or attached to a moving body to indicate to the eye the rate at which it is traveling is a SPEED-GAGE (which see). Such a one is not necessarily a *register*, but merely shows the rate at the time of application or of observation, as the case may be. The indications may be recorded, and thus it becomes a *recorder*. One instrument, to indicate the actual speed of a locomotive, is described in English patent No. 2,692, of 1855. See SPEED-GAGE.

The true speed-register is to be found in those devices designed accurately to register the speed of locomotives or trains of cars at all times between any two points, to show the time taken to travel any distance between the ends of the route, and to indicate the stoppages and delays of trains.

An apparatus of this kind may be found in English patent No. 11,619, of 1847. It has dial-indicators which show the speed of the engine and the position of the train on the line in reference to proximity to stations or sidings. It registers a description of the journey, time occupied at, and the rate between, stations, mile by mile. The record is made upon a strip of paper marked with perpendicular lines, which represent miles, and with horizontal lines, which represent minutes. The paper winds on a cylinder, and is marked by a pencil traversed by a chronometer. The distance traveled in a given time determines the movement of the paper, and the motion of the pencil in the said time combines to make a mark, the result of the two factors. The paper is detached at the end of the journey to be examined, and kept as a record of the trip

English patent, No. 1,673, of 1857, has also a pencil under the control of a clock, and a traveling paper moved by a wheel of the train, the record being the joint product of time and distance.

English patent, No. 2,141, of 1860, indicates the speed of a train by a colored fluid raised or lowered by a lever acting upon a diaphragm, the lever itself being worked by a ball-governor driven by connection to an axle of the engine. A pencil obeys the fluctuations of the fluid and makes a record.

United States patents, on the Governor principle. Benckert's, December 1, 1857. An *indicator.* It has an arrangement of governor-balls acting upon segment cams, which turn the pinion of the indicator finger.

Liernur, November 16, 1858. A speed-*recorder.* By band connection from the axle, the governor is rotated, and its inequalities of rate are made to lift or depress a pencil vertically. The pencil-point rests on a circular disk, which is rotated by clock-work. The radiating and circular lines on the paper are expressive of distance and speed, and the pencil-line is the product of the two factors.

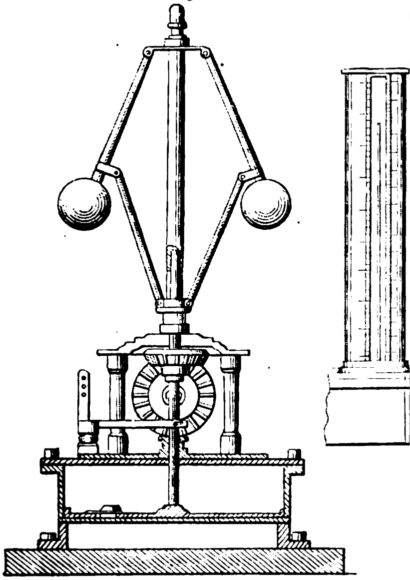
Billings' speed-recorder for railway-cars, March 27, 1860. A ball-governor, through the medium of a circular rack and gear-wheels, imparts motion to a hand, which points out upon a dial the number of miles per hour at which the train is travel-

ing at the moment. Another hand is carried forward by the first hand as the speed is increased, but does not recede with it when the speed diminishes. It thus registers the greatest speed attained during the trip.

Other connected mechanism actuates a set of prickers, which, penetrating at rare intervals an endless strip of paper as it is wound by clock-work machinery from one roll on to another, register the distance traveled; while a second set of prickers, similarly actuated, record the rate of speed at each mile on the same strip of paper. The mechanism is driven from a truck-axle, and is inclosed in a box with a glass front.

Keeler, April 4, 1864. An *indicator*. The balls and connecting arm of an ordinary governor, driven by gear or band connection from the axle, act upon a piston, which raises or lowers

Fig. 5372



Keeler's Speed-Measurer.

the movable bottom of a mercury chamber and elevates or depresses a column of mercury rising from the said chamber.

Bowsher, May 12, 1868. An *indicator*. It has a governor arrangement, the sliding collar actuated by the balls pulling upon a cord, which turns the spindle of the pointer-finger and directs it to figures on a dial.

Bilgram, August 22, 1871. An *indicator*. It has governor-balls, which actuate a sliding sleeve-rack, which revolves the pinion on the axis of the pointer.

Speed and Poage, May 12, 1874. A *recorder* for registering the speed of railway-trains. The governor is connected with a pencil, which rides over a recording sheet and indicates the speed, while the sheet is moved by the axle of the car and indicates the distance passed over.

The following are not actuated by governor-balls: —

English patent, No 1,407, of 1863, makes a diagram on a sheet of paper, showing the speed of a train, with the position and duration of its stoppages. The paper is advanced by clock-work at a uniform rate, and by means of motion derived from the train a pencil is advanced across its surface. The direction of the line made by the pencil will vary as it moves more or less quickly across the advancing paper.

English patent, No. 2,285, of 1863. A disk of paper is moved by a train of wheels from the crank-shaft of the machine. A stylus is raised and lowered at regular intervals, being driven by a chronometer. See also No. 2,912, of 1862.

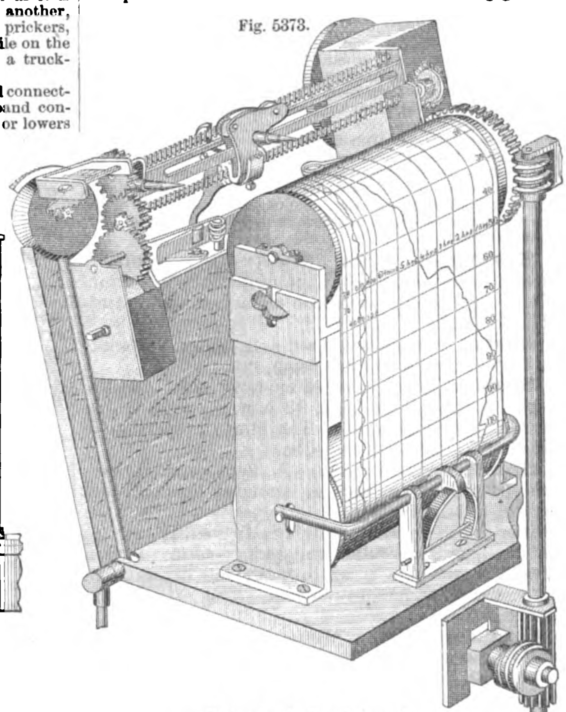
Lewis' velocimeter, November 26, 1867, has a train of gearing, which gives indications at regular intervals of the rate of speed. These are compared with a time-keeper in the same apparatus.

Horn's mileage register, May 5, 1868, has a ringing mechanism operated at each mile; a kind of *odometer*. A striker also marks on a surface traversed at a uniform rate across its path.

Guebhard and Tronchon, April 8, 1873, recording apparatus for cabs and carriages, have a drum driven by clock-work and receiving a record so connected with the vehicle as to give a strong and irregular line when the vehicle is moving, and a light and smooth line when it is at rest. By means of a screw-movement the pencil is carried in oscillating lines to and fro across the drums.

Richardson's speed-recorder, April 29, 1873. An endless revolving chart, driven by the wheels, is ruled with transverse lines to indicate distances, and with longitudinal lines to indicate the time consumed in traveling the said distance. A pencil is actuated by a clock, and made to traverse at a uniform speed across the chart. Thus the endless moving chart, operated by the car-wheel, records distance, and the reciprocating clock-actuated pencil records time. A third feature: a steam-gage has a

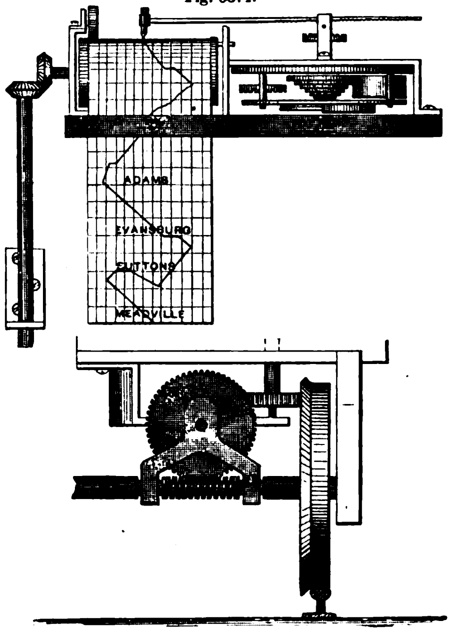
Fig. 5373.



Richardson's Speed-Recorder.

pencil attached to record the steam-pressure upon the chart, so that its variations are apparent for all the time occupied in the journey.

Fig. 5374.



Wythe's Speed-Recorder.

Wythe's speed-recorder for railway-trains, July 28, 1874. The chart is ruled with cross-lines, for distance and time respectively. It is moved by gear from the car-axle. The pencil is moved by clock-work. The result, when the car is moving, is a diagonal line, whose angle will depend upon the speed; the pencil always moves in its own proper direction at the same speed, and the paper slips beneath it at a rate corresponding to that of the car.

Brown's revolution *indicator*, September 1, 1874, has a mercury reservoir and a communicating pipe, which proceeds radially and then bends upwardly. As the device is revolved by the machinery, the mercury obeys the centrifugal impulse, and passing outwardly and up into the tube descends in the axial graduated tube, its sinking being the measure of the speed of rotation.

Elliott's tachometer, July 28, 1874, is for measuring the speed of vessels. It has a pipe extending through the hull of the vessel, to receive the impulse of the water, and another to be acted on by the suction; cocks are so contrived that either a water or a mercury gage can be put in connection with the water-pipes, for low or high speeds respectively. See also LOG; VELOCIMETER.

Speed'y-cut Boot. (*Saddlery.*) A peculiarly shaped knee-boot, designed to protect the knee from injury from the opposite foot of high-stepping trotting horses.

Spelk. A small rod, used as a splint. A spike in thatching. A rod in a loom, etc.

Spel'ter. A commercial name for zinc. *Spelter solder* is made from zinc, 12 ounces; copper, 16: or zinc, 16; copper, 16. The larger proportion of zinc is for a *soft* spelter solder.

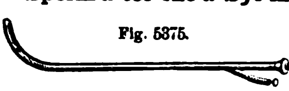
Spen'cer. (*Nautical.*) A four-cornered *fore-and-aft* sail, whose head is extended by a gaff and its foot usually by a sheet. Its position is abaft the *fore* or the *main* mast, and it is frequently bent to an auxiliary spar, called the *spencer-mast.* It is a *trysail* to the *fore* or *main* mast, and differs from a *spanker* or *driver* in position. The latter belong to the *mizzen.*

Spen'cer-mast. (*Nautical.*) A small mast abaft a lower mast for hoisting a trysail.

Spend. (*Mining.*) To break ground, to work a way.

Sperm'a-tor-rhe'a Syr'inge. (*Surgical.*) An instrument for injecting the male urethra with emollients, astringents, or caustic, as the case may require.

Fig. 5375.



Otis' Spermatorrhea Syringe.

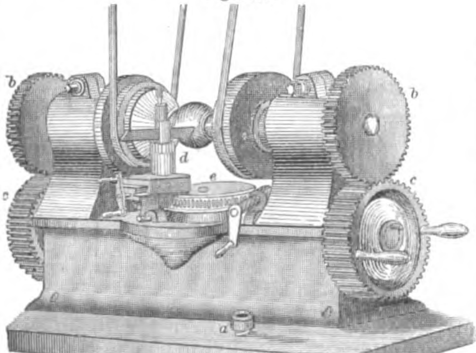
Spetch'es. The trimmings of hides, used for making glue.

Sphe'ra-nau'ti-ca. An old-time nautical instrument, mentioned in Frobisher's voyages.

Sphere. See GLOBE; ARMILLARY SPHERE.

Spher'e-o-type. (*Photography.*) A positive collodion picture taken upon glass by placing a mat before the plate, so as to give a distinct margin to the picture.

Fig. 5376.



Sphere-Turning Lathe.

Sphere-turn'ing Lathe. A lathe for turning billiard-balls and similar objects to a truly spherical form. In Hyatt's (Fig. 5376), the ball is held between chucks *a*, attached to opposite spindles, and moved toward each other by right and left hand screws. These are operated by two spur-wheels *b b* gearing into two other spur-wheels *c c* on a longitudinal horizontal shaft, so that the ball may be chucked centrally over the center around which the tool-post is carried. The tool-post *d* is attached to a disk *e* in the center of the lathe, having a threaded periphery engaged by a worm, by which a circular motion equal in amount to the width of cut of the tool is imparted to it at each revolution of the ball.

Spher'i-cal Boil'er. (*Steam.*) One of globular form or made up of a number of connected globes.

Harrison's steam-boiler consists of an aggregation of small and nearly spherical cast-iron shells, with connecting necks, through which pass bolt-stays holding the several "unit spheres" together; several *plates* of these spheres are connected and wholly immersed in the brick furnace. The inventor has since patented a method for constructing the unit spheres in wrought-iron. See STEAM-BOILER.

Spher'i-cal Case-shot. (*Ordnance.*) A thin, spherical shell filled with bullets. See SHRAPNEL.

Spher'i-cal Lathe. A lathe for turning spheres. (See SPHERE-TURNING LATHE.) See also patents, No. 52,244, Foster, January 23, 1866; No. 49,122, Knowlton, August 1, 1865.

Spher'i-cal Lens. A lens of a spherical shape. Perhaps the earliest form of lens, in the similitude of the drop of dew on a villous leaf, which so beautifully magnifies the filaments.

The spherical lenses have usually an equatorial groove in a plane perpendicular to the axis of the lens. This is closed by an opaque object, leaving a central stem. The object is to exclude light and lateral rays. See PERISCOPIC LENS; CODDINGTON LENS.

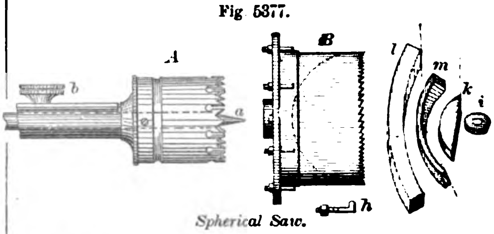
Spher'i-cal Mir'ror. A mirror used in some forms of the CATADIOPTRIC LIGHTS (which see).

Spher'i-cal Saw. An annular saw, as the trephine.

A, Fig. 5377. This usually has a guide-point *a* at the end of a rod, secured by a set-screw *b*, and passing through the tubular stem of the saw. See TREPHINE.

B is a crown saw. These are sometimes as large as 5 feet in diameter and 15 inches deep. In this case the saw is built up of three or four thin plates of steel bent to form portions of the

Fig. 5377.



Spherical Saw.

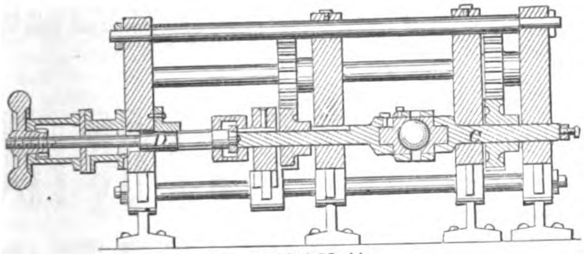
circle, and riveted to an annular ring, which is fixed to the surface chuck of a kind of lathe mandrel by means of hook-bolts *h*; the work is grasped in a slide-rest, which traverses within the saw and parallel to its axis.

i is a rough sheave cut by the crown-saw; *k*, a brush back; *l*, wheel-felly; and *m*, a chair-back, cut by the oblique action of the saw.

A saw of a dished shape, the segment of a sphere, has been used for sawing curvilinear work. The fence was made as the arc of a circle, and had a conductor to receive the work. The circular fence was attached to a three-bar parallel rule, so as always to keep the curvatures of the fence, conductor, and saw parallel with each other.

Spher'i-cal-shot Ma-chine'. A machine for imparting a truly spherical form to steel or iron can-

Fig. 5378.



Shot and Shell Machine.

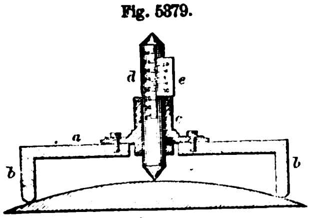
non-balls. The ball, hot from the molds or from subsequent heating, is placed in cups which are preferably caused to rotate in opposite directions and at different speeds. One of the cups is upon a spindle at the end of a shaft *D*, which has longitudinal motion by a tail-center, actuated by a hydraulic press or otherwise, and serves to press the cups together. The other cup-spindle *C* is fixed. The cups are slacked off at times during the operation, to bring fresh surfaces of the ball under operation.

Spher'i-cal Valve. See GLOBE-VALVE, page 988.

Spher'o-graph. An instrument invented for the mechanical application of spherics to navigation. By its aid any possible spherical triangle can be constructed without dividers or scale. — BRANDE.

Sphe-rom'e-ter. An instrument for measuring the curvature of surfaces. It consists of a three-armed frame, standing on three steel pins, which form with each other an equilateral triangle; in the center of the instrument is a vertical screw with a fine thread, and having a large graduated head. The screw is turned downward until its point reaches the surface on which the instrument stands; if this is a true plane, the index of the graduated screw-head should mark zero; if, on the contrary, it is either convex or concave, the corresponding positive or negative reading indicates the degree of sphericity.

Fig. 5379.



Spherometer.

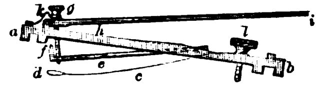
Fig. 5379 is an instrument for measuring the curvature of lenses or speculums or of the tools for grinding them. The arm *a* has two branches *b b*, whose ends are accurately turned and ground to a circular form. The socket *c* contains a sliding index-bar *d* with conical ends, which is divided to fiftieths of an inch; a vernier *e* enables it to be read to $\frac{1}{1000}$ of an inch, or, by estimation, to $\frac{1}{2000}$.

Sphyg'mo-graph. An instrument applied to the pulse to ascertain and record the quickness of its beating and its uniformity or irregularity, as the case may be; also, the degree of force with which the blood is driven through the arteries, — or, in other words, the contractile power of the heart. Of late years this apparatus has been used by physicians for purposes of diagnosis and in various physiological investigations.

It was originally devised by Vierordt, and subsequently greatly improved by Marey.

Marey's instrument, as originally constructed, consists of a long frame *a b*, to which is attached a strong steel spring *c*, about four inches long, and having at its free end a pad *d*, which presses upon the artery; an arm *e*, having a knife-edged

Fig. 5380.



Sphygmograph.

projection *f* at its free end, is attached to the spring *c*, and carries the regulating screw *g*, which governs the amount of vibration of the recording lever *h i*, also provided with a compressing spring *k*; this lever is of the third kind, is very light, and carries a thin steel pen or scratcher at its tip. A screw *l* determines the amount of pressure of the pulse-spring. A recording paper is fixed on a flat metal backing, connected with clock-work mechanism, which runs for about 10 seconds; the whole being attached to the frame *a b*. The instrument is bound on to the arm by a silken cord attached to pegs at its sides. The knife-edged projection *f* taps the lever *h i* at each pulsation with a force proportionate to the strength of the pulse; the lever describes an irregular curve on the paper, indicating the number and strength of the pulsations, and the momentary variations in their force.

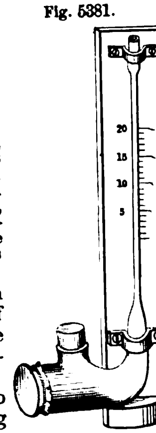
Sphyg-mom'e-ter. An instrument for counting the arterial pulsations.

Praxagoras of Cnidos wrote on the pulse, showing that it was a measure of the force of disease. Herophilus of Alexandria wrote on the pulse, and referred it to the contraction of the heart. Erasistratus, his colleague, described the action of the heart, but supposed that the arteries carried air and the veins blood. Santorio of Padua invented an instrument for measuring the force of the pulse. See his "Commentarius in Primum fere Primi Libri Canonis Avicennæ," Venet, folio 1626.

Sphyg'mo-scope. An instrument for rendering the arterial pulsations visible. It is said to have been invented by Galileo, who, by placing one end of a light mirror upon the artery leading to the thumb and the other upon a fixed object, caused the image of a sunbeam reflected from the mirror on an opposite wall to vibrate in unison with the pulse.

Fig. 5381 is a view of Pond's sphygmoscope, patented April 6, 1875. The essential parts of the instrument are a liquid reservoir or receptacle; an opening in the same, which, whether closed by an elastic and yielding membrane or not, is to be applied to or over the pulsating body; and a fine transparent terminal tube, communicating at one end with the reservoir or receptacle, into which tube the liquid, when the open end of the receptacle is pressed on the pulsating body, will enter, and will therein rise and fall to accord with the movement of the pulsating body, said movement being considerably magnified by the moving liquid, owing to the small diameter of the tube in which it is received.

Fig. 5381.



Pond's Sphygmoscope.

Spi'ca. (*Surgical.*) A form of bandage resembling a spike of barley. The turns of the bandage cross like the letter V, each leaving a portion uncovered.

Spice-mill. A mill similar to a coffee or drug mill, for grinding spices.

A pepper-mill of boxwood is mentioned by Petronius. It was used for black pepper from the East Indies, — a favorite ingredient. See SAUSAGE.

Spic'u-la-for'ceps. (*Surgical.*) A dentist's long-nosed forceps for removing small fragments of bone, etc.

Spi'der. 1. (*Machinery.*) *a.* A skeleton of radiating spokes; as a sprocket-wheel consisting of spokes on a rotating shaft, the ends of the spokes acting as cogs for the links of an endless chain.

b. The internal frame or skeleton of a gear-wheel,

for instance, on which a cogged rim may be bolted, shrunk, or cast.

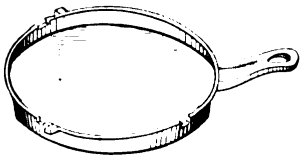
c. The solid interior portion of a piston to which the packing is attached and to whose axis the piston-rod is secured.

2. (*Nautical.*) *a.* An outrigger to keep a block from the ship's side.

b. An iron hoop around the mast for the attachment of the futtock-shrouds.

c. A hoop around a mast provided with belaying-pins.

Fig. 5382.



Spider.

3. (*Culinary.*) *a.* A kitchen utensil, with feet, adapted to be used on the hearth for baking or boiling.

b. A griddle.

4. A three-legged iron stool for supporting a pan or pot upon the hearth. A trivet.

Spi'der-line. (*Optics.*) A filament of spider's web used in micrometers.

Spie'gel-ei'sen. An iron with a natural alloy of from 10 to 12 per cent of manganese. The term is German, *spiegel* signifying a looking-glass, and has reference to the brilliant white luster of the metal.

Spig'ot. A plug to stop a vent or command the opening through a faucet.

Spig'ot (or Fau'cet) Joint. A pipe-joint formed by the insertion of one piece into another.

Spike. 1. A large nail, above 10*d.*

12*d.* spikes are 3¼ inches long, 45 to the pound.
16*d.* spikes are 3½ inches long, 28 to the pound.
20*d.* spikes are 4 inches long, 20 to the pound.
30*d.* spikes are 4½ inches long, 16 to the pound.

Railway-spikes are larger and are of several patterns.

Fig. 5383.

Spikes.

Spikes are known by shape, character, purpose, quality, or size, as —

Flat,	Notched,
Narrow flat,	Barbed,
Wide flat,	Forked,
Grooved,	Cylindrical,
Swelled,	Square, etc.

Spikes (H. Burden, *Troy, N. Y.*).

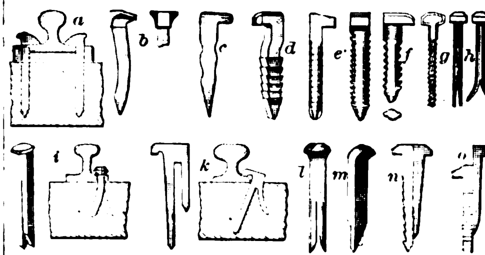
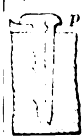
Patented forms of spike specially intended for securing railway-rails to the ties are numerous; in most it is sought to increase the holding power by serrating the edge of the spike or by causing its points to spread apart in driving.

Fig. 5384.



Spikes.



a (Fig. 5384) shows a rail composed of an upper rail and a grooved bedding-piece, secured by spikes of the ordinary kind.

b is curved, to cause it to bear more strongly against the rail, and the head has a shoulder at the back, which comes in contact with the wood before the hooked forepart touches the flange of the rail, in order to lessen and equalize the strain on the head, and prevent its being broken off in driving.

c, the sides are corrugated, so that the wood may swell into the indentations, but not hold the spike too tightly to prevent its being drawn.

d, a part of the shank has a winding surface, so as to cause the spike to twist, engaging the serrations in the wood.

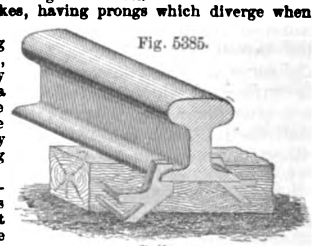
e, the spike has a winged point and spiral barbs upon two of its edges.

f, the shank has a serrated wing on each side.

g, a screw-spike, having the under side of its head so beveled as to bear firmly on the flange of the rail.

h i k l m, split spikes, having prongs which diverge when driven into the wood.

Fig. 5385.



Spike.

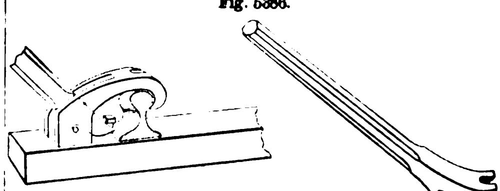
n o p, spikes having serrations on one side, and held firmly by keys; in the latter a projection on the spike enters a notch in the key to keep the key in place after being driven.

Redburn's railway-spike (Fig. 5385) has a body grooved to fit the lower flange of the rail, and two prongs, one above the other, which are driven into the tie, and cannot be withdrawn by the vertical vibratory motion of the rail.

2. (*Ordnance.*) Spikes are used to destroy the efficiency of cannon by plugging the vent. A rat-tail file is a good spike.

Spike-draw'er. A crow-bar with a claw for extracting spikes. The fulcrum piece is based upon the tie and hooked over the rail. The claw of the lever lifts the spike by the head.

Fig. 5386.



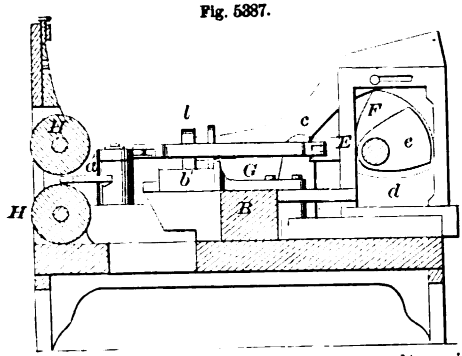
Claw for Drawing Rail-Spikes.

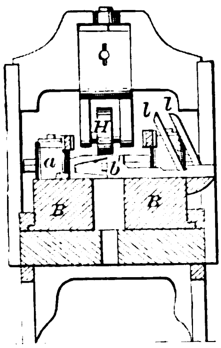
Spike-ex-tract'or. See Spike-drawer.

Spike-ma-chine'. A machine for making spikes from bar-iron.

In Fig. 5387, the rod is fed between the rolls *H H*, the upper one of which rotates in adjustable, and the lower in fixed bearings, and is presented to the action of a pair of cutters carried upon two vertical posts *a a'*, which, by means of a cam *d* and

Fig. 5387.



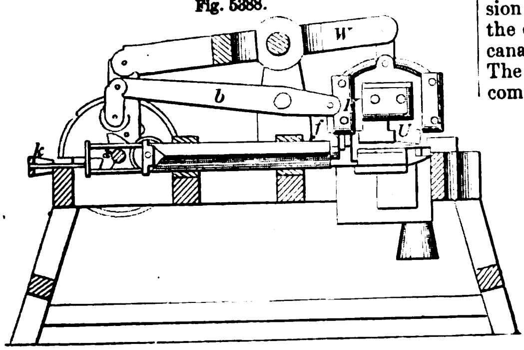


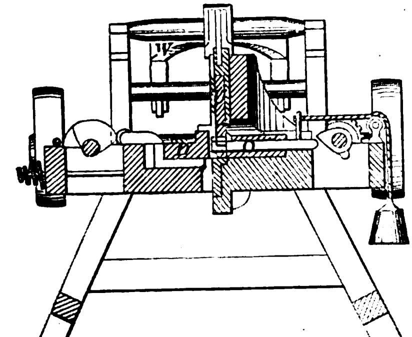
Spike-Machine.

connections, are opened to receive the rod, and closed to form the point of the spike and cut it off. A cam e turning in a yoke E imparts a traversing motion to the carriage B B, and a cam F rocks the lever c, which carries a die b', between which and the stationary die b the body of the spike is formed. The die b' is, by means of inclined parallel guides l l, partially rotated, so as to close gradually on the body of the spike. While the spike is clamped between the dies, the header G, having a slot i, into which passes a pin i', connecting it loosely with the bed, advances with the bed, and is brought in contact with the end of the blank, which projects beyond the dies, at the same time turning on its pivot, so that its pressure is first applied to one side of the head, and is gradually brought to bear squarely upon it at the completion of its stroke.

In Fig. 5388, a gage K is adjusted to determine the length of the spike or bolt, which is first grasped between two moving

Fig. 5388.





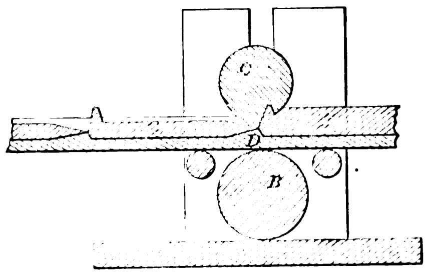
Spike-Making Machine.

dies C D that shape the body. A vertically moving die U, operated by the lever W, forms the point, and a second vertically moving die f, operated by the lever b, the head. The levers W b have pivoted arms, which are turned down, so as to be acted on by cams when spikes are to be made, but are lifted out of contact with the cams in making plain bolts.

A cutter O, advanced by a cam and retracted by a cord and weight, or a spring, severs the blanks.

In Fig. 5389, the bed D is traversed by gearing from the roller B, which also has gear connection with the cam-roller C. The bed is grooved to form the lower half of the spike, the upper

Fig. 5389.



Spike-Machine.

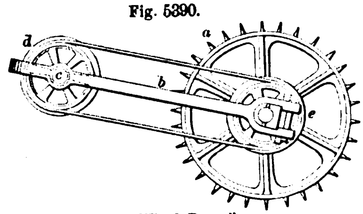
half being formed by the cam-roller, which has a transverse notch that shapes the head as the rod enters between it and the table, and the point is tapered as the spike emerges from between them. Small supporting rolls beneath steady the table and prevent it from tilting.

Spike-plank. (*Nautical.*) In arctic navigation, a platform projecting across the vessel before the mizzen-mast, to enable the ice-master to cross over and see ahead, so as to pilot her clear of the ice. It corresponds with the bridge in steamers.

Spike-tack'le. (*Nautical.*) That by which the carcass of a whale is held alongside while *flensing.* The carcass is turned by the *cant*-tackle, while the *speck* is hauled off by the *speck-purchase.*

Spike-wheel Pro-pel'ler. A mode of propulsion of canal-boats in which a spiked wheel driven by the engine is made to track upon the bottom of the canal and thus draw the boat. Invented by Seaward. The spike-wheel operates outside the boat or in a compartment inside open at bottom. In order to accommodate the wheel to the inequalities of the bed of the canal, the wheel a has its bearings in a swinging frame b, the other end of which is hung to a shaft c, driven by a steam-engine, and having a pulley d, which communicates by a band with a pulley e on the shaft of the spike-wheel.

Fig. 5390.



Spike-Wheel Propeller.

Spile. 1. A small plug of wood for stopping the spile-hole of a barrel or cask. The spile-hole is a small aperture made in the cask when placed on tap, usually near the bung-hole, to afford access to the air, in order to permit the contained liquid to flow freely.

2. A spout for sugar-water (the sap of the sugar-maple tree), which, being inserted in a hole bored in the tree, conducts the water to a trough or pan placed beneath to receive it.

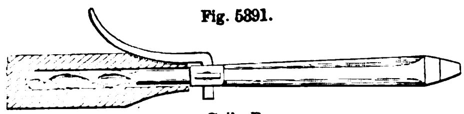
The spiles are sometimes little troughs made by splitting out pieces from a block with a gouge. The same gouge is used to drive into the tree and make a kerf to hold the sharpened end of the spile. A notch is cut by an axe in the tree above the spile, and the sap trickling thereinto is conducted to the bucket.

The tool is known as a *tapping-gouge*.

3. (*Hydraulic Engineering.*) A PILE (which see).

Spile-bor′er. An auger-bit to bore out stuff for spiles. To the shank of the auger that bores the spile is attached an obliquely set knife to taper the end thereof.

Fig. 5891.



Spile-Borer.

Spil′ing. (*Shipbuilding.*) The edge curve of a plank or strake.

Spil′ings. (*Shipbuilding.*) Dimensions taken from a straight-edge or rule to different points on a curve.

Spill. 1. A spile.

2. A roll of paper for lighting. An *alumette.*

3. A small bar or pin of iron.

4. (*Shipwrighting.*) A small peg used to stop the hole left by a spike when drawn out.

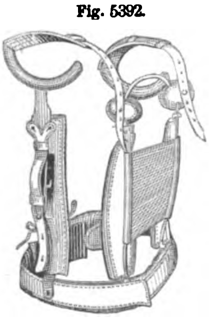
Spill′er. A kind of fishing-line.

Spill′ing-line. (*Nautical.*) A line to spill the wind out of a sail, by keeping it from bellying out when clewed up.

Spill-trough. (*Brass-founding.*) The trough against which the inclined flask rests while the metal is being poured from the crucible. The crucible is above the trough, so that any metal which dribbles or spills is caught into the spill-trough. See BRASS-CASTING, Fig. 877.

Spi′nal Brace. (*Surgical.*) A brace for remedying posterior curvature of the spine (Pott's disease). It consists of a pelvic belt made broad in front to compress the protruding abdomen, two elastic crutches, which tend to elevate the body by pressure against the margins of the scapulæ, and two side-bars, on which are elastic and padded springs that adapt themselves to the sides of the spinal column, and tend to keep the body in an erect position. The bars are connected by a broad elastic band, which exerts a constant pressure on the protuberance. See also TORTICOLLIS BRACE; SCOLIOSIS BRACE; SPINAL-DISTORTION APPARATUS.

Fig. 5392.



Spinal Brace.

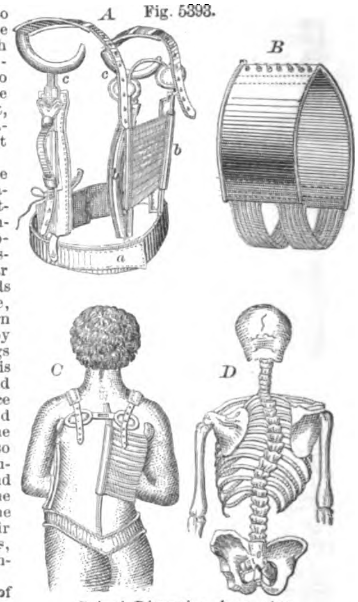
Spi′nal-Dis-tor′tion Ap′pa-ra′tus. (*Surgical.*) An apparatus designed to gradually restore the spine to its normal condition when it has become curved.

A is intended to remedy backward protusion. The belt *a* passes around the pelvis region; the front is made broad to compress the protruding abdomen. An elastic band of silk and rubber, stretched between the side-bars *b b*, bears against the protuberant spine, and to the side-bars are attached elliptic padded springs, which press on each side of the spine, but yield to the motions of the body. Two elastic padded crutches *c c* tend to elevate the body, pressing principally under the margin of the scapulæ, to avoid compression of the axillary veins. The elastic belt *B* is intended to give additional pressure, if needed, but principally to compress the sternum, which generally protrudes. It is also designed to be worn at night, when the apparatus itself is not applied.

C is the brace for lateral curvature, as illustrated at *D*. It consists of a belt supporting a posterior upright bar carrying two pads for the scapulæ, and a leathern band attached by elastic webbings and buttons; this is passed around the protuberance obliquely, and buttoned to the belt in front, so as to exert a gentle pressure, and at the same time tend to turn the ribs around their vertebral axes, thus straightening the spine.

D, the trunk of the human skeleton, illustrating a case of lateral distortion of the spine.

Fig. 5393.

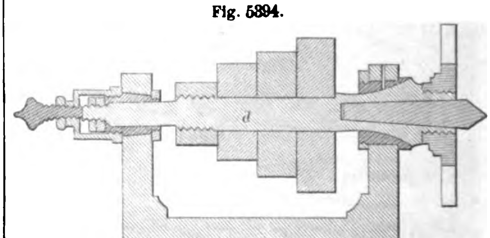


Spinal-Distortion Apparatus.

Spin′dle. A shaft or mandrel which supports a rotating object.

1. (*Lathe.*) The *arbor* or *mandrel* in a lathe. *D* is the live spindle rotating in boxes in the front and rear standards of the *head*. The *live* spindle is in the *head-stock*; the *dead* spindle is in the *tail-stock*, where its function is merely to center and support the object, and not to partake of its movement or impart motion.

Fig. 5394.



Lathe-Head.

2. (*Mill.*) A vertical shaft supporting the upper stone or *runner* of the pair in a flouring-mill.

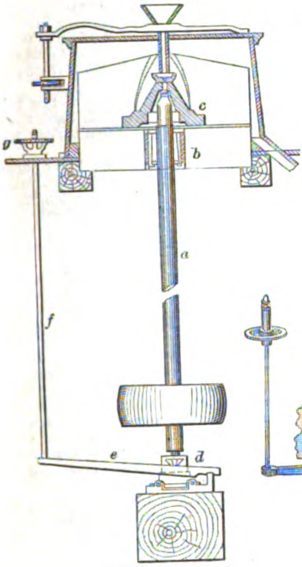
The shaft *a* passes through the lower stationary stone *b*, is connected to the *rynd c* of the upper stone, which it rotates, being driven by gearing or by band-and-pulley connection with the prime motor, and is usually stepped in a block *d*, which, in the present instance, is adjusted to vary the distance between the stones, by means of the lever *e* and rod *f*, screw-threaded at top, and raised or lowered by a nut and hand-wheel *g*.

The parts are known as follows: —

a, spindle.	*g*, damsel.
b, slip-driver.	*h*, backlash-spring.
c, trampot.	*i*, fulcrum.
d, lever.	*k*, pinion.
e, lighter screw.	*l*, set-screw.
f, bail, or balance-rynd.	

3. (*Vehicle.*) The tapering end or *arm* on the end of an axle-tree. The hub of the wheel is slipped on the *spindle*, and is secured there by a linch-pin in some cases, and by a nut in others. See AXLE.

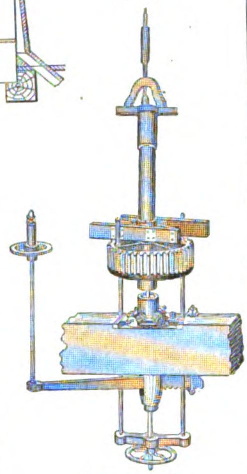
Fig. 5395.



Mill-Spindle.

In the example, the spindle has a collar upon it, with a packing-ring on each side.

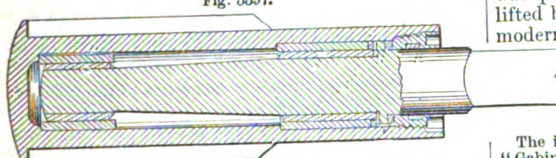
Fig. 5396.



Mill Spindle.

The collar furnishes bearing for the holding-nut attached by an outside screw to the box. The spindle has two collars of hardened steel, and the box two rings of the same, which come in contact and take the friction of the journal.

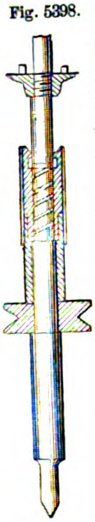
Fig. 5397.



Wagon-Spindle.

4. (*Spinning.*) *a.* A skewer or an axis upon which a bobbin is placed to wind the yarn as it is spun.

Fig. 5398.



Spinning-Spindle.

The kinds, of which there are many varieties, are the —

Live spindle, in which the bobbin is fast on the spindle, and rotates with it.

Dead spindle. A skewer, not movable, on which a bobbin revolves to wind the yarn. The *drag* of the bobbin depends upon its tightness on the spindle, and is adapted to the degree of twist required.

Ring-spindle, one which has a traveling ring upon it. See RING AND TRAVELER.

b. The distaff and spindle — the oldest known form of spinning-machinery, if such it can be called — were familiar to Egyptians, Phœnicians, Hebrews, Arabians, and Hindus, in the time of Abraham, and also to the Greeks in the time of Homer.

In Fig. 5398, the helical oil-elevating groove is cut in the spindle, and ends above in an annular groove in the latter and a coincident groove in the bolster.

c. A *measure of length.* A *spindle* of 18 *hanks* of cotton yarn is 15,120 yards. A *spindle* of 24 *heers* of linen yarn is 14,400 yards.

5. (*Weaving.*) The skewer in a shuttle on which a bobbin or cop of yarn or thread is impaled.

6. The stem of a door-knob, which actuates the latch.

7. A shaft, as of a fusee. The axis of a capstan.

8. The rod which forms the axis of a vane.

9. A round, connecting piece in a chair, as those vertical pieces uniting the seat and slat top.

10. (*Shipwrighting.*) The upper main piece of a made mast.

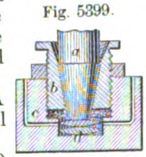
11. (*Founding.*) The pin on which the pattern of a mold is formed.

12. (*Building.*) A newel-post.

Spin′dle-lathe. A lathe with a spindle or mandrel in the *head-stock*, receiving its motion from a band. At one end of the spindle is a point on which the work is centered; the other center is on the *tail-stock*. For hollow turnery, the work is held in a chuck screwed to the mandrel. See LATHE.

Spin′dle-step. The lower bearing of an upright spindle. Used in mill and spinning spindles. (See SPINDLE.) The example has a conical socket and slipping step.

Fig. 5399.



Henry's Spindle-Step.

Fig. 5400.

Spindle-Valve.

Spin′dle-valve. A valve having an axial guide-stem.

Spine. 1. (*Machinery.*) A longitudinal ridge. A fin.

2. A longitudinal slat of a riddle.

Spin′el. Bleached yarn for the manufacture of the broad linen tape known as *inkle.*

Spi-nelle′. A kind of ruby.

Spin′et. (*Music.*) A small instrument of the *harpsichord* kind. It had a single wire for each note, and this was vibrated by a quill. The quill was placed in a *jack*, a vertical piece which was lifted by the key. The keys were arranged as in the modern piano. It probably had catgut strings at first, but afterward had about 30 brass wires for the lower notes and 20 steel ones for the upper. It was used in France as early as A. D. 1515.

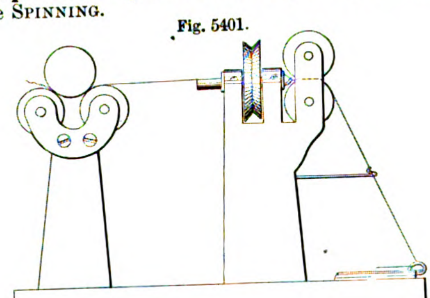
The illustration *q*, Plate XL. page 1692, is from Bonanni's "Gabinetto Armonico," 4to, Rome, 1722. The *spinet* was always triangular, and occupied a place in point of time between the *virginal* and the *harpsichord*. Unlike the former, its strings were strained over a bent bridge, and were struck by quills; and, unlike the latter, it had but a single string to a note. See history of the development of the piano-forte, pages 1690, 1691.

Lord Bacon says: "In *spinets*, as soon as the *spine* is let fall to touch the string, the sound ceases."

The name was also applied to a supplementary instrument tuned an octave above the harpsichord, and placed on or inside that instrument, in some cases sliding therein like a drawer.

Spin′ner. A general term for a spinning-machine. See SPINNING.

Fig. 5401.



Spinner.

Specifically applied to a form of drawing and twisting device, as in Fig. 5401. The twisting devices are placed in proximity to the bite of the drawing-rollers, to enable them to seize hold of and draw the twisted roving evenly from the point of

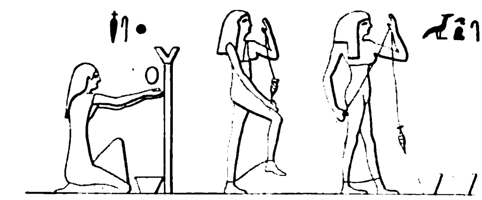
delivery of the feed-rolls to the draw-rolls, and to deliver the same properly drawn to the mechanism which gives the final twist. See also SPINNING-HEAD; DRAWING-HEAD.

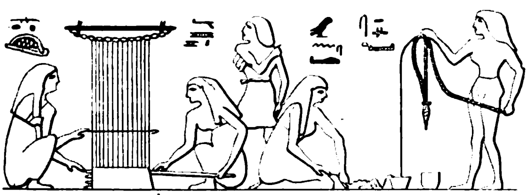
Spin'ning. The process of twisting fiber into a thread or cord.

The earliest representations of the art are in Egypt, to whose ancient inhabitants we are much indebted, and who have left on their temples and tombs enduring monuments of their arts and manners.

With the Egyptians, as with most other nations, the duty of spinning devolved principally on the females. The accompanying illustration is from a tomb at Beni Hassan. The woof was introduced by a hooked stick instead of a shuttle, and was laid double or single.

Fig. 5402.

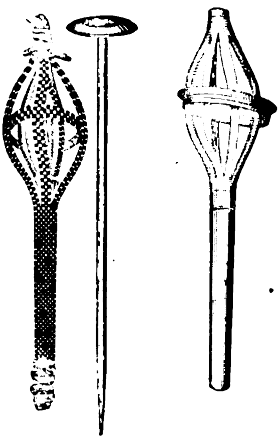




Spinning and Weaving in Ancient Egypt.

The spindles of the ancient Egyptians were made of wood or cane, and the head was made of gypsum or other material, to make it more weighty to increase the impetus in turning. Some were of light plaited work, made of rushes or palm-leaves, stained of various colors. A number of them are in the museums of Europe. One of them, found by Mr. Wilkinson, had some linen thread adhering to it.

Fig. 5403.



Egyptian Spindles.

"Well skilled to cull
The snowy fleece, and wind the twisted wool."

ILIAD, Book III. (*Pope's version*).

The earliest mode of spinning was probably by the distaff and spindle.

The distaff was a cleft stick, about 3 feet long, on which wool, flax, or cotton was wound. It was held under the left arm, the fibers being drawn from it and twisted by the thumb and fore-finger of the right hand. The thread was wound upon a spindle, which was suspended and rotated by the action of the thumb and finger, descending as the thread lengthened until it touched the ground. The *length* was then wound on to the spindle, and the thread secured in a cleft of the reed which formed the spindle. See DISTAFF, page 710.

The notices of spinning in the Bible are restricted to a few passages, which show that the distaff and spindle were employed, and furnish us nothing beyond the practices of the Egyptians.

While the first worker in brass and iron, and the first handler of the harp and organ, are noted in Genesis, we have nothing in regard to the person who first spun and wove. There can be little doubt that it was a gradual work, the growth of centuries of trials; and we may infer that Tubal Cain and Jubal were distinguished links in a chain of inventors and improvers in the metallurgic and musical arts.

The extreme fineness of the Indian cotton fabrics is no new thing, for two Arabian travelers of the ninth century (A. D.) state that "their garments are wove to that degree of fineness that they may be drawn through a ring of moderate size." Marco Polo, in the thirteenth century, mentions the Coromandel coast, and especially Masulipatam, as the home of the finest work.

Tavernier (middle of seventeenth century) states of the turbans of the Indian Mohammedans, that "the rich have them of so fine a cloth, that 25 or 30 ells of it put into a turban will not weigh 4 ounces."

A piece brought to England, from Dacca, by Sir Charles Wilkins, in 1786, "weighed $84\frac{3}{10}$ grains; its length was 5 yards 7 inches, and it consisted of 196 threads. The whole length of thread was 1,018 yards 7 inches. This was about 29 yards to a grain; 203,000 yards to a pound avoirdupois of 7,000 grains; that is, 115 miles, 2 furlongs, and 60 yards." — *Memorandum by Sir Joseph Banks.*

Cotton yarn has been spun in England 350 hanks to the pound, each hank measuring 840 yards, and the whole pound having therefore a length of 167 miles. The extreme fineness of yarns for muslins spun in England is 250 hanks to the pound ($119\frac{1}{4}$ miles), but it is very rarely finer than 220, which is a little coarser than the thread of the Dacca "*web of woven wind.*"

The invention of the spinning-wheel was an era in the history of the art, but we have no name or date to record. It is said to have been introduced into England about the time of Henry VIII., say 300 years ago, but had been used for ages in Hindustan.

The essential improvement consisted in a means for rotating the spindle, the fiber being either presented in carded rovings or from a distaff.

The usual practice with cotton was to card it with coarse wire brushes until the fibers were arranged in one direction, and to present the rovings thus attained, one by one, to the spindle, which was then rapidly revolved by the large wheel by means of a band which ran over the spool of the spindle. The roving was allowed to slip between the finger and thumb of the left hand, while the right turned the wheel, the roving being twisted as it became longer and harder, gradually assuming the condition of yarn or thread. It was then wound upon the reel, another roving attached to the end of the former one, and the spinning resumed.

This is the plan yet adopted in many country places with wool, where the supply for the family, for woolen clothes and stockings, is yet made into yarn by the spinning-wheel, the work being previously carded and made into rovings in the factories, with which the country is well supplied. See SPINNING-WHEEL.

The first successful attempt to spin cotton by machinery was by Wyatt of Lichfield, 1730.

Lewis Paul's patent for spinning by rollers	1738
Lewis Paul's second patent	1758
Arkwright's first patented spinning-frame	1761
Hargreaves' spinning-jenny patent	1763
Arkwright's water-frame patent	1767
Arkwright's combined machines	1775
Crompton's mule	1779
Cotton machinery introduced into France	1787
Cotton machinery introduced into America by Slater, at Pawtucket, R. I.	1789
Hammond's application of the stocking-frame to the weaving of lace	1768
Horton's knotted-frame	1776

James Hargreaves, one of the "martyrs of scientific industry," invented the *spinning-jenny* in 1763. He was persecuted by his fellow-workmen, his machine was broken into pieces by a mob, and he was driven from his native town.

The *jenny*, as at first formed, contained 8 spindles, which were made to revolve by means of a band from a horizontal wheel. Subsequent improvements raised the number to 80 spindles. Then came the mob. After the work on the "jenny" had been resumed, the mob broke forth afresh, and destroyed the carding-machines and jennies throughout Lancashire.

Hargreaves derived the idea of the spinning-jenny from observing the action of a hand-wheel which had been accidentally upset. The spindle being vertical, and continuing to revolve, he drew the roving of wool toward him, into a thread. He then applied himself to invent a contrivance which should hold the roving as it was held by the finger and thumb, the contrivance to run backward on wheels and carry with it a number of threads from as many spindles. This he succeeded in doing. See SPINNING-JENNY.

Hargreaves' place in the history of spinning consists in his being the first to contrive a means whereby one person could attend to the making of several threads simultaneously. In the furtherance of this purpose, he set the spindles upright and held the rovings by a clasp, which answered to the action of the left hand of the spinster. See SPINNING-JENNY.

Still the cotton thread produced was of so soft a nature that it was only used for *weft*, the warp of all English-made cotton goods being of linen, although imported calicoes from the East Indies were of cotton, *warp and weft.*

The next improvement, in order of time, was Arkwright's

spinning-frame, which made a hard-twisted yarn suitable for *warps*.

The progression of the art now introduces us to the great era when *continuity of action* was established, the fiber being fed in a continuous *sliver* through successive pairs of rollers, which move at different rates of speed, and ultimately deliver the roving at such a degree of attenuation as may be desired, the roving passing at once to the spinner, by which it is twisted and wound into a *cop*.

In a more improved form of the invention, the *sliver* is drawn by several successive pairs of drawing-rollers and delivered on to spools or reeds in a condition called *roving*. These are transferred to the spinning-frames, where the rovings are again drawn, twisted, and wound.

The essence of the invention is the *drawing-rollers;* and if the effectiveness of the machine is to determine the paternity, to Arkwright belongs the greater honor.

The idea, however, did not originate with Arkwright, though to him more than any other man are we indebted for the effective machine. Arkwright was but two years old when Lewis Paul patented an improved spinning-machine.

Dyer, in his poem of "The Fleece" (1757), celebrates Paul's machine, as follows: —

"But patient art,
That on experience works, from hour to hour,
Sagacious, has a spiral engine formed,
Which, on a hundred spoles, a hundred threads,
With one huge wheel, by lapse of water, twines,
Few hands requiring; easy-tended work,
That copiously supplies the greedy loom.
Nor hence, ye nymphs, let anger cloud your brows;
The more is wrought, the more is still required;
Blithe o'er your toils, with wonted song, proceed:
Fear not surcharge; your hands will ever find
Ample employment. In the strife of trade,
These curious instruments of speed obtain
Various advantage, and the diligent
Supply with exercise, as fountains sure,
Which, ever gliding, feed the flow'ry lawn."

The preacher was ahead of his times in his perception of the true uses and effects of machinery. This was before Arkwright.

The glory of Lewis Paul's inventions in spinning is obscured by the success of Arkwright. Paul adopted the plan of spinning by the aid of rollers. His first patent is dated June 24, 1738, and the specification states that when the cotton or wool is prepared "one end of the sliver is put between a pair of rollers or cylinders, or some such movement, which, being turned around by their motion, draws in the raw mass of cotton to be spun, in proportion to the velocity given to the rollers. As the cotton passes regularly through or betwixt these rollers, a succession of other rollers, moving proportionally faster than the first, draw the fiber into any degree of fineness that may be desired. Paul acknowledges the receipt of £20,000 from his patents. He died 1759. See SPINNING-HEAD.

Arkwright, the great inventor of spinning-frames, was born December 23, 1736, and began business life as a barber. His improvements followed on the track of those previously patented by Lewis Paul, but their greater success indicates better construction or attention to detail, as well as the advancing demand for labor-saving machines.

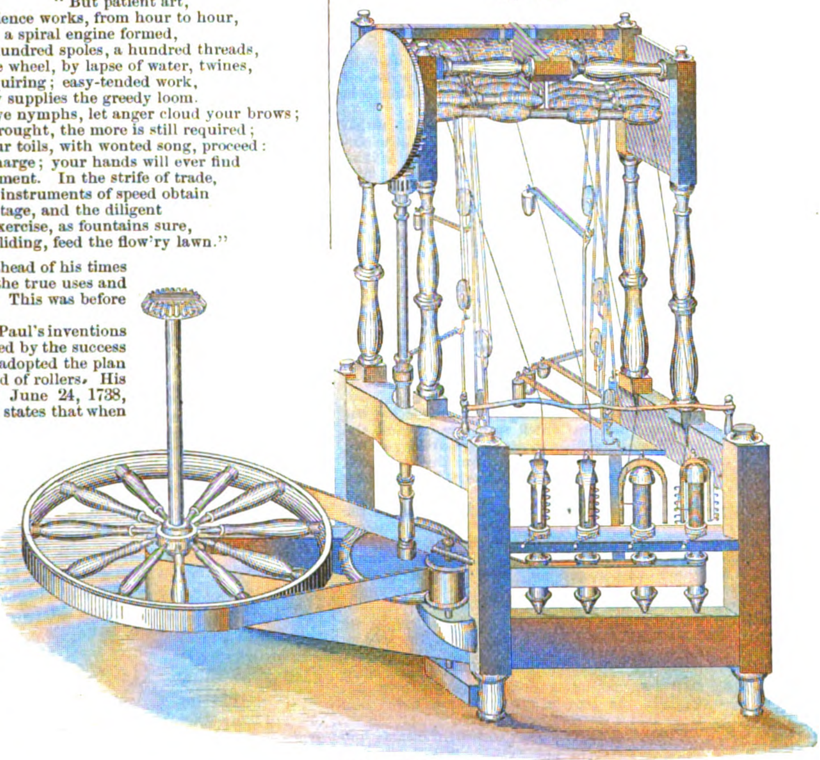
Arkwright was said to be an adept at shaving, and then, leaving the chin, devoted himself to collecting hair for wigs and to dyeing hair. He excelled in that. The perpetual motion next engaged his attention, and in the pursuit of a model maker he discovered Kay, who had some ideas on the subject of spinning cotton. They made a model together, and soon afterward Kay is lost sight of in the matter. They were miserably poor, and probably Kay became tired of the chase. Need and Strutt, of Nottingham, assisted Arkwright, who took out several patents, the most important one in 1769.

It may be mentioned that Kay turned up again in after years to assist in invalidating Arkwright's patent. Kay's wife also helped, and they claimed that a man named High had employed Kay to make what he afterward suggested to Arkwright, and the latter appropriated. Lewis Paul was also there to oppose Arkwright.

Arkwright was the first to introduce the factory system, in which the various operations on fiber are carried on under one roof by operatives managing machinery. Perhaps a single exception may be made in favor of the silk-mills of Italy.

Before Arkwright, the various operations of carding, spinning, and weaving were carried on by cottagers residing within a few miles of the place where the work was given out. Things are very much changed now, work being carried on in immense buildings, forming the nuclei of towns occupied by the operatives. The change from the cotter system, where the workmen and workwomen had the fresh air and garden employment, to the confined and fetid atmosphere of towns, has changed the physical condition of millions, and has not been accomplished without serious riots.

Fig. 5404.



Arkwright's Water-Frame.

In 1789, Samuel Slater, who had been employed by Arkwright, built the first machinery on the Arkwright model ever used in the United States, and ran it in Pawtucket, R. I., by water-power. In 1793, the "Slater Mill," the pioneer factory, was built at that place, and, we are informed, is still standing and used as a manufactory.

· The machinery for which Arkwright took out his patent consisted of various parts, his second specification enumerating no fewer than ten different contrivances, but of these the one that was by far of greatest importance was the device for drawing out the cotton from a coarse to a finer and harder twisted thread, and so rendering it fit to be used for warp as well as weft. This was most ingeniously managed by the application of a principle which had not yet been successfully

introduced in any mechanical operation. The cotton was in the first place drawn off from the skewer on which it was fixed by one pair of rollers, which were made to move at a comparatively slow rate, and which formed it into thread of the first and coarser quality; but at a little distance below the first was placed a second pair of rollers, revolving three, four, or five times as fast, which took it up when it had passed through the others, the effect of which would be to reduce the thread to a degree of fineness so many times greater than that which it originally had. The first pair of rollers might be regarded as the feeders of the second, which could receive no more than these others themselves took up from the skewers. As the second pair of rollers, therefore, revolved, we will say, five times for every one revolution of the first pair, or, which is the same thing, required for their consumption in a given time five times the length of thread that the first did, they could obviously only obtain so much length by drawing out the common portion of thread into five times the original fineness. Nothing could be more beautiful or effective than this contrivance, which, with an additional provision for giving the proper twist to the thread, constitutes what is called the *water-frame* or *throstle*.

Arkwright became very wealthy, built a fine castellated mansion, became high sheriff, was knighted, on two occasions gave £10,000 to each of his ten children, died in 1792, aged 60 years, leaving £500,000, was buried amidst the scenes of his history, a fine monument by Chantrey being placed over his tomb. See THROSTLE; BOBBIN AND FLY FRAME.

It would be a tedious tale to tell of the various suits brought to support the claims of the Arkwright patents, — the one for the drawing-rollers, 1769; and the other for the combination of carding, drawing, and roving machines, 1775.

The case of Arkwright *vs.* Nightingale, and others in which he appears as plaintiff, occupy a prominent position in the records of patent-law decisions. The cases almost rival that of Jarndyce *vs.* Jarndyce, on whose "numerous difficulties, contingencies, masterly fictions, and forms of procedure there had been expended study, ability, eloquence, knowledge, high intellect, the power of the bar, and the matured autumnal fruits of the woolsack." Such is the opinion (paid for) of Counsellor Kenge, as reported by a distinguished writer, a good judge of such matters. Singular that the said author should have summed up the result as "Words, Wigs, Rags, Sheepskin, Plunder, Precedent, Jargon, Gammon, and Spinach."

Next in the list of public benefactors, who devoted himself to the art of cheapening fabrics and elevating labor, appears the name of Samuel Crompton, the inventor of the *mule-spinner*.

The mode of spinning by the drawing-frame subjects the thread to so great tension that it is not possible to draw it as fine as is required for many purposes. It became necessary, therefore, to make machinery more nearly approximating the action of the spinning-wheel, in which the human hand, the finger and thumb, allowed the fiber to escape gradually, giving a moderate twist to the roving as it issues from the hand, and giving the whole length a final twist after it has been sufficiently compacted to bear it.

Samuel Crompton, a youth of 16, worked upon one of the Hargreave jennies in 1769, and five years afterward constructed his spinning-machine, which was called a *mule*, as it was a kind of cross between Arkwright's machine and the Hargreave jenny. It cost him five years of labor, generally after his day's work at weaving was done.

Crompton's first mule was completed in 1779.

He took his machine to pieces to avoid its destruction by the mob, but soon after he fitted the pieces together again, and its success was established, but not his own. Robert Peele and Arkwright used them in their manufactories, making large fortunes by their use. In 1812 the British government awarded him £5,000 as a mark of approbation.

Crompton's first essays were in the same line as Arkwright's, and consisted in sets of drawing-rollers. Mr. Kennedy states: —

"Crompton's first machine contained only about 20 or 30 spindles. He put dents of brass reed-wire into his under rollers, and thus obtained a fluted roller. But the great and important invention of Crompton was his spindle-carriage, and the principle of the thread having no strain upon it till it was completed. The carriage with the spindles could, by the movement of the hand and knee, recede just as the rollers delivered out the elongated thread in a soft state, so that it would allow of a considerable stretch before the thread had to encounter the stress of winding on the spindle. This was the corner-stone of the merits of his invention."

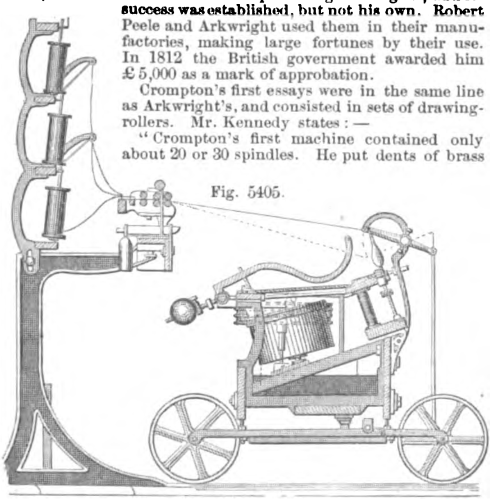


Fig. 5405.

Crompton's Mule.

Crompton worked at home in his residence, "Hall in the Wood," and made such fine yarns that competitors resorted to all mean artifices to ascertain the secret of his success. Finding it could not be kept secret, he concluded to abandon it to the public for a small consideration, subscribed by parties interested. This did not exceed $300. Some of these parties even refused this when the time came to pay.

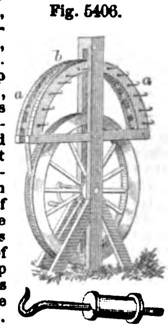
Crompton died June 26, 1827, aged 74. See MULE.

(*Flax.*) The spinning of flax resembles the throstle-spinning of cotton, but the filaments do not adhere together so readily, and, for fine qualities, it is necessary to keep the fiber damp. Water at 120° Fah. is used in preference to cold. The water is contained in a trough the whole length of the spinning-frame, and is thrown off in a dewy spray by the rapid motion of the spindles.

(*Hemp.*) Fig. 5406 is the machine used for spinning hemp into rope-yarns.

It consists of two upright posts with a wheel between them, the band of which passes over a number of rollers or wheels *a*, turning on pivots, with hooked ends, journaled in the semicircular frame *b*. By turning the wheel, these hooks are caused to revolve rapidly. The spinner wraps a bundle of hemp around his body sufficient to finish a yarn, draws out as many fibers as the thickness of the yarn demands, and twists them, attaches the bight to one of the hooks, and walks backward, gradually drawing out the proper supply of fibers from the bundle with his left hand, and allowing them to pass through the two middle fingers of his right hand, so as to regulate the amount delivered to the wheel, which is turned by an assistant. The thickness of the yarn depends on the quantity of hemp which passes through the spinner's hands in a given time and the velocity of the wheel, which governs the degree of twist.

Fig. 5406.

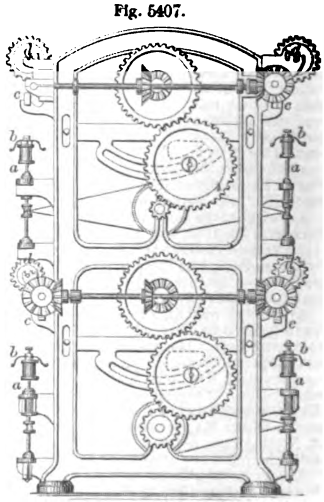


Spinning-Machine.

(*Silk.*) The twisting of silk into a thread is accomplished by machinery substantially similar to that employed for cotton, but the thread of silk being continuous, the *drawing* devices, which gradually attenuate the sliver of cotton, are not called for in the silk-spinner. The bobbins of cleaned silk are mounted on a horizontal rail, and the silk filaments are passed to other bobbins rotating on vertical axes and furnished with flyers, through the eyes of which the filaments are passed. See SILK; SILK-MILL, etc., pages 2179-82.

The silk-spinner is a machine for twisting silk threads, either single or double. An end elevation is shown in Fig. 5407. There are two rows of bobbins and spools on each side, one above the other, driven by two

Fig. 5407.



Silk-Spinning Mill.

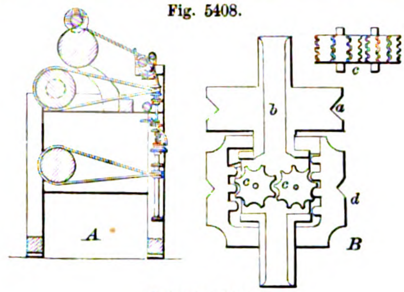
pulleys and belts operating through bevel gearing and spur wheels, one set of which rotates the bobbin-spindles and another the spools. *a a* are the bobbins on which the silk to be twisted is wound; these have flyers *b b* whose rotary motion imparts the twist. Each thread passes through one of a series of guides on guide-bars *c c*, to which a limited traversing motion is imparted, so as to wind it evenly and uniformly upon the spools arranged on the shafts *d d*.

Spin'ning-head. A form of spinner in which the drawing and twisting mechanism are united in one head. This was the first form of spinning-machine, if we except the spinning-wheel. It was invented by Lewis Paul, and patented by him in 1738. His machine had successive pairs of shaving-rolls for elongating the roving, the speed of the consecutive pairs increasing, so that each pulled upon the roving between itself and the succeeding pair, the eventual extension depending upon the relative rates of increase of speed of the successive pairs. He also gave to one or more of the pairs of rollers a revolution at right angles to the plane of their rotation, so as to give a twist to the yarn.

It is not exactly certain why this invention was unsuccessful; it was due primarily to coarse workmanship doubtless, but also to a congenital defect, possibly. Fig. 5408 is a view of an apparatus on a similar principle, patented in the United States 110 years afterward. *A* is an elevation, partly in section, of the machine. *B* is an enlarged view of the drawing and twisting head, and shows a pair of rollers. *a* is the groove for the band which rotates the tube *b* through which the roving passes, and also the wheels *c c*, which, besides their proper motion on their spindle, have rotation on their axes by contact of their cogs with the interior worm of the rotating-case *d*.

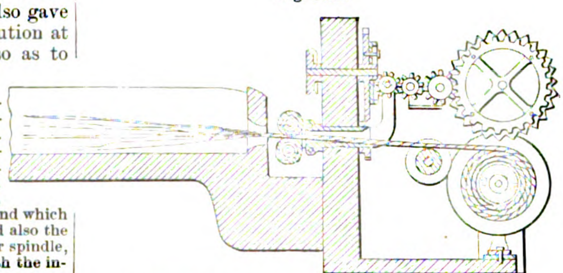
Fig. 5409 is a machine on this principle, for twisting single strands of flax, hemp, etc. The material lies loosely in a trough, from which it enters between the twisting-rollers. The receiving spool is rotated by the positive revolution and weight of the toothed guide-wheels, the strand being guided between them. The bearings of this spool are automatically shifted, that its axis may incline a little, to insure the better laying of the coil; the coil as laid gradually slides the spool upon its axis, first in one, and then in the opposite direction. The barrel of the spool is hollow and compressible, to allow the putting on and off of the heads and removing the material when wound.

Fig. 5408.



Spinning-Head.

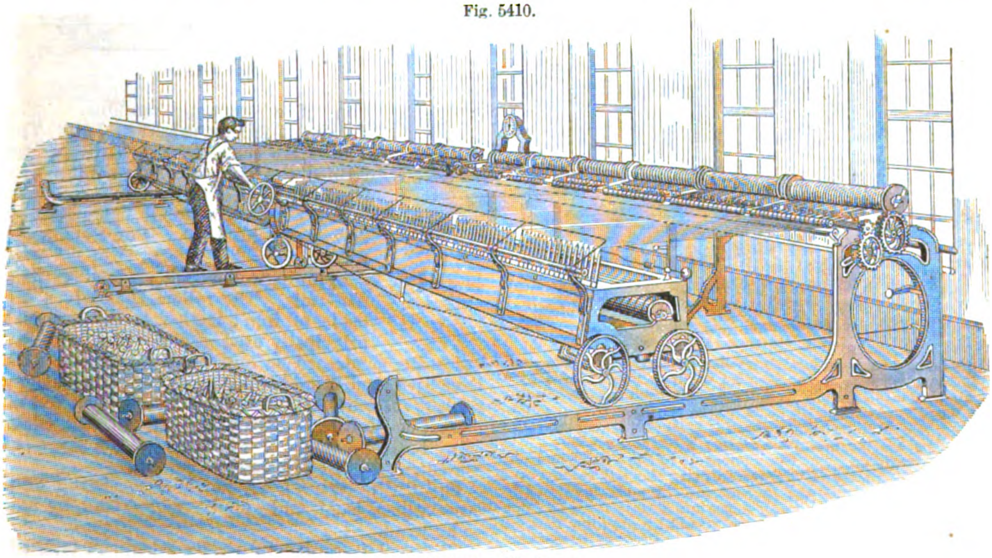
Fig. 5409.



Machine for Twisting and Winding Fibers.

Spin'ning-jack. (*Cotton-manufacture.*) A device for twisting and winding a *sliver* as it comes from the drawing-rollers. It is placed and rotated in the can, the sliver being wound on a bobbin therein. See JACK-FRAME.

Fig. 5410.



Spinning Machinery.

Spin'ning-jen'ny. James Hargreaves' invention, 1767. Up to the time of the invention of the *jenny*, all the yarn and thread of the cotton, flax, and woolen manufactures were made by hand, each thread requiring the attention of one person. The cotton was given out from the card, and occupied the time of a multitude of women and children in the towns, villages, and rural districts in the vicinity of

the looms. The cotton spun by the wheel was of so soft a character that it was only fit for weft, all the English-made cotton goods, at this time, having a linen warp. The cotton goods of the East Indies, imported under the name of *calicoes*, were all of cotton, both *warp* and *weft*, but the machinery at hand in England was yet insufficient for giving the required hard twist to the cotton thread to make it suitable for *warp*.

This was accomplished by Arkwright, a little later, in the invention of the *spinning-frame*.

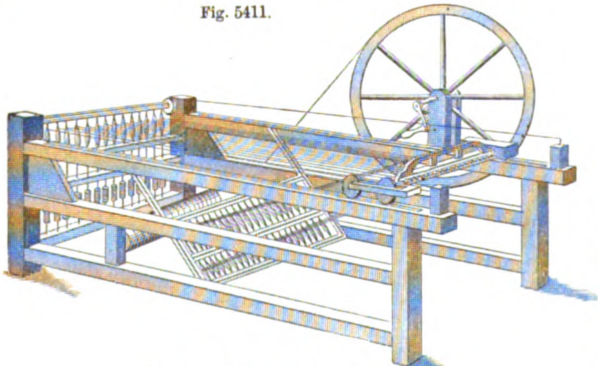
It appears that Hargreaves had long experienced the difficulty of getting a supply of weft-yarn for his loom, he being a weaver by trade. The idea of making a machine by which, under the care of one person, a number of threads might be spun at once, was a favorite project of his, and his success in this particular is what marks his place in the history of the cotton-manufacture.

He at first tried a number of horizontal spindles driven by bands from the same wheel, the rovings being held between the fingers of the left hand. The threads became entangled, and the attempt was unsuccessful. A tradition of the family records that while he was one day spinning, one or more of his twelve children upset the wheel, but continuing to hold the roving in his hand, he observed that it worked equally well, and he took a new start in his projected machine, placing eight vertical spindles in a row, each having a roving attached to it proceeding from a separate spool in another part of the frame.

The next thing was to contrive an apparatus which should simulate the action of as many hands in managing the rovings. This he accomplished with a fluted wooden clasp, which opened and shut like a parallel ruler, and, when pressed together, held the threads fast. The clasp traveled on wheels on the top of the frame, and was managed by the left hand, while the right hand turned the wheel whereby the spindles were rotated. The clasp being withdrawn a short distance from the spindles, the rovings between the two were twisted, and then the clasp was opened and retreated farther. This was repeated until the clasp reached the rear of the frame, when the threads were wound on to the spindles, and the clasp was returned to its recommencing position.

This may be called the first spinning-machine. Its name *jenny* was a modified contraction of the word *engine*, the term *gin* being a common local expression for a machine. The coal-hoisting machine is there called a *gin;* a pump moved by a windmill is called a *gin;* and the famous machine for separating the cotton fiber from the seeds is generally known as a *cotton-gin*. The machine being a *gin*, this mode of spinning was called *ginning*, and the machine a *ginny;* hence *jenny*.

Fig. 5411.



Hargreaves' Spinning-Jenny.

Hargreaves increased the number of spindles to 80, and met with the usual fate of improvers during the last century and the first quarter of the present one. A mob, instigated by jealous rivals, broke into his house and destroyed his machine. He then removed to Nottingham, rebuilt his machine, took out a patent, and lived comfortably on the proceeds of his machine, though his patent was infringed and he made nothing by an exclusive right in it. He died in 1778, leaving but a small estate, having failed entirely in obtaining a proper remuneration for a work of such great national importance.

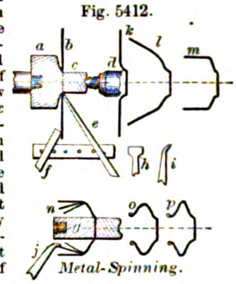
Spin'ning-ma-chine'. See SPINNING; SPINNING-JENNY; THROSTLE; MULE; DRAW-HEAD; BOBBIN AND FLY FRAME, etc., etc. See list under COTTON.

Spin'ning-mill. A name applied to a machine for spinning silk (see Fig. 5129), or to a factory where spinning is carried on.

Spin'ning Met'al. A process of forming circular articles of sheet-metal by pressure applied to the circumference while they are rotated in the lathe. It is analogous to forming pottery on the lathe, and depends for its success on the malleability of the material.

Fig. 5412 illustrates the method commonly employed for producing a teapot from a disk of Britannia metal. The wooden mold or chuck *a* is turned to the form of the lower part of the teapot, and the disk *b* is pinched tight between the flat surfaces of *a* and *c* by the fixed center screw *d* of the lathe, so that *a b* and *c* revolve with the mandrel; a burnisher *e* is held against a pin in the lathe-rest as a fulcrum, and applied near the center of the metal and a wooden stick *f*, held on the opposite side to support the edge. The metal is rapidly bent or swaged through the successive forms *k l m*, so as to fit close against the curved face of the block and its cylindrical part. The mold *a* is then replaced by *g*, and a burnisher — various forms of which, as *h i*, are used — is applied, being first slightly greased, together with a hooked stick or rubber *j*, first to force the metal inward, as shown at *n o p*, and then to curl up the hollow bead, which stiffens the mouth of the finished vessel.

Fig. 5412.



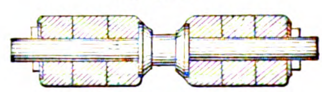
Metal-Spinning.

Sometimes the molds are made of the exact form of the inside of the work, but in several pieces, each smaller than the mouth, so that when the central block is first removed, the others may be successively taken out of the finished vessel, like the parts of a hat-block or of a boot-tree.

Plated candlesticks, the covers of cups and vessels, the bell-mouths of musical instruments, and numerous other articles of thin metal, which are required in great numbers, are produced in a similar manner.

Spin'ning-roll'er. A wheel in the drawing portion of a spinning-machine. (See DRAWING-FRAME, pages 743, 744.) The wheels are made to run in pairs, and formed the basis of the machine first invented by Lewis Paul in 1738, and brought into successful operation by Arkwright in 1769. See SPINNING-HEAD.

Fig. 5413.



Spinning-Roller.

Spinning-rollers are made of various materials. The rollers themselves are made of iron; leather is the material principally used as a covering; rubber, vulcanite, condensed cotton, wood, paper, and cork have been used, also combinations of felt and leather, rubber, vulcanite, or gutta-percha and leather, felt or flannel and leather, cork and leather, felt and cork, as well as compounds of which glue is the principal ingredient; also bichromatized gelatine.

Spin'ning-wheel. A machine consisting of a large wheel, band, and spindle, and driven by foot or by hand.

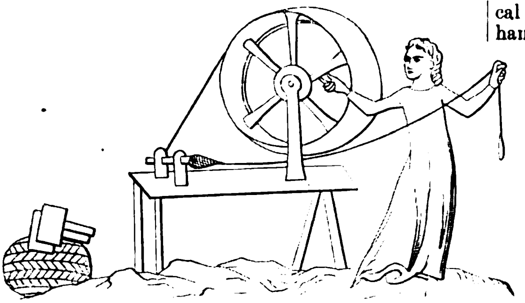
The wool is carded into rolls, which are twisted, drawn, and wound a length at a time, the wheel being turned periodically to twist the yarn. It was the first great improvement upon spinning by a distaff and spindle.

It appears to have been in use for many ages in Hindustan, but did not reach Europe before the sixteenth century. One account states that it was invented at Nuremberg about 1530: the statement is improbable.

The accompanying cut is taken from an illuminated manuscript of the fourteenth century, in the British Museum (M. S. Reg. 10 E. IV.), and represents a lady spinning at her wheel.

The spindle is rotated in horizontal bearings, having a spool, over which the band from the larger wheel passes. A roving,

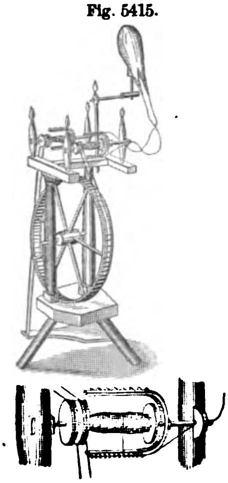
Fig. 5414.



Spinning-Wheel.

being attached to the end of the spindle, is twisted as the latter revolves, the roving being allowed to slip between the finger and thumb of the spinster, who also extends the roving by retracting the hand, or by retiring from the wheel, which continues its motion by the impetus acquired. The required length and hardness of twist being obtained by this combined drawing and twisting operation, the yarn is disengaged from the point of the spindle and wound into a *cop*, the end of the yarn being attached to the end of the spindle, so as to project and allow another roving to be connected thereto.

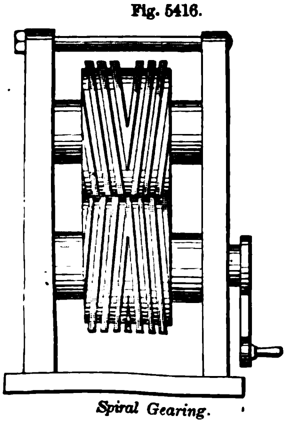
Fig. 5415.



Spinning-Wheel.

Fig. 5415 is an improved form of the old-fashioned hand-spinning wheel. It is set in motion by a treadle, which turns the large wheel, around which are bands passing over two pulleys near the ends of two horizontal spindles, which also carry flyers. The roll of fiber is placed on an upright pin, and the spinster, drawing out two thin slivers, attaches them to the two spindles, passes them between two of the teeth on each spindle, and imparts a rotary motion to the wheel, at the same time drawing out the slivers, which are thus elongated and twisted by the flyers to a degree proportionate to the velocity of the rotation. When the drawn-out sliver has been twisted sufficiently, the yarn is removed from between the teeth of the flyers and wound upon the spindles by reversing their motion, two other slivers are drawn out, and the operation proceeded with as before, and so, forming two continuous threads, until all the fiber in the roll is exhausted.

Fig. 5416.



Spiral Gearing.

Spi'ra. (*Architecture.*) The base of a column. This member did not exist in the Doric order of architecture, but is always present in the Ionic and Corinthian.

Spi'ral Bit. A wood-boring tool adapted to be used in a brace. It is made of a twisted bar of metal, and has a hollow axis. See Bit, *m, s, n*, Fig. 695.

Spi'ral Gear'ing. A gear-wheel having meshing spiral ribs and grooves. The teeth run around the periphery of the gear-wheel, and meet in an angle on a line midway from either edge of the wheel.

Spi'rals, In'stru-ment for Draw'ing. (*Drafting.*) An instrument for drawing scrolls or spirals, either on paper, in the ordinary course of mechanical or architectural drawing, or to lay out scrolls for hand-rails of winding stairs, etc.

Instruments for drawing Spirals and Scrolls.

No. 97,571.	Truesdell	Dec. 7, 1869.

No. 138,053.	Stebbins	April 22, 1873.

Instruments for laying out Stair Curves.

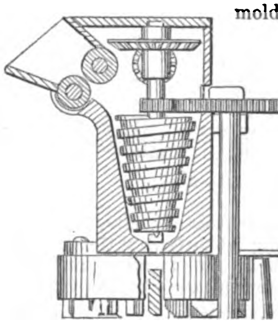
No. 5,380.	Wooster	Dec. 4, 1847.
No. 18,110.	Stewart	Sept. 1, 1857.
No. 24,763.	Shaeffer	July 12, 1859.
No. 66,796.	Clow	July 16, 1867.
No. 75,423.	Hoover	Mar. 10, 1868.
No. 97,707.	Schollar	Dec. 7, 1869.

Spi'ral Pump. A form of the Archimedean screw water-elevator, consisting of a pipe coiled spirally round an inclined axis. It is said to have been invented about 1750 by Andrew Wirz, a pewterer of Zurich, and was employed in Florence with some improvements by Bernoulli, in 1779. See Screw.

Spi'ral-rib Bit. A wood-boring tool adapted to be used in a brace. It has a spiral flange twisted around a cylindrical shaft. See Bit, *o*, Fig. 695.

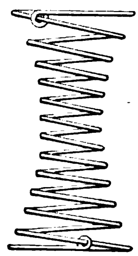
Spi'ral Screw. A screw formed upon a conical or conoidal core. In the example, it serves as a driving-screw to force clay from the hopper into the molds beneath.

Fig. 5417.



Brick-Machine.

Fig. 5418.



Double Helical Spring.

Spi'ral Spring. A coil whose rounds have the same diameter, and which is generally utilized by compression or extension in the line of its axis. The balance-spring of a chronometer hence is spiral, and is utilized by an expanding and contracting action in a plane at right angles to the axis. See Fig. 532.

A helical spring has coils of decreasing diameter as they approach the center, like the mainspring of a watch. (See Movement, Fig. 3246.) The spiral spring is used in Salter's balance and in *dynamometers;* also in bedstead-springs, as in Fig. 623, page 261.

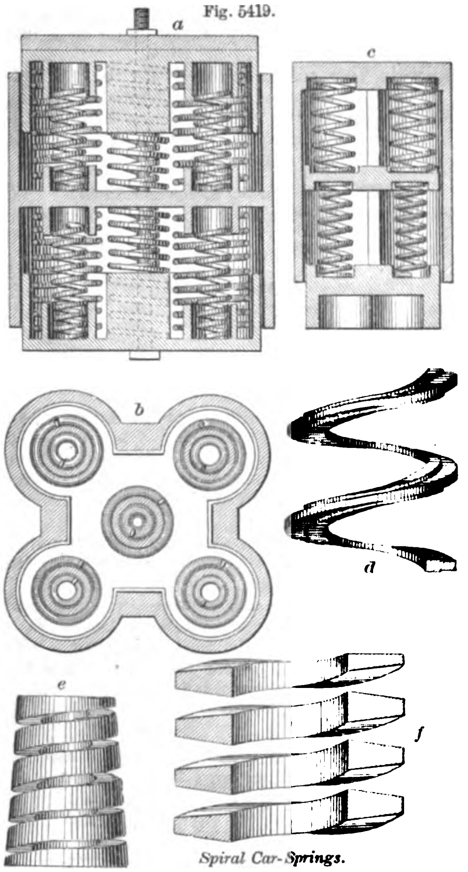
Fig. 5418 shows a double helical bedstead-spring, the coils increasing upward and downward from the point of smallest diameter at the mid-hight.

Fig. 5419 shows some applications of the spiral form to car-springs. A number more are shown at Fig. 1143, page 483.

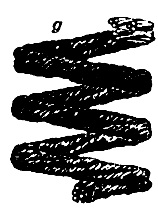
a b are respectively a vertical section and a horizontal section of Godley's car-spring. The case is open at top and bottom, and has a central fixed diaphragm, against which the concentric spirals abut.

c is Godley's spring, with an open end and a sliding partition.

Fig. 5419.



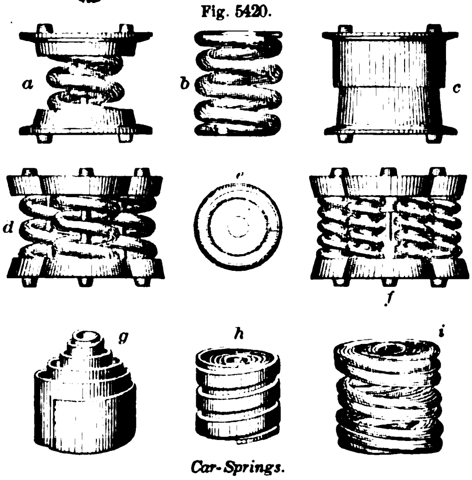
Spiral Car-Springs.



d is another of Godley's springs, having flat surfaces at the portions liable to come together, and webs of lesser thickness beyond the contacting surfaces.

e is Allen's conical spring with spiral coils of upwardly decreasing diameter.

Fig. 5420.



Car-Springs.

f, a spring having an inner edge of greater vertical thickness.

g, a spring made of metallic strands or strips, twisted or braided and then coiled.

In Fig. 5420, *a b c d e f* are springs of the Culmer Spring Company.

g h, Nichols, Pickering, & Co., spiral spring.

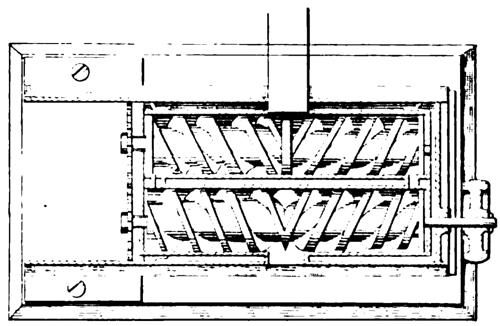
i, the Vose spring.

Spi′ral-spring Coup′ling. A coupling for a pair of shafts meeting at an angle. The ends of the spiral connect to the respective shafts and make a bent coupling. See Fig. 2021.

Spi′ral-vane Steam-en′gine. A form of rotary steam-engine in which the steam acts against a screw which winds around a cylindrical core.

The example shows two such screw-cylinders, having each a right and left hand screw, so arranged that the threads meet in the center, at which point the steam is admitted, and from which point it passes to either end of the cylinder, where it exhausts

Fig. 5421.

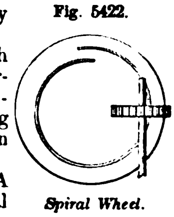


Spiral-Vane Steam-Engine.

into the other cylinder, in which it returns to the center, where an aperture is provided for its escape to the atmosphere. The screws are geared, and upon the shaft of one a pulley is placed for the purpose of transmitting power to any machinery to be driven.

Spi′ral Wheel. The spiral-thread of the disk drives the spur-gear, moving it the distance of one tooth at every revolution.

Fig. 5422.



Spiral Wheel.

Spiral gears are those in which the teeth form an angle to the surface, so that the teeth slip insensibly into engagement, avoiding jar. Each tooth is a small section of a screw. See also Fig. 5416.

Spire. 1. (*Architecture.*) A structure of pyramidal or conical form surmounting a church or cathedral. For hights of spires, see Tower.

2. (*Mining.*) The tube carrying the train to the charge in the blast-hole. Also called the *reed* or *rush*, as the *spires* of grass or rushes are used for the purpose.

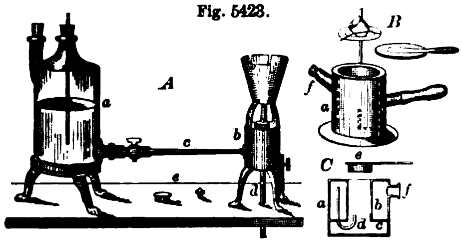
Spir′it-col′ors. A style of calico-printing produced by a mixture of dye-extracts and solution of tin, commonly called *spirit* by dyers. The colors are brilliant but fugitive.

Spir′it-lamp. A lamp burning alcohol. Used for many purposes in the arts where heat rather than light is required.

The blast spirit-lamp (*A*, Fig. 5423) consists of a vessel *a* for containing a mixture of alcohol and turpentine, and a cylinder *b* containing an argand wick supplied with the mixture through the pipe *c*, and subjected to a blast of air from a pipe *d*, which comes up through the table *e*. The blast-pipe can be fixed at different hights, and is supplied with jets of different sizes, to suit the regulated supply of spirit and the hight of the exposed portion of the wick.

The Russian spirit-lamp (B C) consists of an exterior cylinder a, containing a shorter interior annular cylinder b, having a bottom c, through which passes the pipe d, which constitutes the only communication between the interiors of the two cylinders. The outer end of this pipe terminates in a fine orifice. The cup e is then filled with alcohol or pyroxilic spirit, which

Fig. 5423.

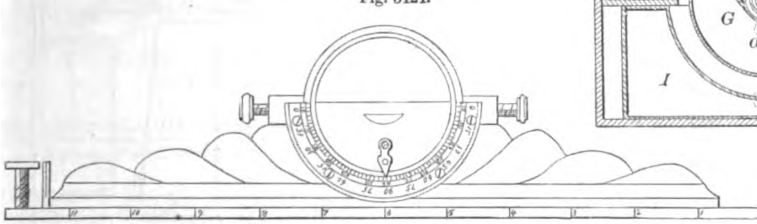


Spirit-Lamps.

is poured into the chamber b through the nozzle f, afterward stopped with a cork. An equal amount is then poured into the outer cylinder a and ignited; this soon causes the spirit in the chamber to boil, the vapor is forced through the tube d, and, being set on fire by the flame, produces a continuous column of burning vapor 6 inches high, which will last from 12 to 16 minutes. The cup e also serves as a cover to the lamp, and is used as an extinguisher.

Spir′it-lev′el. A level consisting of a glass tube nearly filled with alcohol, preferably colored. The remaining space in the tube is a bubble of air, and this occupies a position exactly in the middle of the tube when the latter is perfectly horizontal. The

Fig. 5424.



Davis's Level and Inclinometer.

tube is mounted on a wooden bar, which is laid on a beam or other object to be tested; or it is mounted on a telescope or theodolite, and forms the means of bringing the said instruments to a level position. See LEVEL.

Fig. 5425.

Alcohol-meter.

Nearly in its present form it is supposed to have been invented by Dr. Hooke, some time in the latter part of the seventeenth century.

Another tube is placed in a mortise transversely of the bar, to enable the instrument to be used as a *plumb*.

Fig. 5424 is a level which may also be used as an *inclinometer*, the reading being in degrees or linear measurements. The ring is adjusted for plumbing vertical surfaces, or leveling surfaces, by the movable ring and its set-screw. Inclination from these positions is indicated by a circular scale and index.

Spir′it-lev′el Quad′rant. An instrument furnished with a spirit-level and used for taking altitudes.

Spir′it-me′ter. An instrument for measuring the amount of spirits passing through a pipe or from a still. The ordinary *alcohol-meter* is but an adaptation of the hydrometer, having a special scale in combination with a system of tables to be used by the inspector to test the gravity of the wort and mash, so as, in connection with the known capacity of the vessel and correction for temperature, to ascertain the amount of spirits produced. See HYDROMETER; ALCOHOLMETER.

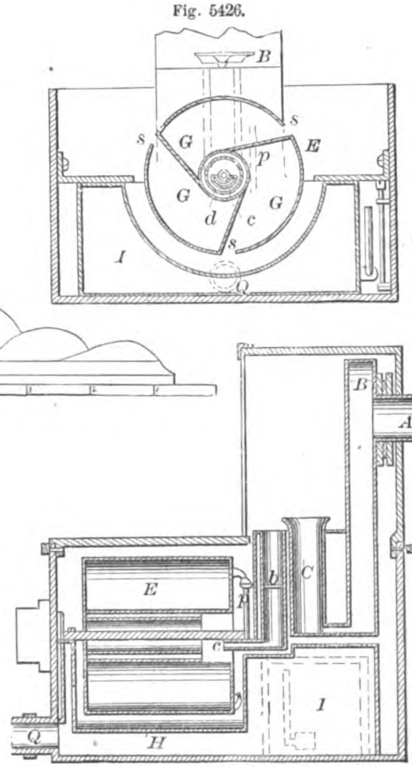
The term spirit-meter is more properly applied to a measuring device; and, for internal revenue purposes, the *high* or *low wines* or spirits are occasionally tested by the hydrometer, to find the specific gravity, the quantity of the spirit at proof being deduced from the two factors.

Spirit-meters are of several kinds: —

1. The rotating drum or tympanum of known capacity, usually divided into chambers, like a gas-meter.
2. The piston vibrating in a cylinder of known capacity, and registering its pulsations.
3. Various applications of the device known as the rotary pump.
4. Vessels of known capacity, alternately filled and discharged; usually suspended from a beam whose oscillations as the lighter one rises and the heavier descends are made to actuate an index mechanism. See also LIQUID-METER; WATER-METER.

(1.) In Augenstein's meter (Fig. 5426), the spirit passes from

Fig. 5426.



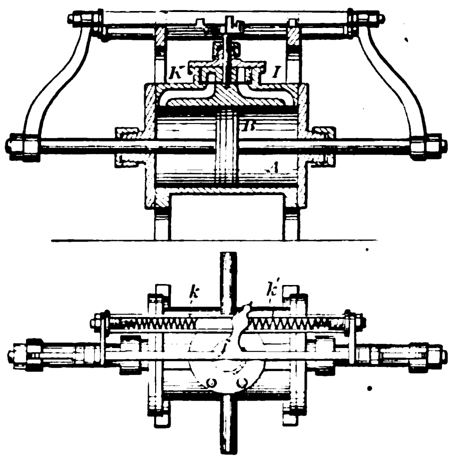
Augenstein's Spirit-Meter.

the worm of the still through the pipe A into the chamber B, and fills the upright cylinder C, whence it overflows into a second upright cylinder containing a straining diaphragm b. It thence flows through the pipe c, and is discharged into the hollow axis of the revolving cylinder E, whence it escapes into that one of its compartments G G G which is at the time in communication with the pipe c. As these become filled, they descend by gravity and discharge their contents through the peripheral openings s s s into the reservoir H, whence the liquor is conducted off by a pipe Q. On the exterior of the cylinder E are a series of brushes, or dippers, which take up a small quantity of the spirit from the chamber H and convey it to a cup, from whence it is conducted by the pipe p to a reservoir I. At suitable intervals the liquor in this reservoir is tested, serving as a sample of all that has passed through the meter. Each of the

compartments G measures a given uniform amount, and the flow of spirit into one or the other of them is continuous. Suitable clock-work mechanism is provided for registering the amount which passes through the apparatus.

(2.) Weaver's meter (Fig. 5427) has a piston B, which is caused to oscillate in the cylinder A, to each end of which the liquid to be measured is alternately admitted through ports K I, opened and closed by a circular valve provided with an arm f,

Fig. 5427.



Weaver's Spirit-Meter.

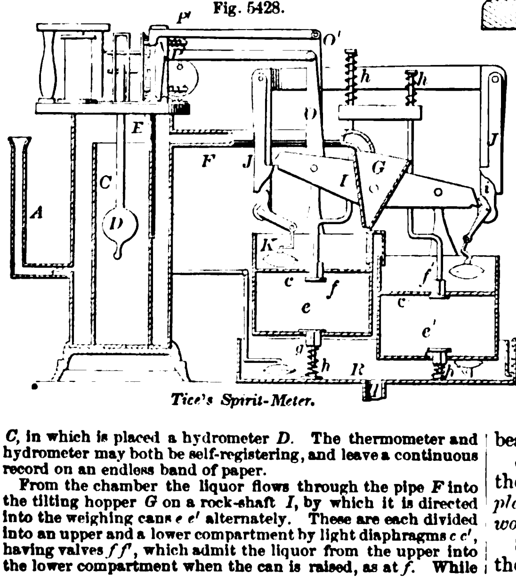
which is moved to and fro by springs k k', one of which is brought into action as the other is released at the end of each stroke.

The valve is circular, and oscillates in a horizontal plane to change the relation of its ports with the inlet and outlet ports. As the piston moves toward the left, the spring in the right-hand end of the tube is compressed in consequence of the resistance opposed thereto by the arm projecting from the valve stem, but when the piston has nearly completed its stroke, said arm is freed and actuated by the compressed spring so as to suddenly reverse the valve. The springs being duplicated, the operation is the same under the opposite movement of the piston.

(3.) The rotary-pump principle is sufficiently illustrated in Figs. 4465, 4466. See also the devices under ROTARY STEAM-ENGINE, Plate LIII. page 1991.

(4.) Tice's meter is shown in Fig. 5428. The spirit coming from the still through the pipe A is received in an exterior chamber containing a thermometer E and an upright cylinder

Fig. 5428.



Tice's Spirit-Meter.

C, in which is placed a hydrometer D. The thermometer and hydrometer may both be self-registering, and leave a continuous record on an endless band of paper.

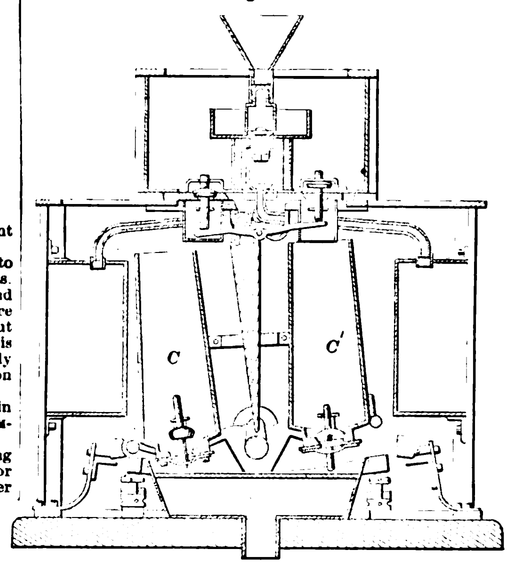
From the chamber the liquor flows through the pipe F into the tilting hopper G on a rock-shaft I, by which it is directed into the weighing cans e e' alternately. These are each divided into an upper and a lower compartment by light diaphragms c c', having valves f f', which admit the liquor from the upper into the lower compartment when the can is raised, as at f. While in this position the elevated arm of the rock-shaft I is engaged by one of the swinging latches J J, which prevents the can from descending until enough liquor has accumulated above the diaphragm f to raise the float K, causing a bent pivoted arm i, to which it is connected, to act against the latch J and release the shaft I, permitting the can to descend. The valve f then closes by the action of the spring h on its stem, while the valve g, provided with a similar spring, opens, and the liquor flows into the trough R, and is conducted away by a pipe q. This operation alternately takes place with each can, the number of times each is filled and emptied being automatically recorded by suitable registering mechanism operated through the medium of the levers O O' P P'. The amount measured each time is that contained in the lower compartment only.

Devices are attached to the meter to indicate if any attempt has been made to tamper with the meter or pass liquor through it without being properly measured in the cans.

In another form of this meter, siphons are employed to discharge the cans, which may be connected to a weigh-beam in order that the strength of the spirit may be ascertained directly from its weight.

Payne's meter (Fig. 5429) consists of a frame containing the tanks C C', which are placed on a vibrating yoke. The distilled spirit passes first into one of the tanks, and when it has filled the tank causes it to overbalance the empty one, which is in turn filled, the first one being emptied automatically at the

Fig. 5429.



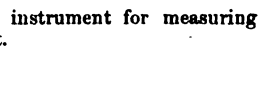
Payne's Spiritometer.

same time by a valve beneath. The tanks are thus filled and emptied alternately; the number of times each is filled and emptied being recorded upon dials by means of suitable mechanism. As the spirit passes through the tunnel into the tank, a small quantity is retained in the sampling device, and caused to flow into the receivers. The sampling device consists of a tube, provided with valves, supported by a suitable mechanism, the valves being so arranged that at each oscillation of the tanks they will allow the sample contained in the tube to pass into the chamber, and from thence into the receiver.

Spir'ket. (*Shipbuilding.*) A space fore and aft between floor-timbers or futtocks of a ship's frame. Distance between *rungs.*

Spir'ket-ing. (*Shipbuilding.*) *a.* The strake of inside planking between the water-ways, which rest upon the deck-beams and the port-sills.

Fig. 5430.



Spirketing, etc.

b. The strake between the upper deck and the *plank-shear.* The *quick-work.*

Spi-rom'e-ter. An instrument for measuring the capacity of the chest.

Fig. 5431.

Brown's Spirometer.

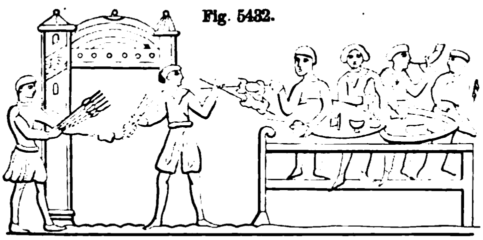
The breath-holder is an inverted chamber submerged in a water-bath. The breath is conducted by a flexible pipe and internal tube, so as to collect in the chamber, which rises in the water. An index is attached to the chamber, and is graduated on its face, so as to indicate against the edge of the index-case the cubic inches of air expired. A *chest-measurer*.

The extreme hight of a column of water which can be supported by the muscular act of expiration, transmitted by the lips, is about six feet. With the majority of wind-instruments, the pressure required for the high notes is considerably greater than that required for the low notes, each instrument having a pressure ratio of its own. The clarinet is an exception to the rule.

Spit. 1. An iron rod, on which meat is impaled for cooking.

Fig. 5432 is a representation from the Bayeux tapestry of a Norman dinner-table. The pieces of meat were handed to the guests on skewers, and fowls upon the spits on which they were roasted.

Fig. 5432.



Norman Waiters serving at Table (Bayeux Tapestry).

One guest is drinking from a horn, another is raising a tankard; wooden platters and a box of salt are probably intended by the other table furnishing.

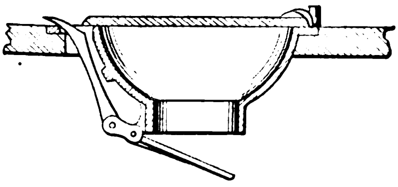
2. (*Weaving.*) A horizontal pin in the chamber of a weaver's shuttle, for receiving the spool or pirn.

Spit-box. A spittoon. A *cuspadore.*

Spit-stick'er. (*Engraving.*) A graver or sculper, with convex faces.

Spit-toon'. A box or crock for saliva. Spittoons for railway-cars are arranged with covers and automatic discharge. Fig. 5433 has a valve at the bottom, which is closed when the lid is lifted, preventing the draft of air through the opening. When the lid is closed, the valve opens and discharges the contents.

Fig. 5433.



Railway-Car Spittoon.

Splash-board. (*Vehicle.*) The leathern or wooden board in front of the driver. A *dash.*

Splash'ers. 1. (*Locomotive.*) Guard-plates placed over the wheels of locomotives to prevent any person coming in contact with them, and also to protect the machinery from wet and dirt projected by the wheels when running.

2. (*Vehicle.*) *a.* A guard over a wheel, to keep dirt from reaching the occupants of the carriage.

b. A guard near the door, to keep the dress from rubbing against the wheel in entering or alighting.

Splay. (*Architecture.*) The inward or outward expansion of an opening; the difference between its greatest and least cross-sections. Instances are found in the slanting or beveled expansion *groin*, in Gothic and Domestic architecture, to doors and windows.

The *splayed* sides of the chimney-jambs are called *covings.*

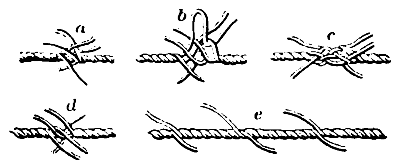
The term *fluing* is applied to the slanting jambs of a Gothic window.

Splay'er. (*Tile-making.*) A segment of a cylinder on which a molded tile is pressed to give it a curved shape, for a pantile, ridge or hip tile, gutter or drain tile.

Splice. 1. (*Nautical.*) The joint by which two ropes are united so as to make one continuous length, or the two ends of a single rope are united, to form a grommet or eye.

In the *short* splice, used for ropes which are not to be rove through blocks, the strands are unlaid for a convenient length, and each passed over one and under another of its correspond-

Fig. 5434.

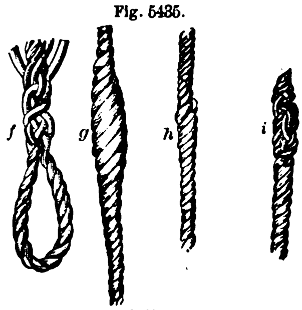


Splices.

ing strands on the opposite rope for a sufficient distance, as shown at *a b c*, Fig. 5434. The ends are then drawn taut, usually trimmed off close, and frequently the splice is covered by serving.

The *long* splice *d e* for ropes which are to pass through blocks is formed by unlaying the strands for a longer distance and laying two belonging to each rope in the scores formed by unlaying the opposite strands of the other. The third strands are split and united after the manner of the short splice, while the ends of the two others are united by splitting and interlacing in the same manner. This distributes the joining over a considerable length, rendering the enlargement scarcely perceptible.

Fig. 5435.



Splices.

f, *ring*-splice.
g, *pudding*-splice.
h, *long* splice.
i, *short* splice.

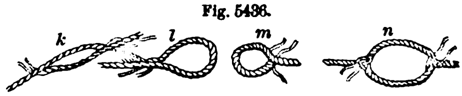
The *long-rolling* splice is used for lead-lines, fishing-lines, etc.

The *cut* or *cant* splice (*k n*, Fig. 5436) is made by cutting a piece from a rope and laying open the ends of the strands. The strands of the piece to which it is to be attached are laid open with the marlinspike, and the ends of the cut-off piece are passed in between the strands of the first.

The *eye*-splice *l m* is made in a precisely similar way, the end of the rope being worked into the standing part.

A *drawing*-splice — principally used for cables — is made by unlaying several fathoms of the two ropes to be joined, making

Fig. 5436.



Splices.

a short splice, tapering the ends of the strands and laying them along in the spaces between the strands of the other cable, where they are secured by seizings. So called, because it is readily taken apart.

A *tapered* splice is formed by gradually tapering the strands of each rope after making a short splice and passing them in between the strands of the other, again tapering and passing through, and so on until the unlaid strands are expended.

2. (*Machinery.*) To unite adjacent pieces by means of overlapping or scarfing the parts together, secured by bolts or fish-plates. See FISHING.

3. (*Carpentry.*) A scarf-joint by which timbers are united. See SCARF.

Spliced Eye. (*Nautical.*) The rope is bent around a thimble, and the end spliced into the standing part.

Splice-piece. (*Railway.*) A fish-plate or break-joint piece at the junction of two rails. See Fig. 2001.

Splic'ing-fid. (*Nautical.*) A tapered wooden pin or marlinspike, used in opening the strands of a rope in splicing. It is sometimes driven by a mallet called a *commander.*

Splic'ing-ham'mer. A hammer having a face at one end and a point at the other, used in splicing.

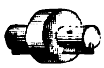
Splic'ing-shack'le. (*Nautical.*) A device for enabling a hempen cable to be bent to a chain-cable. The shackle at the end of the latter has a thimble like a dead-eye, around which the hempen cable is passed, and the *end* spliced to the standing part.

Fig. 5437.

Splicing-Shackle.

Spline. (*Machinery.*) A rectangular key fitting into a seat on a shaft and occupying a groove in the hub of a wheel, which slips thereon longitudinally, but rotates therewith. A *feather.*

Fig. 5438.



Spline.

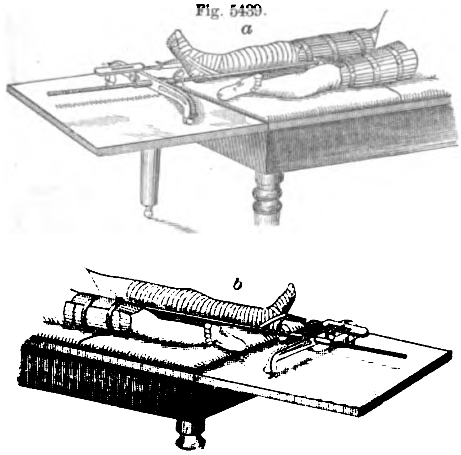
Splin'ing-ma-chine'. (*Metal-working.*) One for cutting key-seats and grooves. See SLOTTING-MACHINE; KEY-SEAT CUTTER.

Splint. 1. (*Surgical.*) A flexible and resisting lamina of wood, metal, bark, leather, or pasteboard, to keep the parts of fractures in apposition and prevent displacement. They are usually padded, and fixed by rollers or tapes.

Splints for fractured limbs are shown in Plates XVIII., XXII., XXVI., XXIX.; extension and counter-extension apparatus in Plates XXII., XXV., of "Magazyn oste Wapen Huys der Chirurgyns door Johannes Scultetus," Doordrecht, 1658.

Fig. 5439 shows an apparatus for the reduction and retention of fractures. The extension of the wounded leg is by means of bandaging tapes and a spring-balance. The counter-extension is by a rod attached to a cross-bar and connected to a splint on the thigh of the sound limb.

Fig. 5439.

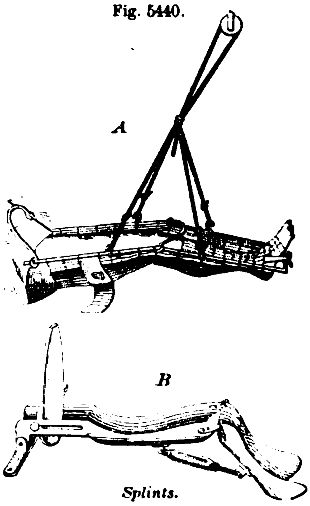


Latta's Splint.

In Fig. 5440, *A* illustrates Hodgen's suspending apparatus, used in treating fractures of the leg and thigh. The splint is a frame of stout wire, and is supported at a point nearly over the seat of the fracture, and a little above the middle of the leg, which is raised and held at the required hight by means of the tackle.

B, Liston's splint; particularly adapted for treatment of fractures of the condyles of the femur and of the upper part of this bone. It is applied to the limb by attaching the foot to the foot-board and the limb to the splint by a roller bandage. The angle of flexion is regulated by the screw.

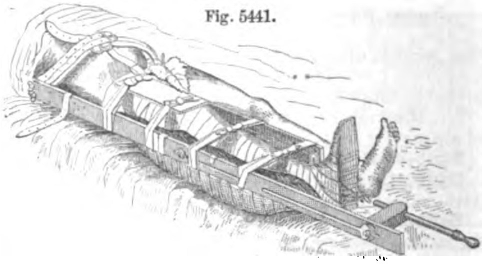
Fig. 5440.



Splints.

Fig. 5441 represents, as applied, Dr. Lente's modification of the New York Hospital apparatus, for treatment of fractures of the thigh. This is based upon the splint originally invented by Desault, and subsequently modified by Drs. Physic and Buck. The outer splint is made in two pieces, one of which slides upon the other, so as to be adjustable to the length of the limb, is retained when adjusted by a set-screw, and is provided with a cushion applied to the outer side of the leg. It has a steel brace passing half-way over the abdomen, and connected to a belt surrounding the pelvic region, and also a perineal band connected to an adjustable plate sliding on the brace before mentioned. Cushioned splints placed beneath the upper part of the thigh and on the inside of the leg are also employed. A broad strip of adhesive plaster is applied on each side of the leg, from a little below the knee, the free ends extending to below the sole of the foot, and are secured to a thin block of wood, having holes at each side for receiving a cord, to which the hook or ring at the end of the screw is attached. The perineal band is adjusted so as to grasp the tuberosity of the ischium, which serves as the point of resistance; and when the splints have been properly adjusted to the leg, and secured together by bandages, the fractured limb is extended as far as the patient can conveniently bear, by means of the screws, after which the bands, being elastic, continue the extension, gradually overcoming the resistance of the contracted muscles, and complete the extension. The hook of the screw is also connected to a spiral spring.

Fig. 5441.



New York Hospital Splint for Fracture of the Thigh.

A removable foot-piece attached by a slide and thumb-screw to a mortise in the external splint is also provided in order to prevent the usual tendency to eversion of the foot, and also by projecting a little beyond the toes to take off the pressure of the bedclothes.

2. A thin strip of wood prepared for use in manufactures, as for making baskets, brooms, matches, etc.

3. A wooden strip for splicing and stiffening a fractured bar or beam.

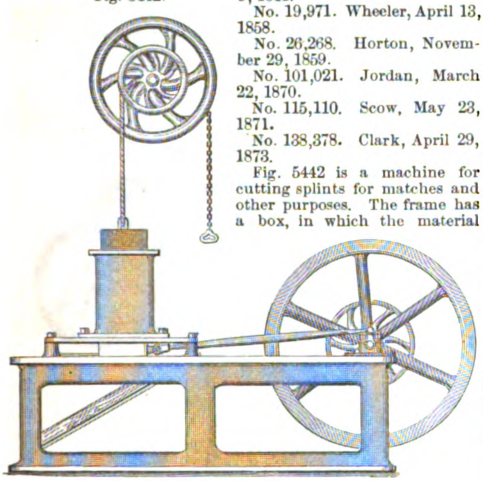
4. (*Ordnance.*) A tapering strip of wood, used to adjust a shell centrally in the bore of a mortar.

Splin′ter-bar. (*Vehicle.*) *a.* A cross-bar in front of a vehicle, to which the traces of the horses are attached, as in coaches and artillery carriages, in which *double* and *single trees* are not used.

b. A cross-bar which supports the spring.

Splint-ma-chine′. A machine for riving or planing small slats or splints for use in making woven-slat blinds, baskets, box-stuff for millinery or fruit, etc. See SLIVERING-MACHINE.

Fig. 5442.



Splint-Machine.

See patents, Gleason, October 9, 1841.

No. 19,971. Wheeler, April 13, 1858.

No. 26,268. Horton, November 29, 1859.

No. 101,021. Jordan, March 22, 1870.

No. 115,110. Scow, May 23, 1871.

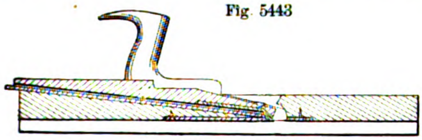
No. 138,378. Clark, April 29, 1873.

Fig. 5442 is a machine for cutting splints for matches and other purposes. The frame has a box, in which the material to be worked up is placed. The cutters are attached to a slide, worked by a connecting rod from the crank-shaft, and the material is pressed down by a weight. The machine cuts 3,500 splints per minute. See also EXCELSIOR-MACHINE, page 815.

Splint-plane. One for riving splints from a block or board, for blind-slats, small boxes, etc. A *scale-board plane.* Patent No. 143,737.

In Fig. 5443, the thickness of the slat is regulated by the spring tongue at the end of the wedge, the tongue being adjusted by a set-screw at the point. The plane is intended for making blind-slats, each one pushing the preceding one out.

Fig. 5443.



Splint-Plane.

See patents No. 52,473, Welsh, February 6, 1866; No. 50,947, Ogborn, November 14, 1865; No. 51,153, Dempsey, November 28, 1865.

Patent No. 52,173, Kleinschmidt and Schlater, January 23, 1866, has a very oblique setting-knife or cutting-bit. Just forward of it is a channel, having the same angle in respect to the plane that the bit has, so that as the shaving is cut by the bit, it is forced out through the channel, which causes it to be twisted around in the form that paper-lighters are made by hand.

Split. 1. (*Weaving.*) One of the flat strips which are arranged in parallel vertical order and form the *reed* of a loom. The *warp*-threads pass between the *splits* or *dents.* The reed is placed in a swinging frame, called the *lay*, *lathe*, or *batten*, and its office is to beat the *weft*-thread up to the *web* to compact the fabric.

2. (*Leather.*) A thin kind of leather made by splitting a hide into two thicknesses.

3. *a.* One of the pieces of an osier after quarternary division through the pith by two knives placed at right angles to each other. These splits are shaved, and the flat strip is then a *skain.*

b. A ribbon of wood rived from a tough piece of green timber, such as hickory, white oak, or black ash. Used in making baskets, hurdles, chair-bottoms, and for many other purposes for which osiers are commonly used in places where they are plentiful. See also SPLINT.

Split-draft. (*Furnace.*) In steam-boilers, when the current of smoke and hot air is divided into two or more flues. In contradistinction to a *direct*, a *reverting*, or a *wheel draft.*

Split-ful. (*Weaving.*) The number of yarns, usually two, which is passed between each *split* or opening in the *reed* of the *batten* or *lathe.* A rod lying athwart the warp divides the yarn-threads into split-fuls, two threads passing alternately over and under it.

Split-leath′er. Leather split by machinery, to economize it or to reduce it to a suitable thickness for a given purpose.

It appears to have been introduced by Nossiter, England, who found the cut surface, when polished by a slicker, to take varnish better than either the flesh or grain side of the hide.

Split-leather is an inferior article, and is used for light boots and shoes, inner soles, linings, carriage upholstery; trunk, portmanteau, and cushion covering. Splits of the smaller skins, such as goat and sheep, are made into wash or glove leather.

Split-pin. A pin or cotter with a head at one end and a split at the other. The ends diverging after passing through an object prevent the accidental retraction of the pin. See also FOX-BOLT and Fig. 2092.

Fig. 5444.

Split-Rings.

Split-ring. A split-ring has an opening by which keys may be introduced to be strung upon it. The metal of the ring is pliable, and the opening closes of itself.

Split′ting-board. (*Mining.*) Said of a dividing board used in mine ventilation to divide the incoming air and direct it to separate districts of the mine.

Split′ting-chis′el. A blacksmith's chisel having a sharper cutting edge than is usually found in chisels for cutting iron. It is intended for dividing the metal longitudinally.

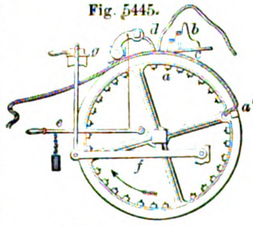
Split′ting-knife. A knife used in a machine for splitting leather. It is sometimes stationary, and is gaged to a distance from a roller over which the *grain-side split* is wound as the hide passes through.

In the more common form of leather-splitting, the knife is six feet in length, the length of the drum, and has a rapid longitudinal vibration in a plane parallel to the axis of the drum. See LEATHER-SPLITTING MACHINE, and next article.

Split′ting-ma-chine′. A machine for dividing a skin of leather parallel with one of its surfaces.

The leather-splitting machine (Fig. 5445) consists of a drum *a*, having an opening *a′* running its whole length; the end of a hide is wedged into this opening, and as the drum is rotated, an endwise traversing motion being at the same time imparted to the knife-carriage *b* by means of a crank, the leather is drawn against the knife *c*, which divides it into two thicknesses, one part passing above and the other below the knife. The hide is held down and wrinkles smoothed out by a plate *d*, extending the whole

Fig. 5445.



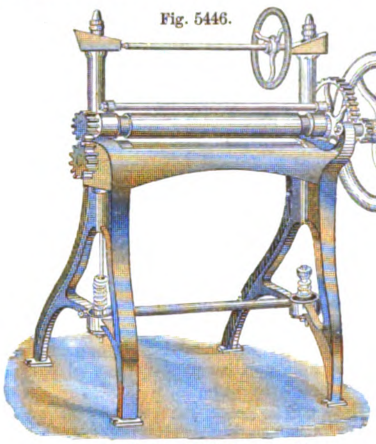
Splitting-Machine.

length of the drum, and connected by a cord to a weighted lever *e*. The bearings of the drum rest upon a lever *f* at each end; this is raised or lowered to vary the thickness of cut by means of a screw *g*.

The knife-carriage *b* is provided with set-screws for setting the edge of the knife straight.

In Fig 5446, the leather is passed between the rolls and against a knife, the depth of the split being regulated by the upper or gage roller, the bearings of which are adjusted vertically by the hand-wheel shaft, right and left screw-threaded at its ends, and playing in wedges.

Fig. 5446.



Leather-Splitting Machine.

Split'ting-saw. (*Wood-working.*) One for resawing thick stuff. See RESAWING-MACHINE.

A circular saw for ripping up thick stuff.

Spoil. (*Civil Engineering.*) Earth dumped by the side of an excavation, to get rid of it when it is in excess of the quantity required for embankments.

Spoke. 1. (*Vehicle.*) *a.* One of the radial arms which connect the *hub* with the *rim* of a wheel. The parts are: the *foot*, which is inserted into the hub; the *shoulder* of the foot; the *tongue* or *tenon*, which is inserted into the felly; the *body*, or part between the hub and felly; the *throat*, a contracted part of the body near the *hub*.

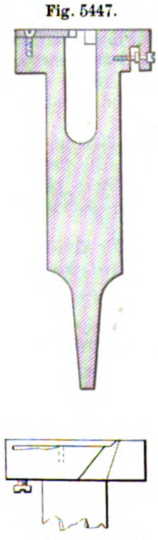
b. A fastening for a wheel to lock it in descending a hill.

2. (*Nautical.*) One of the handles projecting beyond the rim of the steering-wheel by which it is turned.

3. A *round* or *rung* of a ladder.

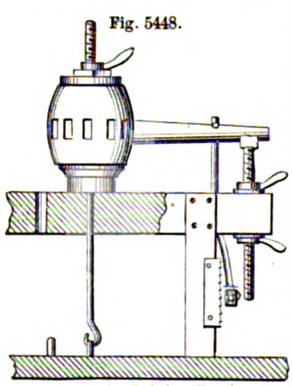
Spoke-au'ger. (*Vehicle.*) A hollow auger employed to make the round tenons on the outer ends of spokes. See AUGER, Figs. 428 – 432.

Fig. 5447.



Spoke-Auger.

Fig. 5448.



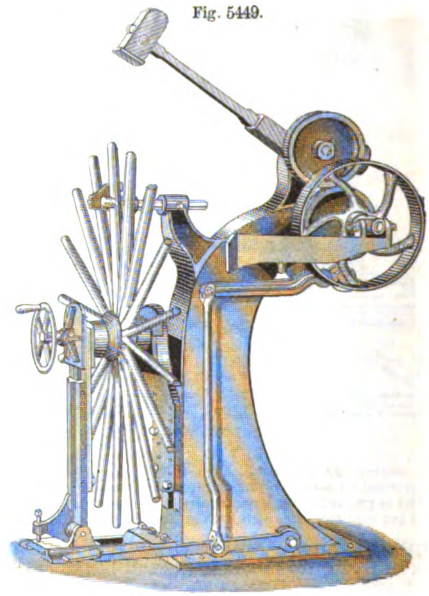
Spoke-Driving Bench.

In the example, the adjustable slide limits the diameter of the opening to form tenons of different sizes. The rankness of cut is adjusted by a screw inserted from the rear of the cutter-head, to act upon the inner surface of the cutter-plate.

Spoke-driv'ing Bench. The hub is clamped on the bench and the spokes supported in turn by a vertically adjustable post; an upper clamp prevents the bouncing of each spoke while being driven by a hand-mallet.

Spoke-driv'ing Ma-chine'. A machine for driving spokes into their mortises in the hub. The swinging mallet is brought into action by depressing the treadle, bringing a friction-wheel on the pulley-shaft against a wheel on the mallet-shaft. The rapidity and force of the blow are proportioned to the pressure on the treadle. The machine is adapted for wheels of from 2 feet to 6 feet in diameter.

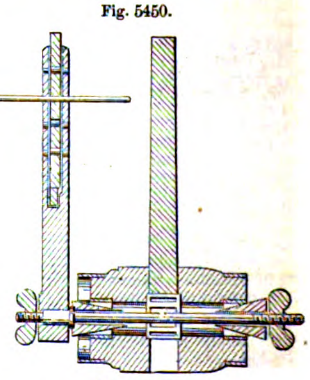
Fig. 5449.



Hosler's Spoke-Driver.

Spoke-gage. An instrument for testing the *set* of spokes in the hub. The mandrel has conical sleeves which abut upon the ends of the boxing, and hold the hub true while the gage-pin in the staff tests the distance of the spokes.

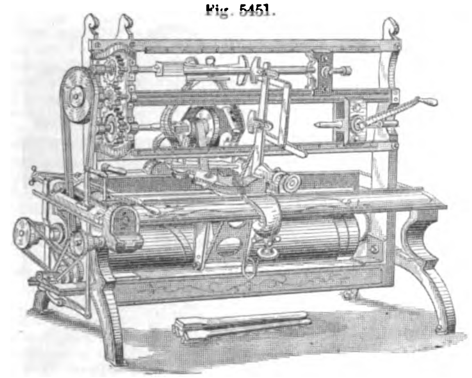
Fig. 5450.



Spoke-Gage.

Spoke-lathe. A lathe for turning irregular forms. The foundation of the machine is the Thomas Blanchard patented machine of 1828, shown at *A*, Fig. 2836, page 1264. Many improvements have been added. See

Fig. 5451.



Spoke-Lathe.

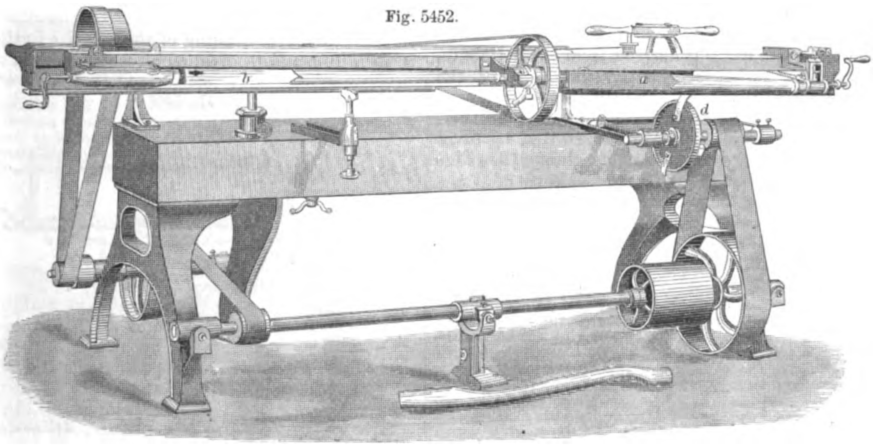
LATHE FOR TURNING IRREGULAR FORMS, pages 1263, 1264.

The spoke is placed between centers in a lathe-head, and is approached to or drawn away from a cutter, in accordance with the shape of a pattern which governs the proximity of the tool to the work. Fig. 5451 shows one modern form. The pattern spoke is in the upper part of the machine, and the guide-pieces on each side govern the position of the revolving cutter, which acts upon the material placed between the lower centers.

The lathe (Fig. 5452) is adapted for turning handles for axes and other implements, as well as spokes. The work *a* and pattern *b* are fixed between centers and revolved upon a carriage, which is automatically traversed in a longitudinal direction, and at the same time swung by the upright guide, bearing against the pattern, so as to present the work to the action of a set of cutters fixed in the rotary head *d*; the amount of this swing and consequent penetration of the cutters is dependent upon the shape of the pattern, of which the work is thus caused to present an exact copy. Adjustments are provided for forming several sizes of work from the same pattern.

Among these may be cited the patent of A. D. Waymouth, of Fitchburg, Mass., July 29, 1856. The improved lathe is so nearly automatic that the necessity for skill is obviated, except in keeping the knives in order and setting them. The headstock has a hollow center, which receives the stick which is to be wrought. A sliding hollow gage *roughs* the stick, leaving it round, and ready to be cut into small pieces. This roughing-gage is pushed upon the stick the length of one of the pieces which is to be made, a lever attached to the tail-stock furnishing the means of applying the force. When the roughing is completed, a knife, operated by a lever worked by the knee, cuts the material to the shape desired, the tool falling back out of the way when its work is done, while another thin knife runs up from the under side, cutting off the finished piece, the gage and the center of the headstock supporting the two ends of the stick until another length is roughed and the operation is repeated. A stick can thus be worked entirely up, cutting off one piece after another until the whole is used.

Fig. 5452.



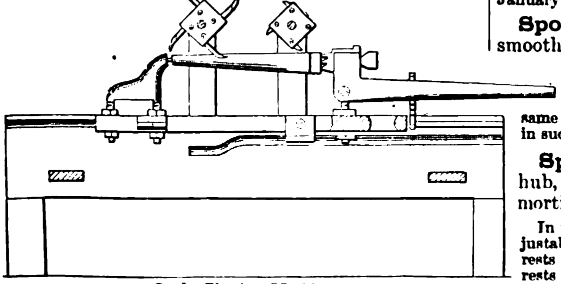
Spoke-Turning Machine.

Spoke-plan'ing Ma-chine'. One for dressing a spoke lengthwise of the stuff, the spoke or the cutter being so moved, the one relatively to the other, that the required shape is produced.

In the example, the piece is clamped between the dog in the bent lever and the opposite center; the clamp lever is held in position by a support placed under it and upon the bench. The carriage is reciprocated on the ways, beneath the roughing and the finishing cutter, a guide-bar determining the presentation to the cutter, so as to confer the proper shape.

See also Benton's patent, March 21, 1854; Olney and Kellogg, January 4, 1859; and Boynton, January 23, 1866.

Fig. 5453.



Spoke-Planing Machine.

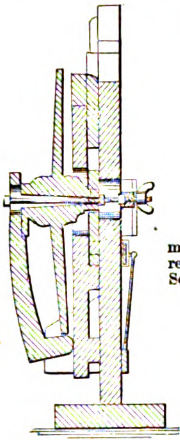
Spoke-pol'ish-ing Ma-chine'. A machine for smoothing spokes after turning and before painting.

Rouse's machine, July 8, 1873, has a continuous sand-belt moving in a direction contrary to the rotation of the spoke. Several articles are placed in the same frame, which are automatically moved to the sand-belt in succession. See also Woolsey's patent, August 24, 1869.

Spoke-set'ter. A machine for centering a hub, so that it may be bored truly for the spoke-mortises.

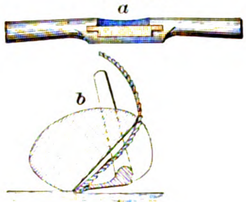
In the example, the standard forms a support for the adjustable portions of the apparatus. The point of the hub rests on a block keyed up by wedges. The butt of the hub rests on a pivoted bar, whose carriage is vertically adjustable on the standard by a lever and rod in the rear. The

Fig. 5454.



Spoke-Setter.

Fig. 5455.



Spokeshave.

mandrel bolt clamps the pivoted hub-rest to a bar on the back of the standard. See also SPOKE-DRIVING MACHINE.

Fig. 5456.

Spokeshave.

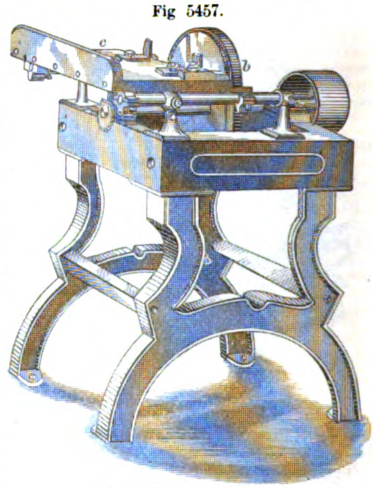
Spoke'shave. A form of plane with a handle at each end. Its name is derived from the article on which it was, perhaps, primarily used. At *a* the sole is presented ; *b* shows the principle of action.

Fig. 5456 has two iron wedges pivoted at their outer and upper angles to the stock, so that by turning them down into their sockets they will wedge and hold the bit fast in its place.

Spoke-siz'ing Ma-chine'. (*Wheelwrighting.*) A machine for planing the sides of spokes and bringing them to a uniform shape ; the edge of the tenon may be tapered at the same operation if desired.

The spoke is placed upon the table *c*, where it is held against a stop, adjustable to different sized spokes ; the table is pushed forward to an amount determined by the previous adjustment of a collar on the stop, bringing the side on the spoke in contact with the cutters on the rapidly rotating cutter-head *b*, which at once dress that side of the spoke and tenon ; it is then turned over, and the other side similarly dressed. On drawing the spoke forward and releasing it from the stop, the desired bevel is given to the edge of the tenon by means of the cutters, the particular inclination being determined by an adjustable angle-gage.

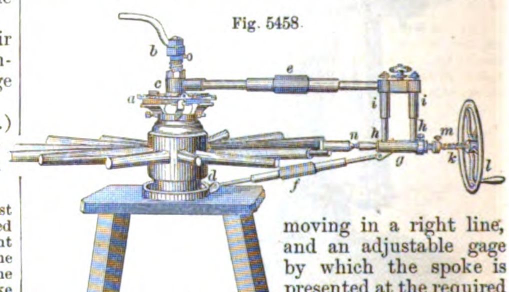
Fig 5457.



Spoke-Sizing Machine.

Spoke-ta'per-ing Ma-chine'. One to taper the edge of the spoke-tenon to fit the bevel heading of the mortise in the hub. It usually consists of a reciprocating chisel-cutter, moving in a right line, and an adjustable gage by which the spoke is presented at the required angle. See Foster's patent, August 8, 1865.

Fig. 5458.

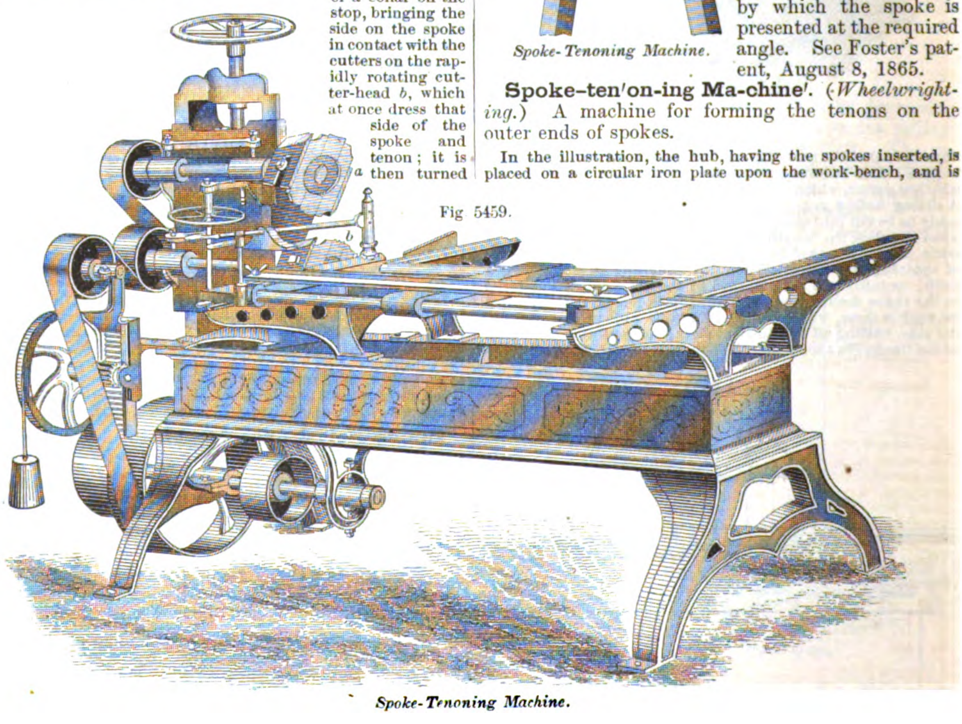


Spoke-Tenoning Machine.

Spoke-ten'on-ing Ma-chine'. (*Wheelwrighting.*) A machine for forming the tenons on the outer ends of spokes.

In the illustration, the hub, having the spokes inserted, is placed on a circular iron plate upon the work-bench, and is

Fig 5459.



Spoke-Tenoning Machine.

held fast by adjustable clutches upon the head-piece *a*. The whole apparatus is secured to the bench by a screw and nut and lever *b*. Surrounding the screw is a collar *c*, and in like manner the bottom plate is surrounded by a collar *d*. From these collars extend jointed adjustable arms *e f*, the middle part of each of which is a right and left hand nut corresponding to screws on the ends of the other joints. These arms carry at their ends the brace-guide *g*, which has vertical adjustment to suit different-sized hubs by means of two screws simultaneously operated by a hand-wheel, and working in the tubes *h h*, which slide in the tubes *i i*. In the end of the brace-guide is a nut, which is not threaded on its outer side, and turns freely in the guide unless held by a set-screw; when this is made fast the screw-shaft *k* feeds in either direction, according as the hand-wheel *l* is turned to the right or left.

The depth of tenon is gaged by a collar *m*, adjustable at any point on this shaft. The tenons are formed by a hollow auger held by the brace *n*, the apparatus being rotated around the fixed hub as a center.

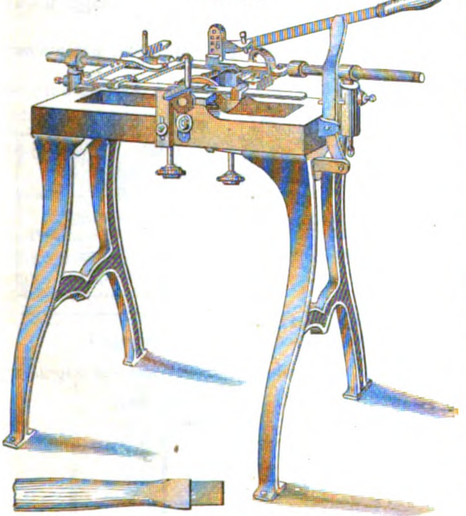
That shown in Fig. 5459 is adapted for tenoning cabinet work as well as spokes. The two cutter-heads *a b* are raised or lowered by means of a screw and hand-wheel to each, and are adjustable to vary the thickness of the tenon or the depth of the shoulder as required, the carriage always remaining stationary.

For spoke-tenoning it is provided with a light adjustable attachment on the carriage for grasping the spoke, and a saw for cutting it off to the proper length, at the same time that the tenon is cut.

Spoke-throat′ing Ma-chine′. The *throat* of a spoke is the portion of diminished thickness a short distance from the hub, to give a certain degree of flexibility to the spoke. See the lower figure in the illustration, where it is purposely slightly exaggerated, to show it the more clearly.

The machine (Fig. 5460) is intended for shaping and smoothing the throats or necks of spokes, preparatory to insertion in the hubs. It has an iron frame. The cutter-head revolves on a steel shaft, running in self-oiling boxes, and can be so constructed as to make the throat of any desired shape. The frame

Fig. 5460.



Spoke-Throating Machine.

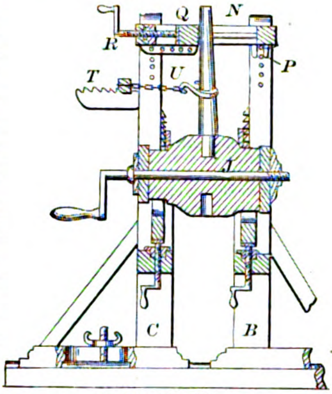
upon which the spoke to be throated rests is hinged on a slide-bar which passes back and forth over a guide, which, in connection with the knives on the cutter-head, regulates the shape of the throat. The spoke is placed under a lever, and held firmly while passing back and forth; ordinary spokes can be throated on both sides by simply changing the guard, which is accomplished by the hand-lever on the end of the machine.

Spoke-turn′ing Ma-chine′. See SPOKE-LATHE.

Spok′ing-ma-chine′. One for setting spokes in the hub with a uniform *dish*. See GATHER; SWING.

It has a fixed standard *A* and a movable standard *C*, carrying pillow-blocks adjustable as to hight by means of screws, and a head *N*, which may, to vary its elevation, be hinged in either one of a series of notches *P*. The hub is laid with its ends resting in the pillow-blocks, and clamped by the rod *J*, which works into a nut, and the spoke is adjusted to the required dish, and firmly held, while being driven, by means of a gage-block *Q*, operated by a cranked screw *R*, while a hook and chain *U*, attached to a beveled-edged lever engaging one of the notches in the rack *T*, holds it to the gage and prevents its moving too far in the opposite direction. Each *spoke* is successively driven and the wheel removed, the head *N* being turned on its hinge.

Fig. 5461.



Spoking-Machine.

Spole-frame. (*Rope-making.*) One of the parts of a rope-making machine. Each *spole-frame* has apparatus for determining the torsion and tension of each strand, and a cluster of three *spole-frames* combines the three strands into a rope. See ROPE-MAKING MACHINE.

Spon′cion. See SPONSON.

Sponge. 1. A compound radiate protozoan having a reticulated horny tissue, forming a skeleton for the gelatinous creatures which have silicious secretions.

Or, it may be defined as a soft gelatinous mass, mostly supported by an internal skeleton composed of reticularly anastomosing horny fibers, in or among which are usually imbedded silicious or calcareous spicula.

The best sponges for toilet use come from the Ægean, and are found in about eight fathoms of water. As in the time of Aristotle, they are gathered by a brotherhood of divers, who inhabit the islands off the Carian coast, and those between Rhodes and Calymnos. A coarse quality of sponge is found on the coasts of Florida and the West Indies. These are gathered with long-hafted forks. To remove the sarcode, the sponge is buried for some days in the sand, until the animal matter rots, and then the horny keratose is soaked and washed.

"Some have proposed even to stuff the sofas and chairs with sponge, on the idea that that will make the occupiers more amorous." — ATHENÆUS, Epil. B. I. 32 (A. D. 220)

For the purpose of stuffing mattresses, it is dipped in glycerine to give it the required resiliency.

See United States patents, —

No. 38,813, Davis, June 9, 1863. Sponge is pressed into a mold of any desired shape, dried therein, and, after removal, covered with water-proof material.

No. 41,589, Alden, February 16, 1864. All calcareous substances are removed by means of muriatic acid. It is then subjected to the action of a picker or *stuff* engine, by which it is cut into small particles and afterward baked or heated in an oven.

No. 48,970, Moith, July 25, 1865. The impurities are removed from the sponge, by means of weak acid, and then saturating it with a composition of equal parts of glycerine and water, the sponge being afterward subjected to moderate pressure to remove the surplus composition.

No. 59,714, Doremus, November 13, 1866. Sponge is cut in small pieces, and is moistened with solution of chloride of magnesium, or other deliquescent salt.

No. 72,322, Paraf, December 17, 1867. The sponge, when purified, if too hard, is soaked in water containing from 10 to 20 per cent of glycerine, after which it is cut into small pieces and carded. It is then felted or spun.

No. 102,760, Braun and Schmidt, describes a process for bleaching sponges, by treating them in a solution in water of permanganate of soda or potash and sulphate, or of other alkalies, and subsequently washing them in a solution of hyposulphite of soda or a bath of liquid or gaseous sulphurous acid.

No. 101,776, Smith. A multiple sponge, composed of a series of small pieces of sponge, which are connected by concealed thread.

No. 106,076, Ohlsen. A coach-cleaning sponge, consisting of

a net filled with pieces of sponge and held by jaws, one of which has a socket to contain a handle.

No. 136,310, Devlan, February 25, 1873. Car and window washer. A head with a stationary and a movable jaw, between which is a sponge, from which water is ejected.

No. 132,333. Sweeny, October 15, 1872. A carpet lining of sponge and cotton.

Bleached Sponge (*Spongia dealbata*). Ordinary sponge soaked in dilute hydrochloric acid to remove calcareous matter, then in water repeatedly, squeezing it out; then in water with chlorine or sulphuric acid in solution; wash in clean water, scented with rose or orange-flower water, and dry.

Many varieties of sponge are found in warm seas, but that of commerce is almost exclusively derived from the Grecian Archipelago, Syria, Barbary, and the West Indies. The Syrian or Turkish, also known as toilet sponge, is most esteemed. Next in value, and closely resembling it, is that from the Grecian Archipelago. Coarser varieties, valuable on account of their firmness and tenacity, come from Greece and Barbary. That from the West Indies is harsher, coarser, and less durable than the Mediterranean kinds.

On the Barbary coast sponge-fishing is most actively prosecuted during the months of December, January, and February; at other seasons the places where the sponges grow are overgrown with sea-weeds, which are swept away by the storms occurring in November and December.

The summer fisheries are conducted in shallower water by divers or by wading; the produce is less and the quality inferior. Three methods — spearing, diving, and dredging — are employed. The Greeks, who are the most skillful and successful sponge-fishers, employ small boats, carrying a rower and a spearman, the latter of whom views the bottom through a tin tube, furnished with a sheet of glass at the lower end, which is held beneath the surface of the water. He manages to transfix sponges at a depth of sixty feet by using three or four spears, thrown with such quickness and accuracy that the end of the first is struck by the second before it disappears beneath the surface, imparting an additional impetus and enabling it to reach the sponge. The Sicilians also employ small row-boats; they do not use the eye-tube, have not acquired the knack of using three or four spears, and are less successful than the Greeks. The Arabs employ sail-boats, carrying from four to seven men, one of whom acts as spearman, while the others manage the boat; they are less skillful and successful than either the Greeks or Sicilians.

2. Artificial sponge is made of caoutchouc by imbedding intimately and evenly throughout the plastic magma of gum some sugar or other granulated material, which may be subsequently dissolved, leaving the gum porous.

No. 97,880, Chesterman, Nov. 19, 1861, uses golden sulphuret of antimony, and *sets* the rubber by vulcanizing it in its extended form. The ingredients are incorporated into a homogeneous mass on hot rollers and are afterward expanded and vulcanized.

See also 94,631, Moulton, Sept. 7, 1869, for inking-rollers.

Goodyear, No. 25,110, August 16, 1859, has a woven fabric with a thin, porous covering of caoutchouc; and No. 25,192, a porous fabric of woven cloth covered with gum and faced with flock.

3. (*Ordnance.*) A mop for cleaning the bore of a cannon after a discharge.

The sponge-head is a wooden cylinder covered with a fabric, of which the warp is hemp and the weft woolen yarn, woven in loops like a Brussels carpet.

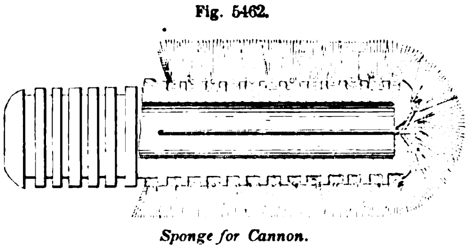
Alum-dressed sheepskin with the wool on is sometimes used.

In field-service, the *rammer* is at one end of the staff and the sponge at the other.

A rope sponge has a rope staff instead of a stiff one, and is used on shipboard in bad weather when the lower ports cannot be opened for the service of the guns except at the moments of firing.

A hair-brush is used for this service with rifled guns. In the

Fig. 5462.



Sponge for Cannon.

example, a hollow head, as usual, is made to fit the rammer or sponge staff, and a spiral groove is turned on its outside from one end to the other; a mat of horse or horned-cattle hair is then laid around the stock and lashed down by wire wound upon it, over the grooves, imbedding it in the same.

4. (*Metallurgy.*) *a.* Iron in soft or pasty condition, as delivered in a ball from the puddling-furnace, ready for the squeezer, shingling-hammer, or tilt-hammer.

b. Iron ore reduced but not melted, preserving its former shape, but porous and lighter by the removal of foreign matters.

c. Platinum in a foraminous condition, resembling sponge. See Fig. 2622, page 1152.

d. The gold remaining from the *parting* process after the silver has been dissolved by nitric acid from the alloy of gold and silver. See CUPELLATION.

e. Silver in a partly reduced condition ready for refining.

5. (*Surgical.*) Used for washing and cleansing wounds and ulcers, for absorbing acrid discharges, as a compress for hemorrhages, tent for dilating wounds, in which latter case it is immersed in wax and cooled.

Sponge is added to ordinary paper-pulp in making bibulous paper, for dressing and tents for wounds.

Burnt sponge (*Spongia usta*) calcined in a crucible, used as medicine.

Waxed sponge (*Spongia cerata*). Sponge dipped into melted wax, pressed between iron plates, and cut up into pieces to form sponge tents.

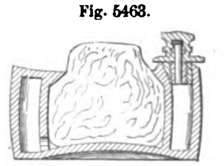
6. (*Baking.*) Raised dough, full of globules of carbonic acid and ready for baking.

Sponge–cov′er. (*Ordnance.*) A pocket of Russia duck, to cover a cannon sponge. Its interior diameter is the caliber of the piece, and it is closed by a draw-string.

Sponge–cup. A dish with a sponge to wipe pens upon.

In Fig. 5463, the sponge-cup is surrounded by an annular

Fig. 5463.



Sponge-Cup.

Fig. 5464.

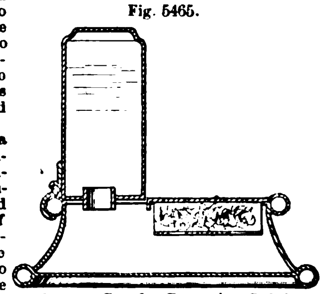
Sponge-Cup.

water-chamber, and connects therewith at an opening on a low level. Water is admitted to the sponge by allowing access of air to the water-chamber

In Fig. 5464, the novelty consists in combining a spring with the sponge, within a suitable water-cup, so that after the sponge has been pressed into the water and moistened, and allowed to rise, all superfluous water will be drained from it.

Fig. 5465 is a sponge-cup for gumming labels. The adhesive solution saturates the sponge, and minute portions of the solution penetrate through the perforated plate, so that on sliding the label over the plate the gum is applied.

Fig. 5465.

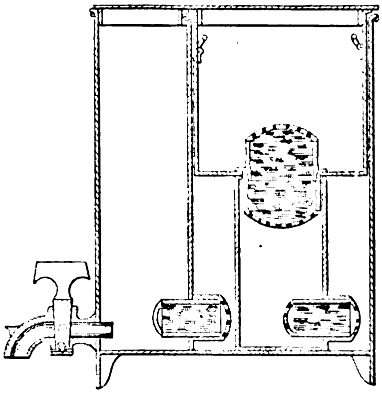


Sponge-Cup for Gumming Labels.

Sponge–fil′ter. One in which water passes through sponge to deprive it of its earthy matters held in suspension.

In the example, the water passes from the upper chamber through sponge into a chamber beneath;

Fig. 5466.



Sponge-Filter.

thence, by one or more tubes filled with sponge, into a compartment which has a discharge-faucet.

Sponge-tent. (*Surgical.*) Used for dilating wounds. It is formed by dipping sponge into hot wax plaster, and pressing it till cold between two iron plates. It is then cut into pieces.

Spon'gi-o-pi'line. (*Surgical.*) A substitute for a poultice, made of an absorbent stratum of sponge and fiber on an india-rubber backing.

Spon'son. (*Shipbuilding.*) The angular space before and abaft the paddle-box against the ship's side.

Spon'son-beam. (*Shipbuilding.*) One of the two projecting beams uniting the paddle-box beam with the ship's side.

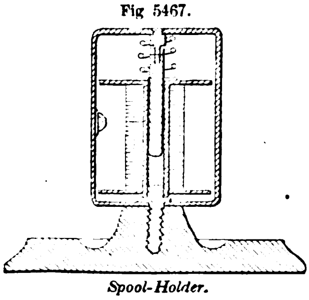
Spon'son-rim. (*Shipbuilding.*) The *wale* connecting the paddle-beam with the ship's side.

Spon-toon'. (*Weapon.*) A pike formerly carried by infantry officers.

Spool. A hollow cylinder upon which thread may be wound. It assumes various forms, — the ordinary spool for sewing-thread; the spool for winding-machines, and otherwise called a *bobbin*: the spool to hold the thread in a shuttle, and revolving on a spindle in the latter.

Spool-hold'er. 1. A stand for a spool or spools of sewing-thread.

Fig 5467.



Spool-Holder.

2. A creel on which spools or bobbins are placed on skewers for warping.

3. A skewer on a sewing-machine to hold a spool of thread.

Spool'ing. The winding of yarn or thread upon *bobbins*: either *pirns*, for netting; *shuttles*, *spools*, or *cops*, for weaving; little wooden *spools*, for sewing; small metallic *spools*, for sewing-machine shuttles, or round bobbins for the machines using the rotary hook below the cloth-plate.

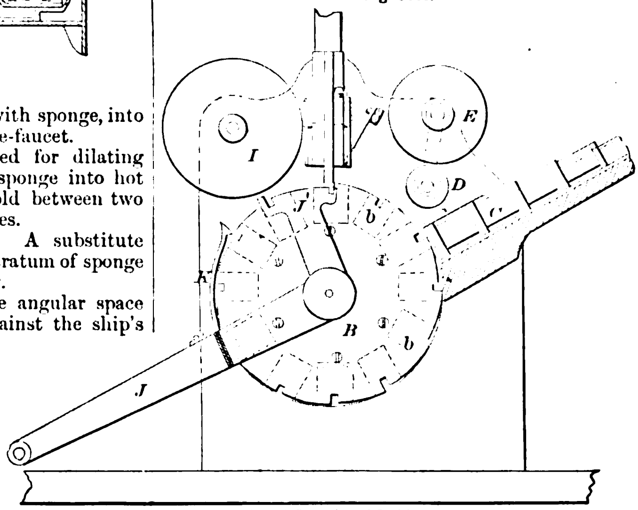
Spool'ing-ma-chine'. (*Cotton-manufacture.*) A machine on which cotton-thread is wound on to wooden spools. The spool is placed on a rotating spindle, and the thread is guided on to it by a steel finger, which delivers the thread in coils, whose layers have a gradually increasing length as the thread is built up against the conical ends of the spool. As each reel is filled, the thread is broken and the end inserted in a notch at the edge of the spool.

Weild's machine for winding sewing-thread upon spools, January 22, 1869, is an automatic machine. It takes the empty spools, winds the thread upon them, stops when they are filled, nicks the edge of the spool, inserts the thread therein, breaks the thread, discharges the filled spools, takes empty ones, starts the machine to wind the thread upon them, and so on continuously.

Spool-la'bel-ing Ma-chine'. A machine for sticking the labels on spools of cotton, etc.

In that illustrated, the spools are delivered consecutively from a trough C into the peripheral pockets $b\,b$ of a cylinder B, which is caused to rotate by the engagement of a catch K on the lever J. E is a paste delivery roller, and D a pasting-roller, which is

Fig. 5468.



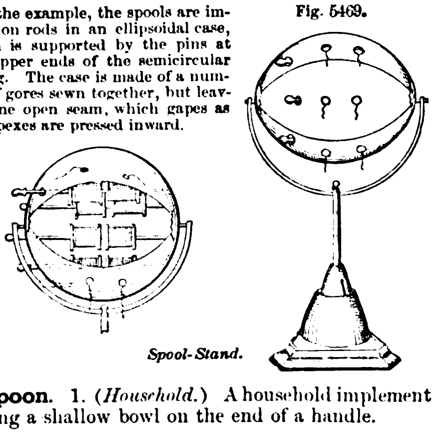
Spool-Labeling Machine.

brought in contact with the end of each spool as it passes by; G is a tube containing the labels, which are pressed downward by a weight, but held within the tube by a catch at each side; this tube drops by gravity at each backward movement of the lever J, bringing the lowermost label in contact with the pasted end of the spool, by which it is drawn between the catches and, passing under the roller I, is pressed securely against the spools. The arm J' lifts the label-carrier out of the way at each backward movement of the lever J.

Spool-stand. A frame for holding various-sized spools for work-table purposes or for exhibition in stores.

In the example, the spools are impaled on rods in an ellipsoidal case, which is supported by the pins at the upper ends of the semicircular spring. The case is made of a number of gores sewn together, but leaving one open seam, which gapes as the apexes are pressed inward.

Fig. 5469.



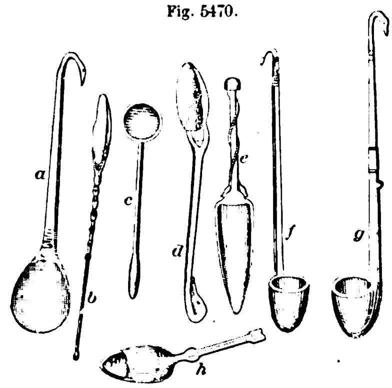
Spool-Stand.

Spoon. 1. (*Household.*) A household implement having a shallow bowl on the end of a handle.

Ancient Egyptian spoons were made shell-shaped, of glass, stone, marble, wood, shell, and ivory. They were handsomely carved. A number are in the Abbott Collection, New York, brought from a tomb at Abouseer (1430 B. C.), Sakkarah, and elsewhere.

The spoons (Fig. 5470, *a b c d e*) are from the collections of Wilkinson, Burton, and Salt. The three on the left are of bronze; the next is of wood, and the right-hand one is of ivory. Others (*f g*) are in the form of dippers or ladles, and resemble the Roman *simpulum*. They were usually of bronze, and

Fig. 5470.



Egyptian Spoons.

frequently gilt. The length of the one represented at *f* is 18 inches; the cup is 3 inches deep, 2¼ inches in diameter. Some of the handles are hinged, others have sliding collars.

The Greeks used spoons at meals. The *cochlear* had a pointed end for picking snails out of the shells, and a flatter end for eating eggs.

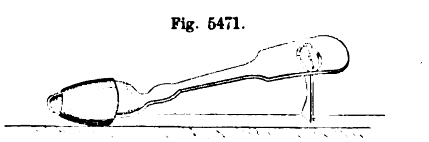
"He needs a long spoon that must eat with the devil." — SHAKESPEARE.

"Paid my silversmith £22 18 *s.* for spoons, forks, and sugar-box." — PEPYS' *Diary*, 1664.

Spoons are made of various materials, sizes, and shapes. The latter for different purposes, — for cooking, serving food, for soup, eggs, mustard, and what not.

Spoons for the use of the mustached, and for the administration of medicine to invalids in a recumbent posture, are made with a shield which converts the pointed end into a funnel. *h* is a modern mustache-spoon.

Fig. 5471.



Medicine-Spoon.

2. (*Cotton-manufacture.*) A weighted and gravitating arm in the stop-motion of a drawing-machine, which is kept in position by the tension of the sliver, and falls when the sliver breaks or the can is emptied, and thereby arrests the motion of the machine.

Spoon-bit. A wood-boring tool adapted to be used in a brace. It has a rounding end, assuming a conoidal form, terminating the grooved semicylinder which constitutes the *barrel* of the tool. See BIT, Fig. 693, *b*.

Spoon-chis'el. A bent chisel with the basil on both sides, used by sculptors.

Spoon-gouge. (*Joinery.*) A gouge with a crooked end, used in hollowing out deep parts of wood.

Sports'man's Knife. One containing a number of tools, to be used in emergencies.

Spot-lens. (*Optics.*) A condensing lens in a microscope, in which the light is confined to an annular opening, the circular middle portion being obstructed by a *spot*, which forms the dark background behind the semi-translucent illuminated object.

Spout. 1. The discharging chute, ajutage, or tubular ventage of a vessel or machine whence issues the liquid or comminuted material; as, the spout of a pitcher, the issuing nozzle for the ground meal from the mill-stones, etc. See AJUTAGE.

2. (*Mining.*) *a.* A channel of the same size as the air-head, driven from the air-head into the gate-road at intervals of about fifteen yards, so as always to keep the communication as forward as possible.

b. The chute which carries the coal or ore from the wagon and dumps it into a car or ship.

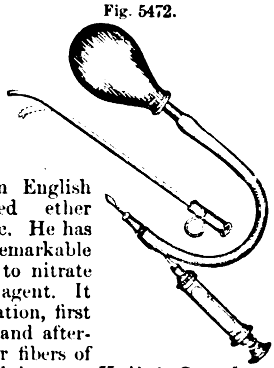
Spout-plane. (*Carpentry.*) A round-soled plane used in hollowing out stuff for spouting and troughs.

Spray. 1. (*Founding.*) A set of castings attached by their individual *sprues* to the main stem, which occupy the runner and its branches by which the metal entered the mold and was led to the various places it was required to fill.

2. The vapor from an atomizer.

Spray-in'stru-ment. (*Surgical.*) One for the administration of an anæsthetic or refrigerant in a finely divided liquid form. See ATOMIZER, page 183; ANÆSTHETIC APPARATUS, pages 92, 93; FOOT-BELLOWS, Fig. 2062.

Fig. 5472.



Huckley's Spray-Instrument for the Eustachian Canal.

Fig. 5472 is an instrument for the eustachian canal.

Dr. Richardson, an English physician, introduced ether spray as an anæsthetic. He has lately made some remarkable statements in regard to nitrate of amyl as a remedial agent. It causes extreme relaxation, first of the blood-vessels, and afterward of the muscular fibers of the body, being useful in cases of spasmodic diseases, including tetanus and spasms produced by strychnia and in *angina pectoris*. It is deemed possible that hydrophobia may be brought under the range of successful treatment. See also Fig. 1814.

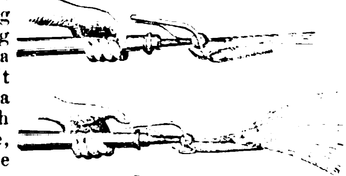
Spread'er. 1. (*Flax-manufacture.*) A machine in which the *stricks* of *line*, fresh from the *heckle*, are drawn out and combined so as to make a *sliver*, and eventually a *roving*, to be operated upon by the spinning machinery.

A first, second, and third drawing gradually attenuate the material, which, in the first place, is fed upon a feeding apron, but in the subsequent operations is fed as a sliver. A number of slivers are doubled and drawn, and the operation in this respect resembles the drawing-frame of the cotton-manufacture, but the flax-machine has a series of combs or *gills*, through which the slivers are drawn. This feature — of pins to imitate the action of the fingers in holding or retaining the flax with regularity as it is drawn out by the rollers — has given a name to the machine, which is called the *gill-frame* or *gill-head*, probably from the French word *aiguille* (needle).

The machine for which the *gill-frame* was substituted was one with a succession of rollers, over and under which the *line* was passed.

2. A device for flattening and spreading the jet from a hose-pipe. It consists of a flat blade with thumb-piece, pivoted at the end of the noz-

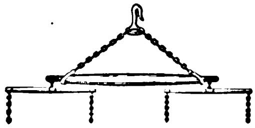
Fig. 5473.



Jet-Spreader.

zle, and thrown up to receive the impact of the stream and spread it into a sheet by pressing on the thumb-piece; in its normal position it is kept down by a spring.

Fig. 5474.



Spreader.

3. (*Vehicle.*) A stick which stretches apart the ends of a chain to which the single-trees are attached. It is a substitute for a double-tree, the hook at the midlength of the chain being attached to the pole-iron, to a log-chain, or what not.

Spread'ing-frame. (*Flax-manufacture.*) A machine in which a number of *stricks* or slivers of flax are spread and conducted to a system of drawing-rollers, whereby they are united and drawn into one. See DRAWING.

Spread'ing-fur'nace. (*Glass.*) A heated chamber in which cracked cylinders of sheet-glass are laid, in order to spread out into sheets. The glass is blown into *pears;* elongated into *cylinders;* cracked longitudinally by a cold iron or cut by shears; flattened in the spreading-furnace; and annealed in the *leer*, which is immediately adjacent and in communication with the furnace. See SHEET-GLASS.

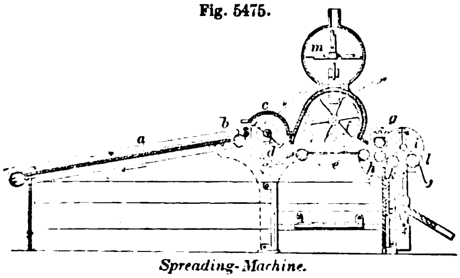
Spread'ing-ham'mer. The second hammer of the gold-beater, used after the *quartiers* are packaged with interleaves of vellum (Fr. *marteau à chasser*).

It is more convex than its predecessor, the *commencing-hammer*, has a face 2 inches in diameter, and weighs 4 or 5 pounds. See GOLD-BEATER'S HAMMER, page 993.

Spread'ing-ma-chine'. (*Cotton-manufacture.*) A machine in which cotton is subjected to the batting process and formed into a continuous band ready for carding.

The cotton is laid upon the endless feed-cloth *a* and fed between the nipping-rollers *b*, whence it is drawn into the drum *c* and subjected to the action of the revolving batting arms *d*, by which the dirt is beaten out of it. It is then received upon a second feed-cloth *e*, and being compressed between this and the roller *f* is carried between the two rollers *g h*, pressed together

Fig. 5475.



Spreading-Machine.

by weights, and is finally wound upon the roller *i*, which is held down upon two other rollers *k l*, so that the band of fiber is compacted as it winds upon the first-named roller. The feed-cloth *a* is divided into equal parts by transverse lines, so that by increasing or diminishing the equal weighed amounts of cotton laid upon each division different thicknesses of batting may be produced. The dust arising during the process is carried off by the fan-blower *m*. See SCUTCHER.

Spread'ing-ov'en. (*Glass-making.*) The FLATTENING-FURNACE (which see).

Spread'ing-plate. (*Glass-making.*) A flat hearth-stone or plate on which a split cylinder of glass is placed, to be opened into a flat plate. See FLATTING-FURNACE; CYLINDER-GLASS.

Spread Win'dow-glass. See SHEET-GLASS.

Spren'gel-pump. An air-pump or aspirator (see Fig. 393, page 170). It is considered in a paper by W. Crookes on the Atomic Weight of Thallium, Phil. Trans. 1873, Vol. CLXIII. p. 295.

Sprig. 1. *a.* A small square-bodied nail whose head consists of a slightly projecting lip on one side only. A small brad. See NAIL.

b. A brad or triangular piece of tin plate, to confine a pane of glass in a sash until the putty dries.

2. (*Nautical.*) An eyebolt with a barbed shank.

3. (*Fabric.*) A small, isolated ornament of the nature of a branch, woven or printed on textile fabrics.

For the formation of woven sprigs, there are often as many shuttles as colors, or a number of little swivel-looms, such as are used for the weaving of tapes, are introduced occasionally.

Spring. 1. An elastic substance of any kind, interposed between two objects, in order to impart or check motion, or permit them to yield relatively to each other.

The ancients made springs of bronze, which contained only from 3 to 4 per cent of tin. It was, as is supposed, carefully tempered and hammered.

No carriage-springs are found among the nations of antiquity, including the Romans. Carriages were not a general mode of transit until roads were made good. In England, till one hundred years since, the riding-horse and the pack-horse were the principal dependence for travelers and merchants.

The suspension of carriage-bodies by straps was in use about the middle of the seventeenth century. The date of its invention is not known.

Springs of coiled wire are much used for balances, for chair and sofa cushions and backs, mattresses, and in various other domestic applications where no great amount of strength is required. See WIRE SPRING; SPIRAL SPRING; CAR-SPRING, Fig. 1143. See under the following heads: —

Accumulator.	Spring-bar.
Atmospheric spring.	Spring-beam.
Bolster-spring.	Spring-blade knife.
Carriage-spring.	Spring-block.
Car-spring.	Spring-coupling.
Coiled spring.	Spring-draft.
C-spring.	Spring-faucet.
Door-spring.	Spring-head.
Draft-spring.	Spring-hinge.
Draw-spring.	Springing.
Driving-spring.	Spring-lock.
Elliptic spring.	Spring-mattress.
Furniture-spring.	Spring-polisher.
Hair-spring.	Spring-proof.
Half-elliptic spring.	Spring-punch.
Hammer-tail spring.	Spring-seat.
Helical spring.	Spring-tool.
India-rubber spring.	Spring-wagon.
Leading-spring.	Strut-spring.
Main-spring.	Tempering springs.
Pneumatic spring.	Tug-spring.
Proving-machine.	Volute spring.
Spiral spring.	Wagon-spring.
Spring (nautical).	Watch-spring.
Spring-balance.	Wire spring.

2. (*Nautical.*) *a.* A rope or hawser passed from the stern of a ship and made fast to the cable on the anchor from the bow, by which she is riding. The object is to bring the broadside to bear in any direction.

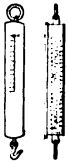
b. A check on a cable while unshackling it.

Spring'al. (*Weapon.*) An ancient form of military engine for throwing stones and darts.

Spring-back. (*Bookbinding.*) A mode of binding in which a spring in the back throws up the folded edge so as to make the leaves lie flatly.

Spring-bal'ance. A balance in which the weight of an object is determined from the tension or compression of a spring provided with an index and scale.

Fig. 5476



Salter's Spring-Balance.

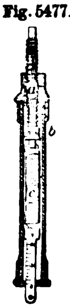
In Salter's spring-balance, the spring is spiral and inclosed in a cylindrical box, at whose upper end is a suspending ring. The hook from which the object to be weighed is suspended is connected by a rod to a piston above the spring, so that the weight has the effect of condensing the spring, a finger on the rod projecting through a long slot in the case and indicating the weight upon a graduated and numbered scale.

In Martin's modification, the interior rod is furnished with a rack moving a pinion on the arbor of an

index-finger, which traverses a circular dial on the outer case. This permits a much more minute reading.

In Fig. 5477, the supporting screw *a* of the spring *b* is connected to the latter by a swivel-joint, to allow of the rotation of the screw, in order to adjust the zero of the scale to the bottom of the case *c*. The highest graduation visible indicates the weight of a body suspended from the scale.

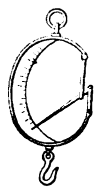
Fig. 5477.



Spring-Balance.

Another spring-balance is made in the form of a letter C, the upper end being suspended by a ring, and the lower end affording attachment for the hook whereby the object is suspended. As the *bow* opens a finger traverses a graduated arc and registers the weight.

Fig. 5478.



Spring-Balance.

Harris' spring-balance has a semicircular spring in a case, the straightening of the spring moving a rack, pinion, and index-finger, which traverses a dial-plate having in concentric circles the various systems of weights of different countries within the range of its compass.

Marriott's has an elliptical spring somewhat similarly placed.

Regnier's dynamometer has an elliptic spring. See DYNAMOMETER for this and several other spring-balances.

Spring-bal'ance Valve. (*Steam.*) A spiral spring weighing-balance, with an index and pointer attached to the end of the lever, by which the pressure upon the safety-valve is adjusted.

Spring-bar. 1. (*Saddlery.*) A stirrup-loop with a spring side which opens to release the stirrup-leather if a rider be thrown from the saddle, but remains closed under ordinary circumstances.

2. (*Vehicle.*) A bar parallel with the axle and resting upon the middle of the elliptic spring. The *body* rests by loops upon the ends of the spring-bar.

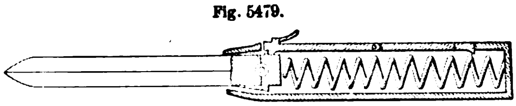
Spring-beam. 1. (*Shipbuilding.*) The fore-and-aft timber uniting the outer ends of the paddle-box beams. The *sponsons* are curved timbers uniting the spring-beam to the sides, fore and aft of the paddle-box.

2. An elastic bar at the top of a tilt-hammer, mortising-machine, or jig-saw, to accelerate the fall or give the return motion, as the case may be.

3. (*Carpentry.*) A beam stretching across a barn without a central support, so as to leave the two bents of the barn floor free for various uses.

Spring-blade Knife. A pocket-knife whose

Fig. 5479.



Spring Dirk-Knife.

blade is thrown out or held out by a spring. In the ordinary pocket-knife, the blade is held by the spring in open or closed position.

In the example, the blade is projected longitudinally from the handle by a spiral spring; catches on the handle maintain it in either its projected or retracted position.

Fig. 5480.

Spring-Block.

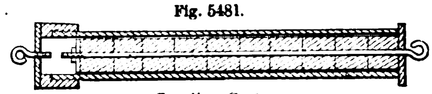
Spring-block. (*Nautical.*) A common block or dead-eye connected to a ring-bolt by a spiral spring. It is attached to the sheets, so as to give a certain amount of elasticity and assist the vessel in sailing. Invented by Hopkinson.

Spring-board. (*Gymnastics.*) An elastic board used in vaulting.

Spring-box. The barrel containing the spring in a watch or other mechanism. The *barrel.*

Spring-coup'ling. A connecting device between cars, for attaching the draft-team to street-cars, etc. The example is a series of india-rubber cylinders inclosed in a frame of rods, and with two end disks to which

Fig. 5481.



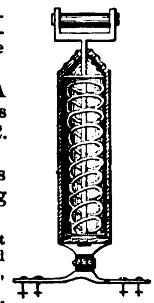
Coupling-Spring.

the coupling-ring and hook are respectively connected, so as to condense the caoutchouc when a strain is brought upon it.

Springs have been used for tugs in attaching draft animals to loads. They present an elastic resistance when the animal pulls, and tend to save him from the strain incident to sudden jerks.

The clip at the end of the spring is attached to the vehicle, and the roller is attached either behind the single-tree of the horse or at the end of his trace-tug.

Fig. 5482.



Draft-Spring.

Spring'er. (*Architecture.*) *a.* A lower voussoir of an arch. One rests on each *skewback*, *abutment*, or *impost*.

b. The rib of a groined roof.

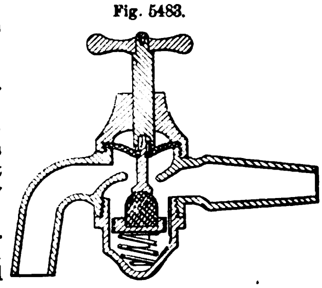
Spring-fau'cet. One which is closed by a spring when the opening force is withdrawn.

In Fig. 5483, the valve is depressed against the force of the spring by a key entered above. When the pressure is withdrawn, the spring forces the valve against its seat.

In Fig. 5484, the ball-valve is kept to its seat by a spring-plunger, excepting when the plunger is withdrawn.

In Fig. 5485, the tube has a flexible lining, which is compressed by a spring-stopper at one point; pressing down this spring permits the flow of the liquid.

Fig. 5483.

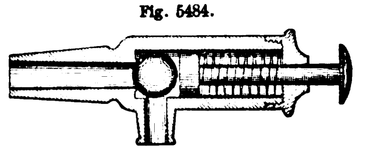


Self-Closing Faucet.

Spring-fore'-lock. A cotter-key whose entering end springs apart to keep it from accidentally withdrawing.

Spring-gun. (*Weapon.*) A gun which is fired by the stumbling of a trespasser upon it or against a wire connected with the trigger.

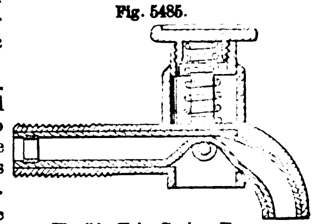
Fig. 5484.



Spring-Faucet.

Spring-head. A box, clutch, or connection at the point of contact of the outer ends of an elliptic spring.

Fig. 5485.



Flexible-Tube Spring-Faucet.

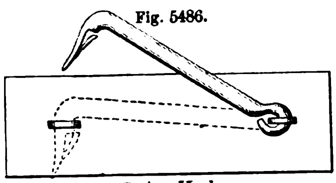
Spring-hinge. A hinge provided with a spring to shut it after the door to which it is attached is opened.

A beautiful elastic spring-hinge is attached by the mason-spider of the Tropics and Southern Europe to the earth-kneaded door of his cell. The cell is subterranean and tapestried with silk; the door closes of itself after each entrance and exit of the

cavern's occupant, and so neat is the fit that it is almost impossible to distinguish the line of junction of the door and the cellar-way even when the observer has just witnessed the closure of the lid.

Spring-hook. 1. A hook having a spring-latch to prevent disengagement.

Fig. 5486.



Spring-Hook.

2. (*Steam-engine.*) In the English practice, one of the hooks fixing the driving-wheel spring to the frame of a locomotive-engine. A screw on the end of the hook regulates the weight on the driving-wheels.

Spring'ing. (*Architecture.*) The bottom stone of an arch which lies on the impost. A *springer.*

Spring'ing-line. (*Architecture.*) The line from which an arch rises. The line of the *springers* on the *imposts*, and from which the *versed sine* or *rise* is calculated.

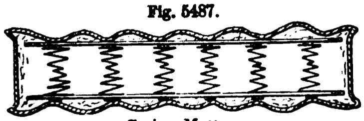
Spring-latch. One that snaps into the keeper after yielding to the pressure against it.

Spring-line. In a ponton-bridge, a line passing diagonally from one ponton to another.

Spring-lock. (*Locksmithing.*) A lock in which the bolt slips back when the catch or hasp is applied and returns by a spring to engage the *hasp, catch,* or *staple.* It is thus *self-locking.*

Spring-mat'tress. One having metallic springs beneath the hair or moss filling.

Fig. 5487.



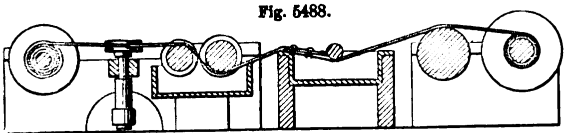
Spring-Mattress.

Spring-pin. (*Locomotive.*) In the English practice, a rod between the springs and axle-boxes, to regulate the pressure on the axles.

Spring-pol'ish-er. A machine for polishing wire or flat metallic ribbon-steel for springs.

In the example, from the burring-rollers the spring is conducted between the burnishing-rollers, which act on the opposite surfaces of the spring simultaneously. It then passes

Fig. 5488.



Machine for Polishing Metal Springs.

through the bath of molten lead, into which it is depressed by a roller. The bath has a bluing heat, and the spring after leaving it is wound on a reel.

Spring-proof. The strength and temper of springs is tested by suspending from them a weight or causing them to be subjected to a strain equivalent to a certain weight adapted to their capacity.

The main-spring of United States small-arms is proved (1) by a weight of 70 to 75 pounds, which should cause the spring to bend to a given mark without breaking or setting; (2) by being required to stand at the position of full cock for 12 hours in a spring-proof containing 35 main-springs.

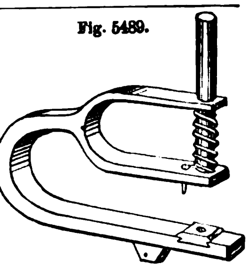
The sear-spring is required to sustain a strain of about 20 pounds.

Spring-punch. One which has a spring to retract the plunger after the blow or the pressure, as the case may be.

Fig. 5489 is designed to be used by blacksmiths in punching bar-iron, and held in place upon the anvil by the lug, which enters a hole in the face of the anvil.

Fig. 5490 is a hand-punch which has a spring to open the handles, and so withdraw the plunger from the ticket which has been punched.

Fig. 5489.

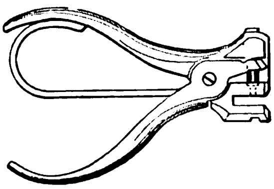


Spring-Punch

Spring Safe'ty-valve. (*Steam-engine.*) One arranged to resist a definite amount of steam pressure, through the medium of a spring or springs.

Spring-search'-er. A steel-pronged tool to search for defects in the bore of a cannon.

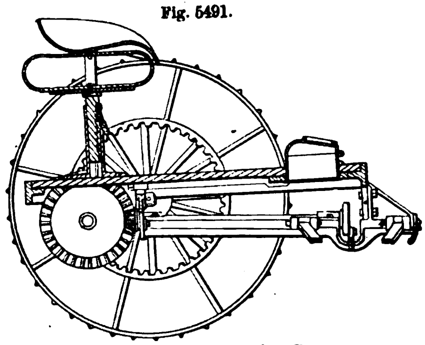
Fig. 5490.



Hand-Punch.

Spring-seat. (*Vehicle.*) A seat having a spring or springs beneath it, and placed in a wagon, on a sulky plow, rake, or harvester. These vehicles not having springs between the bed or frame and the axle, the seat itself is made to rest on springs.

Fig. 5491.



Mowing-Machine Spring-Seat.

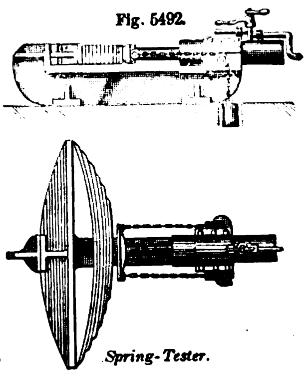
Fig. 5491 shows a spring-seat applied to a mowing-machine.

Elliptic, half-elliptic, S-shaped, spiral, and caoutchouc springs are used for this purpose.

Spring-spike. A spike with a spring, used for temporarily spiking a gun.

Spring-stay. (*Nautical.*) A preventer stay, used to assist a principal stay.

Fig. 5492.



Spring-Tester.

Spring Take-up. (*Knitting-machine.*) An elastic finger fixed to the needle-carrier, to take up the slack yarn at the end of each stroke. The spring take-up has an eye formed in its end, through which the yarn is passed. The yarn passes

around pins or guides to and from the spring take-up.

Spring-test'er. A form of hydrostatic press adapted to the compression of railway-car and locomotive springs, to test their integrity and strength.

In using the machine, the accumulator is charged with air at a pressure of about 300 pounds per square inch, the power-pumps are started, and water is pumped into the accumulator until the requisite pressure is attained, which is indicated by the rising of the safety-valve. On opening the stop-valve, the accumulated pressure acts suddenly on the ram and compresses the spring.

Spring-tool. (*Glass-making.*) The light tongs of the glass-blower whereby handles and light objects are grasped.

Fig. 5493.

Spring-Tool.

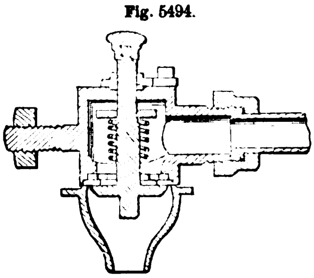
Spring-trap. 1. One whose falling bar or door is operated by a spring as soon as the detent is released by the tampering with the bait by the animal. See TRAP; ANIMAL TRAP.

2. A form of steam-trap.

Spring-valve. One in which the valve is held to its seat by a spring, except as temporarily depressed by the hand to allow the flow of water.

The valve-stem has a fixed and a removable disk. The former constitutes the valve, and the latter forms a bearing for one end of a spiral spring, the other end of which rests against a perforated disk fixed in the case. The valve-seat is of rubber. The water is admitted by depression of the stem.

Fig. 5494.



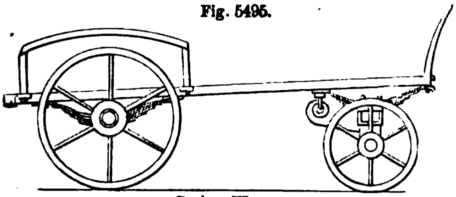
Spring-Valve.

Spring-vise. 1. One whose jaws have an appreciable amount of grip by the force resident in a compressing spring.

2. A small vise used for confining the main-spring of a gun-lock when the lock is to be taken apart. They are issued to the troops in the proportion of one to each ten muskets.

Spring-wag'on. One whose bed rests by springs on the axles. In the example, the bed rests by springs on the hind axle, and the front is supported by springs on the bolster of the fore axle; volute spring-braces attach the bed to the bolster.

Fig. 5495.



Spring-Wagon.

Sprink'ler. A form of watering-pot as old as the Greek and Roman times. It had a bottom with fine perforations and a single hole at top. It was filled by submerging it in water; then, being held vertically, the water would not run out so long as the upper hole was closed by the pressure of the finger.

a in the figure is from Fludd's work, "De Naturæ," 1618. *b* is a glass sprinkler found in Pompeii. The part shown in outline had been broken off before the discovery. It is on the same principle as the wine-taster or *velinche*. *c* is also of glass, and is supposed to have been a wine-taster, the liquid having been drawn by suction at the small end, or, as Ewbank conjectures, by simply immersing the larger end in a vessel and stopping the small end with the finger, as is practiced at the present day. See THIEF-TUBE.

Fig. 5496.

Sprinklers.

(*a*, Fludd, 1618.) (*b*, *c*, Pompeii.)

The clothes-sprinkler *à la Chinoise* is the mouth, which discharges the water in a splutter of spray.

Sprit. (*Nautical.*) A diagonal spar which raises the peak of a boat's sail, the lower end resting in a becket called the *snotter*. It serves instead of a *gaff*.

Sprit'sail. (*Nautical.*) *a.* A four-cornered sail, bent to the mast at its weather-leech, and having its peak extended by a raking spar called a *sprit*. The *heel* of the *sprit* rests in a *grommet* (*snotter*), which may be slipped on the mast. It is a common form of sail for boats.

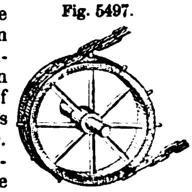
b. A sail set on the bowsprit.

Sprit'sail-yard. (*Nautical.*) A spar, occasionally used, crossing below the bowsprit a little abaft of the dolphin-striker, and used for securing the rigging of the jib-boom and flying jib-boom.

A pair of spars pointing obliquely downward at opposite sides of the bowsprit are sometimes used instead of the *spritsail-yard*. These spars are known as *spritsail-gaffs*.

Sprock'et-wheel. A wheel whose projecting pins are adapted to receive the links of a chain. The latter may communicate motion to the wheel, or conversely. The relative distance of the links on the chain is equal to the peripheral distance apart of the pins on the wheel, and the engagement of the links with the pins prevents slipping. See Fig. 1230, page 520.

Fig. 5497.



Sprocket-Wheel.

By a modification, the sprockets may be forked, and thus made to partially embrace the links of the chain, instead of being pointed and entering into the links. Such are seen on some forms of water-elevators.

Spruce. (*Leather.*) Prussia leather; *pruce.*

Sprue. (*Founding.*) *a.* The *ingate* of a mold, through which the metal is poured.

b. The piece of metal attached to a casting, occupying the *gate* through which the metal was poured. As the metal rises in the *gate* it indicates that the mold is filled, and when cooled the *sprue* is knocked off.

Fig. 5498.

Molders' Sprue.

The *sprue* of a type is called a *jet*.

c. A piece of metal or wood used by a molder in making the *ingate* through the sand.

Spud. 1. (*Husbandry.*) A sharp, straight, narrow spade, with a long handle. It is used for digging post-holes, and digging out heavy-rooted weeds, such as burdock, wild parsnip, elecampane, thistles, iron-weed, etc.

2. (*Well-boring.*) A spade-shaped implement, used in fishing for broken tools in a well.

Spun-gold. A flatted silver-gilt wire, wound on a thread of yellow silk. GOLD-THREAD.

Spun-silk. A cheap article produced from short-fibered and waste silk, in contradistinction to the long fibers wound from the cocoon and *thrown*. See SILK. It is frequently mixed with cotton.

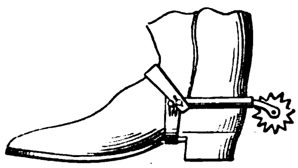
Spun-sil'ver. Thread of coarse silk, or *singles*, wound with flattened silver wire.

Spun-yarn. (*Nautical.*) A line formed of a number of yarns twisted together, but not *laid up*. Used for seizings, serving, etc.

Spur. 1. (*Manege.*) An instrument attached to the heel, and having a rowel or wheel of points to prick a horse's side.

Spurs were used by the Greeks and Romans. They are referred to by Plautus (died B. C. 184) and by other Latin authors.

Fig. 5499.



Spur.

The *rim* is the part inclosing the heel of the boot; the *neck*, the part between the *rowel* and the *rim*; the *rowel*, a wheel with sharp radial points.

Spurs are represented on seals of the eleventh century. They were common among the Saxons, being made of brass or iron, and fastened to the shoe by a leathern thong. Instead of a rowel, the rear had a single fixed, sharp point. The rowel is noticed in the reign of Henry III. Anciently the knight wore golden spurs, and his squire spurs of silver.

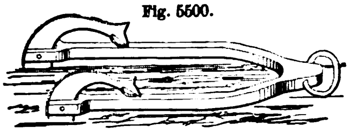
2. (*Shipbuilding.*) *a.* A shore extending from the bilgeway, and fayed and bolted to the bottom of the ship on the stocks.

b. A curved piece of timber, serving as a half-beam to support a deck where a hatchway occurs.

c. A compass timber or knee, having one arm bolted to the deck-beams and a vertical arm bolted to the bitts, which are additionally secured thereby.

3. (*Nautical.*) *a.* A sole with spikes, to enable a seaman to stand on a whale while flensing.

Fig. 5500.



Anchor.

b. A prong on the arm of some forms of anchor, to assist in turning the lower arm from the shank.

4. (*Hydraulic Engineering.*) A projection carried out from the bank of a river to deflect the current and protect the bank. It is made of masonry, of piles, or of earth revetted by gabions or fascines. See GROIN; CROY.

5. (*Carpentry.*) A strut or brace strengthening a rafter, or stiffening a post.

6. (*Architecture.*) A buttress.

7. (*Fortification.*) *a.* A tower or blockhouse in the outworks before the port.

b. A wall that crosses part of a rampart and connects to the interior work.

Spur-gear'ing. One with radial cogs. See SPUR-WHEEL.

Spur'ling-line. (*Nautical.*) *a.* A line from the steering-wheel to the *tell-tale* in the cabin, by which the position of the tiller may be observed without going on deck.

b. A line with *fair-leaders*, for running ropes.

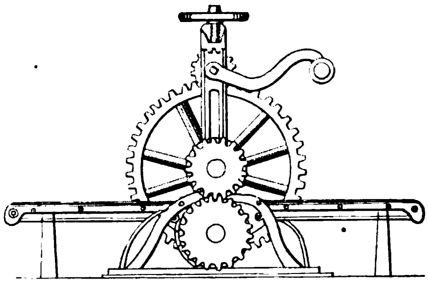
Spurn. (*Mining.*) *Spurns* are small ties or connections left between the coals hanging and the ribs and pillars, to insure safety to the miner during the operation of cutting.

Spurn-wa'ter. (*Nautical.*) A channel at the end of a deck, to restrain the water.

Spur-wheel. The ordinary form of cog-wheel. The cogs are radial and peripheral, and are adapted to engage counterpart cogs on another wheel. See list under GEARING.

The pitch-lines of the *driving* and the *driven* wheel are in one plane.

Fig. 5501.



Spur-Gearing.

Proportions of wheels. Spur and bevel gear: —

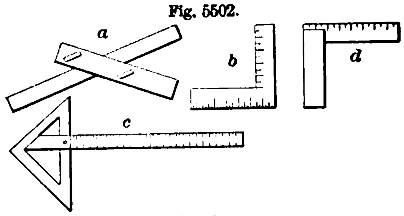
Height of tooth	= $^{12}/_{15}$ths of pitch.
Height below pitch line	= $^{13}/_{30}$ths "
Height above pitch line	= $^{11}/_{30}$ths "
Thickness of tooth	= $^{19}/_{40}$ths "
Breadth of wheel	= $2\frac{1}{2}$ times the pitch.
Edge of rim	= space.
Feather under rim	= "
Thickness of feathers	= thickness of tooth.
Breadth of arms	= pitch × 2.
Thickness round eye	= pitch.
Feather round boss	= length of tooth.

Sputch'eon. The inner part of the mouthpiece of a sword scabbard, which retains the lining in place.

Spy-glass. A telescope. The term is rather maritime.

Square. 1. An implement used by artificers for laying off lines to which work is to be sawed or cut. It consists essentially of two pieces at right angles to each other, one of which is sometimes pivoted, so

Fig. 5502.



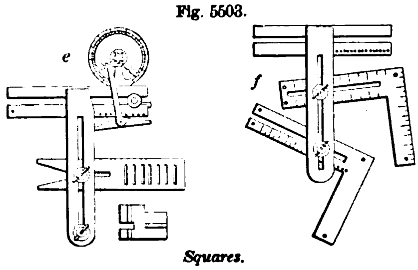
a, *T-square* and *Bevel*.
b, *Machinists'* flat, steel square.
c, Ames's *Universal* square.
d, *Steel* square; *try*-square; *trial*-square.

that other angles than a right angle may be scribed or measured.

The *miter*-square is a bevel-square, set to an angle of 45°. See also BEVEL-SQUARE, Fig. 670, page 279.

e, *f*, are squares for laying off complex joints. The first is provided with a short straight-edge attached to an arm with a segment-rack meshing with a pinion carrying an index and

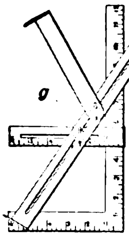
Fig. 5503.



Squares.

graduated circle or arc, enabling small angles to be laid off and measured; also, a supplementary arm, having longitudinal transverse and angular adjustments on the principal arm. The

Fig. 5504.



Square.

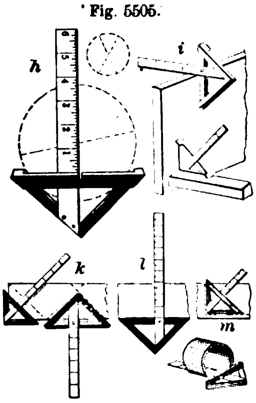
second has two supplemental graduated squares having all three of these adjustments.

In *g*, the sliding bar moves along one arm of the graduated square. The straight-edge is clamped to the bar by a set-screw. The relative positions are adjusted by the set-screws in the elongated slots of the bar and straight-edge.

The square, Fig. 5505, combines *five different instruments*, viz. the try-square, the miter, the T-square, the graduated rule, and the center-square, for finding the center of a circle.

h shows its application as a center-square. Put the instrument over the circle, as the end of a bolt or shaft, with the arms resting against the circumference, in which position one edge of the rule will cross the center. Mark a straight line in this position; apply the instrument again to another part of the circumference, and mark another line crossing the first. The point where the two lines cross each other will be the center of the circle. *i* shows the application of the instrument as a carpenter's try-square and an outside-square, *k* as a miter, *l* as a T-square and a graduated rule, *m* as an outside-square for drawing and a T-square for machinists.

Fig. 5505.

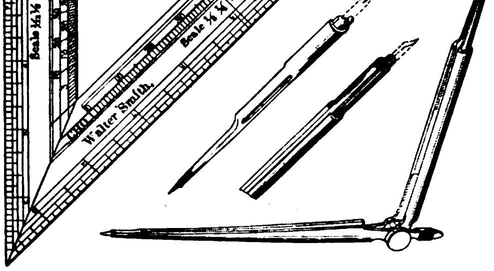


Ames' Universal Square.

The school-square of Walter Smith is a drawing-implement formed of two sides of a square connected by a diagonal, the outer edges provided with various scales, and the inner with a scale of angles, forming in one implement a square, triangle, and protractor. It stands in the place of a number of separate instruments, — the rule, set-square, scale, and protractor.

The other figures represent a pocket instrument, containing a circle-pen, a writing-pen, dividers, and pencil-holder. The instrument has a reversible extension leg, which has a fixed point, a pencil-holder, and a pen-holder slide.

Fig. 5506.

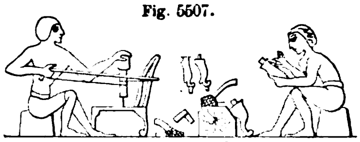


Smith's School-Square and Dividers.

Theodorus of Samos was probably a very successful architect, but it is not likely that he was, as Pliny states, the inventor of the square and the level. The builders of Athens, Thebes, and Sparta, and the early cities of the plains of the Euphrates and Tigris, we may reasonably suppose, had squares, levels, and plumbs, as well as the hammer and lever credited by the same Pliny to Cinyra of Cyprus.

It will surprise no one who knows what *good work*, *square work*, was made by the ancient Egyptians to be informed that they used a square, but the association of the tools in the accompanying cut brings to our view the state of the art in the year 1490 B. C. The chair-legs were "got out" by the adze and tested by the square in the days when the lathe was not.

Fig. 5507.



Carpenter's Square, etc. (from Thebes).

The square was regarded in ancient times as the sign of completeness. Simonides speaks of a man being "square as to his feet, his hands, and his mind." Aristotle has the same kind of comparison. We yet hear of working and acting "on the square," having accounts "all square," and of "square meals," complete and satisfying.

The square (*norma*) is represented on Roman tombs. In some cases it is a right-angled triangle; in other examples the hypothenuse is omitted, — the modern form. See CARPENTER'S TOOLS, page 473.

The Japanese have iron squares, marked with degrees. Their measures are brass, very light and fluted. On one side the inch, or what stands for the inch with us, is 1 1/16 inches, and divided into ten parts. On the other side is a different scale, measuring 1 13/16 English inches, and divided into twelve parts.

2. (*Nautical.*) *a.* That part of the shank of an anchor to which the *stock* and shackle are attached. See ANCHOR.

b. To *square away* is to square the yards by the braces and run before the wind.

3. (*Bookbinding.*) The projection of a board beyond the book-edge.

4. (*Horology.*) *a.* That portion of the *arbor* on which the winding-key is placed.

b. A similar part on the arbor of the hands of a watch, whereby they are set.

5. (*Glazing.*) A pane of glass.

6. (*Carpentry.*) 100 feet, — that is, 10 × 10; a unit of measurement used in boarding and roofing.

7. (*Printing.*) A certain number of lines in a column, of nearly equal height and width.

Square-file. A file which is square in its transverse section. It is usually taper, and has one *safe* side. It is used as an *entering* file in starting *key-ways* and grooves for *splines*, *cotters*, and *wedges*.

Square-frame. (*Shipbuilding.*) A frame square with the line of the keel, having no beveling.

Square-joint. A mode of joining wooden stuff in which the edges are brought squarely together, without rabbeting, tongue, or feather. See JOINT.

Square-rab'bet Plane. (*Joinery.*) One for making a rabbet at an angle of 90° with the working face.

Square-rig. (*Nautical.*) That rig in which the lower sails are suspended from horizontal yards, as distinguished from *fore-and-aft* rig. See FORE-AND-AFT SAIL.

Square-roof. (*Carpentry.*) One in which the principal rafters meet at a right angle. See ROOF. See Fig. 4420, 10; Fig. 4421, 17.

Square-sail. (*Nautical.*) *a.* A four-sided sail, whose middle position is athwartship. It is supported by a *yard*, *slung* at its mid-length by a *truss* or *parral*. It is distinguished from sails which are extended by stays, booms, gaffs, lateens, sprits, etc.

Of a square-sail, —
The upper edge is the *head*.
The lower edge is the *foot*.
The side edges are *leeches*.

The lower corners are *clews*; they are stretched by ropes called *sheets*, and are drawn up to the *bunt* of the yard by *clew-lines*.

The *bowline* is attached by *bowline-bridles* to the *leech* of the sail, to keep the weather-edge drawn forward when the ship is close-hauled.

Buntlines are in front of the sail, and are for hauling up the foot of the sail to the yard in furling.

Leech-lines pass to the leech, and are for hauling up the leech to the yard in furling.

The *slab-lines* are similar to the *leech-lines*, but pass abaft the sail.

Reef-tackles have a twofold purchase, and are used for hauling up the leeches of courses and topsails to the yard-arms before furling them.

Gaskets are plaited ropes for tying up the furled sail.

b. A sail set on the foremasts of schooners, and on the masts of sloops and cutters, when sailing before the wind in light weather.

Square-sail Boom. (*Nautical.*) A spar used to extend the outer lower corners of square-sails in schooners, sloops, and cutters.

Square-stern. (*Shipbuilding.*) A build in which the wing-transom is at right angles to the stern-post, in contradistinction to *round* stern.

Square-tim′ber. (*Shipbuilding.*) One standing square with, that is, perpendicular to, the keel.

Square-tucks. (*Shipbuilding.*) The flat surfaces left at the stern of a vessel when the planks of the bottom are not worked round to the wing-transom, but end in the fashion-piece.

Squat. (*Mining.*) *a.* Tin ore, mixed with spar.

b. A small separate vein of ore.

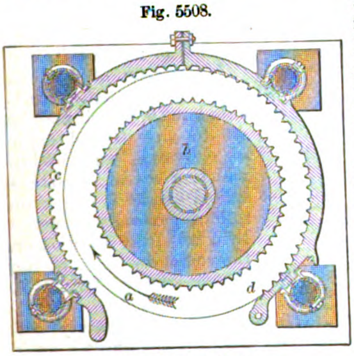
Squee′gee. 1. (*Nautical.*) A scrubber, consisting of a plate of gutta-percha at the end of a handle. *Squilgee.*

2. The same kind of tool is used in wiping superfluous moisture from plates.

Squeez′er. (*Metal-working.*) A machine which takes the ball of puddled iron and reduces it to a compact mass, ready for the rolls. In one form it is a toothed or corrugated wheel or segment, turning within an outer eccentric casing in such manner as to be rolled by the contact of the two, being squeezed between the gradually narrowing space between the surfaces of the wheel and the case.

In Ralston's rotary squeezer the ball of metal is inserted at *a*, and is carried around in the direction shown by the arrow by the ridged roller *b*, which, rotating in that direction, compresses it between itself and the ridged eccentric casing *c* as the sectional area of the space between the two diminishes; expressing the cinder and delivering the ball at the opening *d*.

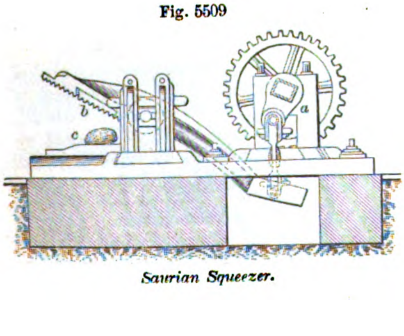
Fig. 5508.



Ralston's Rotary Squeezer.

The Saurian squeezer is so called from its similarity to the jaws of a saurian,—a crocodile, for instance. The upper jaw *b* is moved by a crank *a* on a pivot, in the manner of the movable jaw of a pair of heavy shears. The palate and lower jaw are corrugated. Its office is to compact and shape the ball *c* of puddled iron, and squeeze out the dross.

Fig. 5509



Saurian Squeezer.

Squeez′ing-box. (*Pottery.*) A metallic cylinder having a hole in the bottom, through which clay is pressed for shaping the handles, etc., of earthenware.

Squib. (*Pyrotechny.*) A paper case filled with powder.

Squid-jig′ger. A trolling-hook for catching squids for bait. See patent, Fitzgerald, January 13, 1874, No. 146,443.

Squid-throw′er. A device like a catapult for throwing a fishing-line seaward, carrying the squid-bait. Used in blue-fishing. See patent, Peck, November 10, 1874, No. 156,648.

Squil′gee. (*Nautical.*) An instrument like a hoe, covered with leather, to rub the decks after washing.

Squinch. (*Architecture.*) A small pendentive arch formed across the angle of a square tower to support the side of a superimposed octagon. Also called a *sconce.*

Squir′rel. One of the small rollers, provided with cards, and acting in conjunction with the large cylinder of a carding-machine in opening the knots and bringing the filaments into parallelism. See CARDING-MACHINE.

Squirt. A SYRINGE (which see).

Stab′ber. 1. (*Leather.*) A pegging-awl. A pricker.

2. (*Nautical.*) A marlinspike.

3. (*Domestic.*) A lady's awl for opening holes for eyelets.

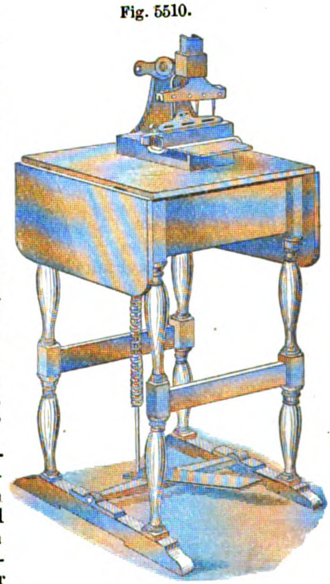
Stab′bing. 1. (*Bookbinding.*) *a.* The puncturing of the boards for the slips.

b. The perforation of a pile of folded sheets for a *stitching* twine. A cheap substitute for *sewing.*

2. (*Masonry.*) The picking or roughening of a brick wall, in order to make plaster adhere thereto.

Stab′bing-ma-chine′. (*Bookbinding.*) A machine for perforating a pile of folded and gathered signatures for the insertion of the *stitching*-thread. It is a cheap substitute for *sewing.* The thread is reeved through these holes a short distance from the folded edge of the signatures and tied.

Fig. 5510.



Stabbing-Machine.

Three awls are adjustably inserted in a vertically sliding head, depressed by means of a treadle; after puncturing the set of sheets, the head is thrown up by a spiral spring when the foot is lifted from the treadle.

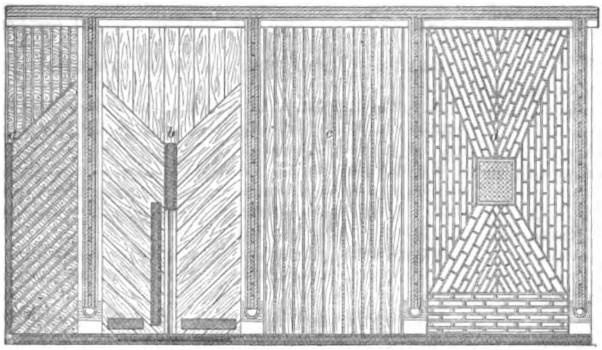
See also No. 114,286, Glass, May 2, 1871; No. 116,757, Reynolds, July 4, 1871.

Stab′bing-press. A bookbinder's press, in which pointed rods are driven through the folded sheets near the back, to stitch them together. A substitute for sewing. See STABBING-MACHINE.

Sta′ble. A house for horses or cattle.

a. A half-plan of stall with wooden block floor. The edges

Fig. 5511.



Jackson's Stable-Flooring.

of the blocks are beveled, forming gutters to prevent the horses from slipping; their surfaces are treated with coal-tar or asphaltum.

b, diagonally laid plank floor; top removed from central gutter.

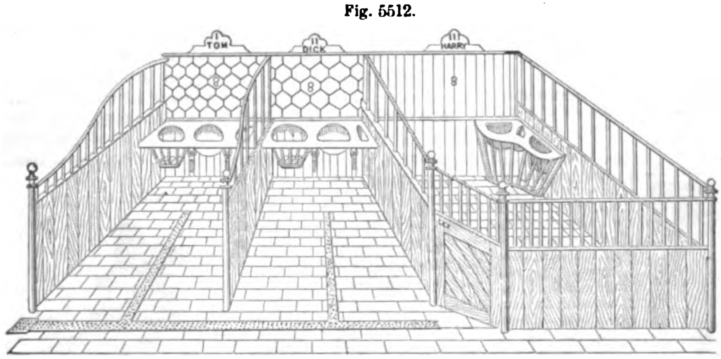
c, floor with slats and interstices, sloping two inches from rear to front.

d, brick floor, with sides sloping toward central cesspool and trap, connecting with drain-pipe.

Besides those shown, a variety of wood-block and concrete floors, and many forms of gratings, are used for stable-floors. The great requisites of a good floor are dryness, warmth, and perfect cleanliness.

Fig. 5512 shows some forms of stable-fittings.

Fig. 5512.



Jackson's Stable-Fittings.

Sta'ble-clean'er. A manure-drag for removing used litter from stables.

Stack. 1. *a.* A chimney of masonry or brick-work, usually belonging to an engine or other furnace. To term a smoke-pipe or metallic chimney a stack is but a loose use of the word, to say the least.

b. (*Architecture.*) A cluster of chimneys.

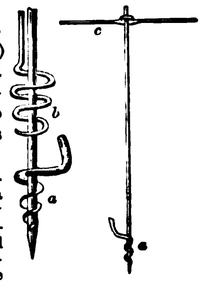
2. (*Husbandry.*) A structure of hay, or grain in sheaves, having, when of perfect shape, a conical top, and a frustum of an inverted conoid for a base.

The term *stack* is applied in the United States to those which are round in plan; *rick* to those which are elongated in plan.

3. (*Military.*) A number of small fire-arms stood up together so that their bayonets cross. See STACKING-HOOK.

Stack-bor'er. (*Husbandry.*) An implement for taking a cylindrical plug out of a stack, so as to admit air when the hay is heating to a dangerous extent.

Fig. 5513.



Stack-Borer.

It consists of two parts, — a leading screw and cutting lip *a*, and a drawing screw *b*. Each is worked by a cross-handle *c*, in the usual manner. The tool *a* is entered first, and cuts out the plug; being then withdrawn, the tool *b* is inserted in the manner of a cork-screw, and withdraws the plug of hay.

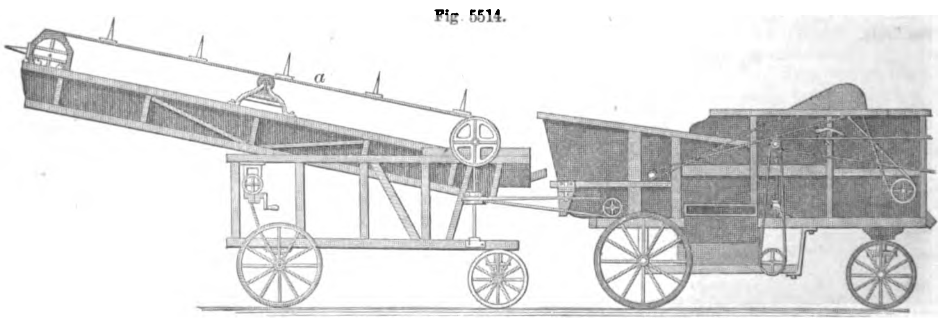
The policy of letting air to the center *after* the heating has taken place is disputed, as it admits oxygen to increase the energy of the action. This, however, does not concern us now. Such is the tool.

Stack'er. A machine adapted for delivering straw from the thrashing-machine on to the stack, or hay from a wagon on to a stack or into a loft.

It consists of a truck carrying a trough of suitable length, which may be set to any desired angle of elevation, and within which a wide, endless spiked band *a* is carried on rollers, generally operated by a belt from a pulley on the screen-cylinder of the thrashing-machine. See HORSE-POWER, Fig. 2570, page 1126.

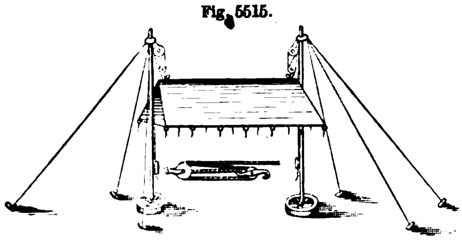
Stack-guard. (*Husbandry.*) A temporary roof capable of elevation, and designed to protect a stack or rick of hay or grain in process of formation; may be made by a couple of poles stayed by guys and

Fig. 5514.



Stacker.

Fig. 5515.



Stack-Guard.

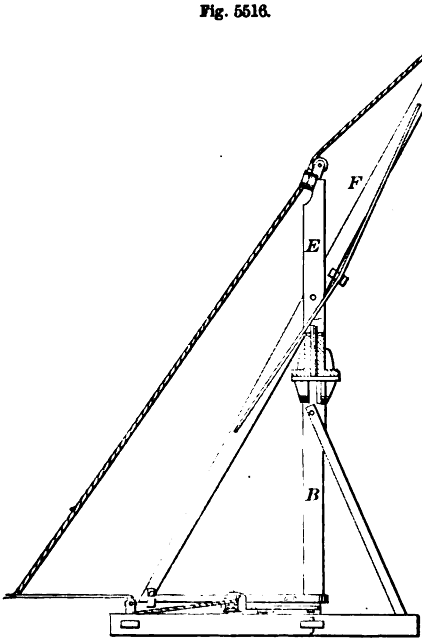
planted in wheels. The awning is stretched upon a frame, and suspended by tackle from each spar.

Stack'ing-band. (*Husbandry.*) A rope used in binding thatch upon a stack.

Stack'ing-der'rick. A form of derrick for use in the field or stack-yard for lifting hay on to the stack.

A horse hay-fork is employed, and is slung from the

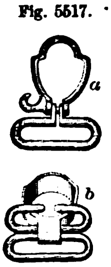
Fig. 5516.



Hay-Derrick.

yard *F*, which is secured by a parral to the topmast *E*; this is swiveled on the post *B*, so as to give circular sweep to the end of the yard. The hoisting-rope passes over pulleys on the yard, mast, and base-piece.

Fig. 5517.



Stacking-Hook, etc.

Stack'ing-hook. (*Fire-arms.*) A hook attached to the upper band of a rifle or carbine, to enable the arms to be stacked without using the wiping-rod or attaching the bayonet. Invented by Lieut.-Col. E. Rice, U. S. A., and adapted for use upon arms manufactured by the government.

a, upper band, with stacking-hook and swivel for sling.

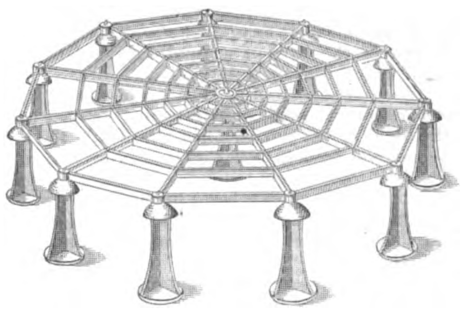
b, upper band, with stacking-swivel and sling-swivel.

Stack'ing-stage. (*Husbandry.*) A scaffold used in building stacks.

Stack'ing-swiv'el. A swivel attached to the upper band of a breech-loading rifle or carbine, to enable stacks to be formed without attaching the bayonet or using the wiper. See STACKING-HOOK.

Stack-stand. (*Agriculture.*) A device for supporting a stack of hay or grain at a sufficient distance above the ground to preserve it dry beneath and prevent the ravages of vermin. It consists of a central foot, around which are arranged a series of pillars, connected to the central one by radial bars; braces connect the pillars and radial bars with each other. The supports are of cast-iron, and the other parts of wrought-iron.

Fig. 5518.



Stack-Stand.

More care is lavished upon stack-stands in Britain than in the United States. A stack-stand in the West is a mere foundation of rails, usually a square of the length of a rail, say 11 feet, or else 11 × 22. Some carry up the sides for a round or two.

The British stack-yard, when conducted in the most approved style, has stands in rows for the reception of grain, the stacks being carefully thatched. On the foundation are erected posts, which support the floor. In the center is an open, pyramidal structure, affording an opening for access of air to the center of the stack.

Stad'da. The double-bladed saw of a comb-maker. See COMB.

Stad'dle. (*Husbandry.*) A circular platform, supported on posts, and designed for a stack-stand, to raise the grain above the reach of vermin.

For large stacks the staddle has several concentric circles, or the annular platform connects by converging-rods with a central post.

Stad'dle-stand. (*Husbandry.*) A stack-stand.

Stad'dle-roof. A protection for a stack.

Stade. 1. A landing, or wharf. A *staith*.

2. A measure of distance. A *stadium*, or furlong. See STADIUM.

Sta-dim'e-ter. An instrument invented by Messrs. Paucellier and Wagner, of the French topographical corps, for ascertaining the distance between two points. It consists of a horizontal, graduated rule, mounted on an upright staff. It is viewed through an inverting telescope provided with a micrometer. The number of divisions of the micrometer that cover a certain number of the divisions on the rule indicates the distance between it and the telescope.

Sta'di-um. 1. An instrument for approximately measuring distances by the visual angle subtended by them. It is made of sheet-metal, brass or silver, and has a tapering slit, on the edges of which are marked the distances at which a man of ordinary size would just appear to fill the aperture when the instrument is held a certain distance from the eye. This distance is regulated by a string held between the teeth.

2. An ancient measure of length, = 600 Greek feet, 625 Roman feet, or 125 Roman paces, = 606.75

feet English. This was the length of the Olympic foot-race course.

Staff. 1. The handle of a tool or implement.

2. A pillar or stake, for support; as the Jacob staff of a circumferenter. See *b*, Fig. 2710.

3. A straight-edge, for testing or truing a line or surface.

4. (*Milling.*) The *proof*-staff, *red*-staff, *tram*-staff, used in testing the face of the stone, or ascertaining whether it runs exactly horizontal.

5. (*Surveying.*) *a.* A graduated stick, used in leveling. See Fig. 2913.

b. A Jacob's staff. See Fig. 2710.

6. (*Plastering.*) A slat placed at a salient angle of an interior wall flush with the plastering on either side, to form a protection thereto. An *angle-staff.*

7. A *round*, *rung*, *rundle*, or *step* of a ladder.

8. One of the bars of a rundle; a certain open style of wagon-bed, made like a crate.

9. (*Shipbuilding.*) A measuring and spacing rule. The *cutting-down* staff is a rod, having marked upon it the hight of the *cutting-down* line above the keel at the several frames. See CUTTING-DOWN LINE.

The *half-breadth* staff is a rod, having marked upon it half the length of each beam in the ship.

The *hight*-staff is a rod having marked upon it the hight above the keel of all the frames at the beam-line of the ship.

The *room and space* staff is for regulating the distances apart of the frames.

10. (*Nautical.*) A pole for a flag. The *ensign*-staff is erected over the stern; the *jack*-staff, over the bowsprit cap.

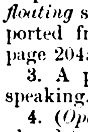
11. (*Surgical.*) A curved and grooved steel instrument introduced through the urethra into the bladder in the operation of lithotomy, and serving as a director for the gorget or knife.

12. (*Music.*) The five lines and four spaces on which notes of tunes are written.

Staff-an′gle. (*Plastering.*) A slat at a salient angle of an interior wall to protect the plastering. See STAFF-BEAD.

Staff-bead. A species of angle-staff. A beaded strip of wood placed at a vertical exterior angle in an apartment, and serving to protect the plastering, and as a guide in *floating*. It is made flush with the surface of the plaster, and is secured by nails to bond plugging or wooden bricks fixed in the walls.

Fig. 5519.



Staff-Bead.

Stage. 1. A landing at a quay or pier. It sometimes rises and subsides with the tide, or is lowered or raised to suit the varying hight of water.

2. A platform on which workmen stand in painting, pointing, calking, scraping, etc., a wall or a ship. A *hanging* stage is suspended by ropes. A *floating* stage rests on the water. A *scaffold* is supported from beneath by poles or framework. See page 2045.

3. A platform or rostrum for acting or public speaking.

4. (*Optics.*) A platform on which an object is placed to be viewed by a microscope.

Stages are of various constructions, as *lever-stage*, *magnetic stage*, *mechanical stage*, etc.

The mechanical stage has horizontal and vertical mechanical movements, sliding object-holder, and revolving fitting.

5. A vehicle traveling on a regular route for carrying passengers.

Stage-coach. A vehicle for passengers running on a regular route.

Stage-coaches appear to have been introduced into Britain by Henry Anderson, who, about 1610, brought them from Stralsund, Pomerania, and was granted a patent for the privilege of running them between Edinburgh and Leith. Some fourteen or fifteen years afterward they had become known in England. In 1659 the Coventry coach is referred to, and in 1661 the Oxford coach, which took two days to reach London (55 miles). In 1669 an Oxford coach ran from London to Oxford in thirteen hours, in summer. In 1742, however, the Oxford stage was still two days on the road. In 1662, owing perhaps to the revolution, there were but six coaches on all the roads in the country, among them one to Aylesbury, next year one to St. Albans. In 1672 they appear to have become so numerous that one John Cresset wrote against them as being mischievous to the public, destructive to trade, and prejudicial to land; they destroyed the breed of good horses, hindered the breed of good watermen, and encouraged the gentry to visit London too often.

A few years previously one of these gentry wrote: "This traval has so indisposed mee yt I am resolved never to ride up again in a coach." How the knights and ladies, of whom, according to his account, his fellow-passengers were made up, stood it, does not appear.

In 1677 there was a Chester, in 1679 a Birmingham, and in 1680 a Bedford coach. In 1682 the journey between Nottingham and London occupied four days (130 miles). The coaches had projections, called *boots*, on each side, where passengers sat with their backs to the body of the carriage. In 1678, Provost Campbell established a coach to run from Glasgow to Edinburgh, "drawn by six able horses, to leave Edinboro' ilk Monday morning and return again (God willing) ilk Saturday night." In 1706 the time between London and York, by coach, was four days, and in 1734 John Dale notified the public that a coach would set out from Edinburgh to London (400 miles) *toward the end of each week*, and perform the journey in nine days being three days less than "any coach that travels that road."

Twenty years later, however, the Edinburgh stage-coach, "a new, genteel, two-end glass machine, hung on steel springs, exceedingly light and easy," took ten days in summer and twelve in winter to perform this distance. In 1754 the prospectus of the "flying coach" set forth that, "however incredible it may appear, this coach will actually (barring accidents) arrive in London four days and a half after leaving Manchester." Three years later the Liverpool flying coach undertook to do the distance between that city and London in three days.

No great improvements in speed were made until Palmer, who, according to De Quincey, was twice as great a man as Galileo, because he not only invented mail-coaches (of more general practical utility than Jupiter's satellites), but married the daughter of a duke and succeeded in getting the post-office to use them. This revolutionized the whole business. The Manchester mail did its 187 miles in 19 hours; the Liverpool mail its 203 miles in 20 hours 50 minutes; the Devonport mail its 227 miles in 20 hours; the Holyhead mail its 261 miles in 26 hours 55 minutes; while the Edinburgh mail traveled its whole distance of 400 miles in 40 hours. Other light coaches carrying passengers only rivaled the mail-stages in speed.

To obtain these results everything was thoroughly systematized, and no expense was spared; little time was lost in changing horses, everything being ready prepared when the coach arrived at each station. The number of horses required was at the rate of each mile; thus the "Wonder" had 154 horses, 154 miles being the distance from London to Shrewsbury. The horses were fine animals, abundantly fed, and rested 23 hours out of the 24, besides remaining quiet every fourth day; their work was, however, very severe while it lasted.

The coaches were built so as to combine great strength with lightness, and were termed paper-coaches by the jehus of the slower turn-outs.

They carried no luggage on the roof, but four outside passengers, one on the box and three behind, and in addition to the coachman were provided with a guard, quite an important official, dressed in the royal livery, whose duty it was particularly to see to the safety of the mails.

Stage-for′ceps. (*Optics.*) A device for holding an object upon the stage of a compound microscope.

Stage-mi-crom′e-ter. (*Optics.*) One adapted to the stage of a microscope, to measure an object within the field of view. Invented by Joseph Jackson Lister.

It consists of a slip of glass, on which lines have been ruled by a diamond, at a certain distance apart, — $^1/_{1000}$, $^1/_{2000}$, $^1/_{5000}$, or $^1/_{10000}$ of an inch. The machine whereby this is effected may be similar to the engraver's ruling-machine, by which the fine sky-tints are ruled on steel-plates. See also NOBERT'S PLATES.

The micrometer is inserted in the eye-piece of the microscope, and so arranged that it may be moved across the field of vision by the aid of a screw.

Stage-plate. (*Optics.*) A glass plate $4 \times 1\frac{1}{2}$ inches, on the stage of a microscope, having a narrow ledge of glass cemented along one edge to hold an object when the instrument is inclined. It may form the bottom plate of a *growing-slide.*

Stage-wag'on. (*Vehicle.*) A vehicle carrying goods on a regular route.

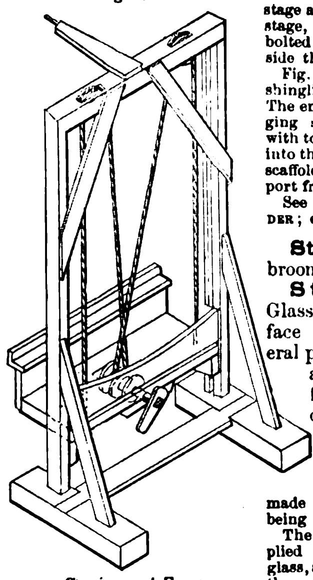
Stag'ger. (*Vehicle.*) To set spokes in a hub so that they are alternately on the respective sides of a median line, in order to give them a broader base, and a consequently greater stiffness to the wheel against lateral strain. The mortises are said to be *dodging*.

Stag'gered Wheel. (*Vehicle.*) One whose spokes are set in and out alternately where they enter the hub.

Sta'ging. A form of scaffold used by builders, painters, and others.

In Fig. 5520, the staging rises between guide-posts, the elevating power being a winch, ropes, and pulleys.

Fig. 5520.



Staging and Frame.

In Fig. 5521, the outer frame has an upper, braced stage and a lower suspended stage, and its uprights are bolted to vertical pieces inside the building.

Fig. 5522 is a staging for shingling or repairing roofs. The ends of the portable staging support are provided with toothed plates, which fit into the roof and prevent the scaffolding placed on the support from slipping.

See also SCAFFOLD; LADDER; etc.

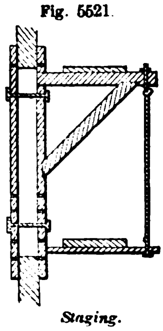
Stail. A mop or broom handle.

Stained-glass. Glass painted on the surface with various mineral pigments, which are afterward fused and fixed by the application of heat.

The glass should be colorless, uniform, and difficult of fusion; crown glass, made with but little alkali, being preferred.

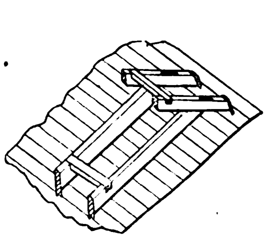
The design on paper is applied to the back of the glass, and the outlines traced through with a fine pencil in dark colors, after which the proper pigments to produce, when burnt, the various colors, are applied to the face of the glass, previously coated with gum-water. Where lights are required, the colors are partially removed by a quill pen without a split. Where two colors adjoin which are apt to run into each other during fusion, one is applied on the back of the glass.

Fig. 5521.



Staging.

Fig. 5522.



Roof-Staging.

The plates are burnt in a close muffle of fire-clay, closed by folding doors of iron having peep-holes, through which the progress of the work may be viewed, and test-strips, containing the several pigments, withdrawn. The plates are laid on a layer of dry sifted lime, sometimes in several layers, with lime interposed between each. The fire is raised very gradually, to prevent cracking the glass, and a full heat is maintained for three or four hours, after which it is gradually allowed to die out to anneal the glass. See GLASS-STAINING, page 983; GLASS-COLORING, page 977.

Stain'ing Wood.

Ebonized black, for moldings, frames, etc.: Strong vinegar, 1 gallon; extract of logwood, 2 pounds; green copperas, ½ pound; China blue, ¼ pound; nut-galls, 2 ounces. Boil in an iron pot over a slow fire; when cool, the mixture is ready for use. Add to the above ½ pint iron-rust, prepared by steeping iron filings in strong vinegar.

Stain for the sap part of black-walnut: Strong vinegar, 1 gallon; burnt umber, dry, 1 pound; rose-pink, ½ pound; Vandyke brown, burnt, ½ pound. Mix, let them stand one day, and apply with a sponge.

Walnut stain for pine and white woods: Very thin sized shellac, 1 gallon; dry burnt umber, 1 pound; dry burnt sienna, 1 pound; lamp-black, ¼ pound. Shake until well mixed. Apply one coat with a brush, sand-paper, and apply a coat of shellac varnish.

Bright rosewood stain: Alcohol, 1 gallon; cam-wood, 1½ pounds; red-saunders, ½ pound; extract of logwood, 1 pound; aquafortis, 2 ounces. When dissolved it is ready for use. Apply in three coats, sand-paper, grain with iron rust, shade with asphaltum, thinned with spirits of turpentine; when dry apply a thin coat of shellac, sand-paper when dry, and varnish.

Satin-wood stain: Alcohol, 1 quart; ground turmeric, 3 ounces; powdered gamboge, 1½ ounces. Strain through fine muslin, and apply two coats with sponge; sand-paper and varnish.

Black stain for pine or white wood: Water, 1 gallon; logwood chips, 1 pound; black copperas, ½ pound; extract of logwood, ½ pound; indigo blue, ½ pound; lamp-black, 2 ounces. Boil over a slow fire; when cool, strain and add ¼ ounce nut-galls.

Crimson stain: Alcohol, 1 quart; Brazil wood, 3 ounces; cochineal, ½ ounce; saffron, 1 ounce. Steep and strain.

Stair. (*Carpentry.*) One of a series of steps for ascending from one story to another.

The *riser* is the vertical portion of a step.

The *tread* is the flat portion on which the feet rest.

The *nosing* is the rounded front edge of a *tread* projecting beyond the face of the *riser*.

A *staircase* is the complete arrangement of supporting frame, casing, balusters, etc.

Flyers ascend in a straight line, and form a *flight*.

Winders ascend spirally, around a solid or open *newel*; or they connect *flights*.

A *well-staircase* has an open *newel*.

A *stairway* is a *staircase* bounded by walls or casing.

A comfortably proportioned staircase is a modern contrivance, unknown to Egyptian, Greek, or Roman.

The first bottom step is the *curtail* step, when its end has a round turn, on which the *newel* or baluster-post is placed. See NEWEL.

The top step is the *landing*.

A resting-place at the end of a flight, midway of the two floors, is a *half-space* or *quarter-space*, according to extent.

Stairs are known by the following names: —

Corkscrew.	Geometrical.
Dog-legged.	Open newel.
French-flight.	Solid newel.

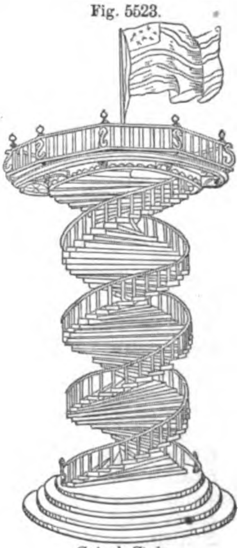
Fig. 5523 is a spiral staircase, in which the steps are perforated at the center and secured upon a central post, so that the respective ends of the steps belong to separate adjacent staircases, at opposite sides of the central post.

Fig. 5524 shows on a larger scale two stairs of a set. The iron stairs are cast hollow, and with an end portion, which forms part of the solid newel in the center. A succession of these pieces forms the stairs.

See also Close's patent, No. 111,610, February 7, 1871, in which a number of segmental plates are arranged in a space above a spiral stairway, and can be operated so as to open or close the stairway, to prevent fire from communicating from story to story of a building, and also to prevent heat from ascending from a lower to an upper story.

Instruments are made for laying out scrolls and curves for stair-work. See SPIRAL; INSTRUMENT FOR DRAWING.

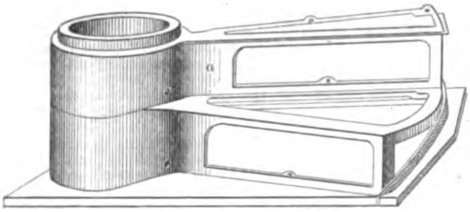
Fig. 5523.



Spiral Stair.

A stair with double risers is economical of room. Each foot

Fig. 5524.

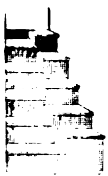


Spiral Stair.

treads its own side of the stairs, ascending a riser at each step, and only advancing at each second step.

Artificial flights of steps are among the most ancient monuments. The pyramids themselves, now that the envelope which filled the steps has worn off, form the most magnificent artificial flights of steps in the world. The stairs at the Nilometer of Elephanta, and those of Benares on the Ganges, are other notable examples; the former are mentioned by Strabo.

Fig. 5525.



Double-Riser Stairs.

Stairs are mentioned several times in the Bible, as are also steps; the *steps* of the altar, of the king's throne, etc.

Great as is the convenience of a stairs or interior flight of steps, it was a comparatively uncommon thing until a recent date, except in the form of a ladder.

The ladder is once referred to in the Bible, in the vision of Jacob, but may be presumed to have been quite a well-known contrivance. We know by the Egyptian paintings that scaling-ladders were common in the wars of the great Pharaohs. Also, that they were a regular part of the military equipment of the Romans.

Perhaps the first notice of regular stairs occurs in the description of Solomon's temple at Jerusalem. This structure was 30 cubits high, say 50 feet, and it may be inferred that the stairs had one exterior and one interior flight.

"The door for the middle chamber *was* in the right side of the house; and they went up with winding stairs into the middle *chamber*, and out of the middle into the third"

The italics are the addenda of the translators. The middle story of the three, which would be called the *first* story in England, and which we call the *second* story, appears to have had a door on the outside, "the right side" to a person facing the principal entrance; but the winding stairs led "out of the middle (2d story) into the third" (story).

If we assume the "winding stairs" to have been of the simplest form, they were made to wind around a central post, the outer edges of the *treads* being supported by a circular wall of posts. The hight of the stories may have been 20, 20, and 10, unless the dimensions given (50 feet perpendicular) include the roof; but this was probably flat, as usual in Palestine. The assumption that the building was after the Greek model is absurd, as the earliest Greek order, the *Doric*, did not commence till 350 years afterward. Persons with Masonic enthusiasm, without a Mason's knowledge, in stating that the order was Corinthian, have anticipated Callimachus 650 years. The Corinthian order was unknown until the period of the Macedonian conquest of the southern states of Greece.

The staircase of the *Scala Santa* at Rome consists of three flights. The middle one has 28 steps, which are stated to have been sent from Jerusalem to Rome by Helena, the devout and highly successful explorer. These steps are stated to have been formerly in the house of Pilate, and to have been ascended by our Saviour in his progress to the judgment-hall of the capricious Roman. The pilgrims ascend them on their knees.

"A winding stair-ladder joined on to the open chamber, leading to the secret walk, and a banqueting-room capable of containing nine couches, constructed and furnished in the Egyptian style." — Description of the ship of Ptolemy Philopator, by Callixenus, and quoted by *Athenæus* in the "Deipnosophists."

The staircase became a prominent feature in interior architecture in the reign of Elizabeth of England.

Stair'case. A set of steps in a house to ascend from one story to another.

A *geometrical staircase* is one in which the stairs have an open newel, each step being supported by the wall at one end only. See STAIR.

Stair-head. The top of a flight of stairs.

Stair-rod. A rod confining a stair-carpet at the receding angle where the riser and tread meet.

Stair'way. A flight of steps; a *staircase.*

Staith. An elevated railroad-staging, from which coal-cars discharge their loads into cars or vessels beneath. See Fig. 1357.

Stake. 1. (*Currying.*) A post on which a skin is stretched while currying or graining.

2. (*Husbandry.*) *a.* An upright bar to support a vine or tree.

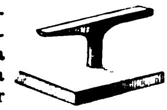
b. One of the uprights of a wattled fence or screen.

c. One of the pieces of timber leaning against the corner of a worm-fence, and serving with its fellow on the other side to hold the *rider* rail.

3. (*Railway.*) An upright bar held by staples on the edge of the bed of a platform car, to hold on the load of lumber, or the side and end boards which hold the coal, gravel, etc.

4. (*Vehicle.*) The upright or standard on the bolster of a wagon, to keep the bed, a log, or a load of lumber from shifting off sideways. See Fig. 705.

Fig. 5526.



Stake.

5. (*Metal-working.*) A small anvil used by blacksmiths and sheet-metal workers. It usually has a tang, by which it is *stuck* in a square socket of a bench, block, or anvil. It has various forms in the different trades.

a (Fig. 5527), a *hatchet* stake, from 2 to 10 inches wide, and used for bending the thin metals, as the edge of an anvil is used for bending thicker metal, by the blacksmith.

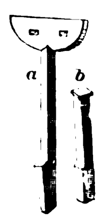
b, a stake with a rounded edge.

c, a stake with a rounded top.

d, a stake with a ridged top.

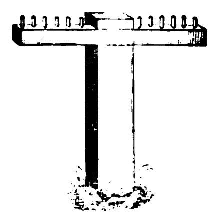
e, a stake with a conoidal top.

Fig. 5527.



Stakes.

Fig. 5528.

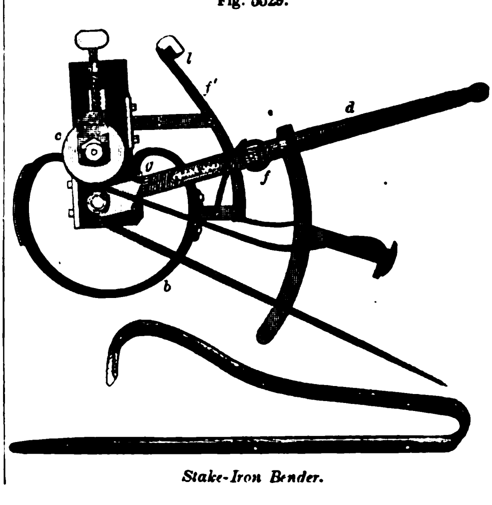


Stake-Head.

Stakes are also known by their purpose, as *chasing*, *dressing*, *planishing* stakes.

6. (*Shipwrighting.*) A regular course of planking on a ship. A *strake.*

Fig. 5529.



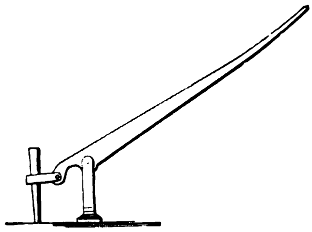
Stake-Iron Bender.

Stake-head. (*Rope-making.*) A horizontal bar supported by a post and stationed at intervals in the length of a ropewalk, to support the yarns while spinning. The upper edge of the bar has pegs to separate the yarns which are spun by the respective whirls in the spinner. Fig. 5528.

Stake-ir'on Bend'er. A machine for bending stake-irons for the bolsters of wagons.

The machine is composed of an adjustable roll *c*, a supporting bow or ring *b*, and a lever *d*. The stake-iron is bent by three operations. In the first the straight-rod is clamped at *l*, and bent by the roller *f* on the lever *d*, over the curved surface *f'*. In the second the rod is gaged in slot *g*, in lever *d*, and bent by the lever between it and the main roll *c*. In the third operation the middle of the rod is gaged as in the second, and bent by the same agencies into the finished form shown in the figure. The lower portion of the figure shows a finished stake-iron.

Fig. 5530.



Stake-Puller.

Stake-pull'er. A lever rigged to lift stakes, poles, or posts from the ground. See also POST-PULLER.

Stak-tom'e-ter. A drop measurer. A *pipette* or *burette*.

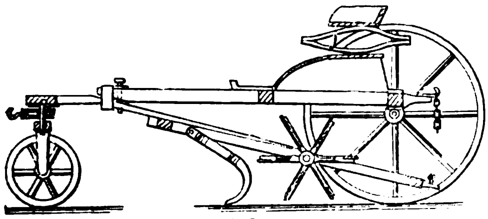
Stal'der. A trestle for casks.

Stalk. 1. (*Founding.*) An iron rod armed with spikes, forming the nucleus of a core.

2. A tall chimney, usually of a furnace. A *stack*.

Stalk-cut'ter. (*Husbandry.*) An implement for cutting old corn-stalks in the field in order that

Fig. 5531.



Stalk-Cutter.

they may be readily plowed in. The frame with the rotating knives is dragged beneath the main frame, which rests on wheels. Shares precede the cutter-wheel and draw the stalks into lines, so that they are cut across by the knives.

The "Eureka" stalk-cutter is capable of being turned into a roller by placing shells over the cutting-cylinders.

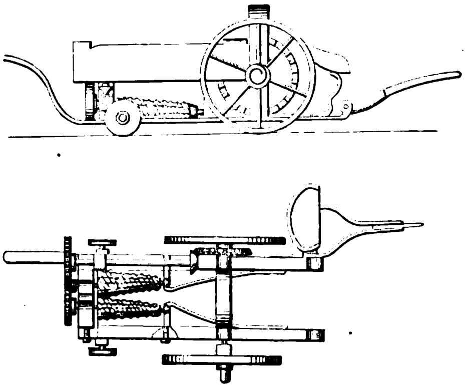
Stalk-pull'er. (*Husbandry.*) An implement for pulling cotton and hemp stalks from the ground, in order that they may be raked into windrow and burnt.

In the example, the arch straddles the stalks, the plates form a throat to direct them to the rollers, which tear them up and cast them on one side of the machine.

Stall. 1. (*Mining.*) An opening made between pillars in the direction that the work is progressing, or transversely. A *room*. See POST AND STALL.

2. A compartment in a cathedral, a market, a stable.

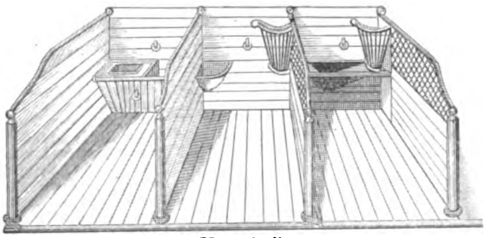
Fig. 5532.



Stalk-Puller.

Stalls for horses and oxen, for fatting cattle and calves, were common among the Hebrews. The references to stalled oxen and calves of the stall are sufficient to show that the people knew well what it meant. The daily provision of meat for Solomon's household was 10 fat oxen and 20 oxen from the pasture; the distinction is well understood. David had 40,000 stalls for horses.

Fig. 5533.



Horse-Stalls.

Fig. 5533 is a range of open stalls. The hay-racks are of cast-iron, with wrought-iron bars. The mangers for grain, of which three different patterns are shown, have iron flanges, to prevent the horse from cribbing. See also STABLE.

"And Duncan's horses,
Beauteous and swift, the minions of their race,
Turned wild in nature, broke their stalls, flung out."

Stall-boards. A series of floors on to which soil or ore is pitched successively in excavating.

Used in digging sewers, etc., in which the soil is pitched from floor to floor until it reaches the surface.

Sta'min. (*Fabric.*) A slight woolen cloth; *linsey-woolsey*.

Stam'mel. (*Fabric.*) A fine woolen cloth.

Stamp. 1. An engraved block by which a mark may be delivered by pressure.

The stamps and seals of ancient Egypt were cameo and intaglio. They generally had a royal name, and were of the shape of a cartouche. Dr. Abbott's collection in New York has old Egyptian stamps in porcelain, wood, gold, and stone.

The Romans used stamps, and the Babylonian signet-rings and brick show that the impressional art is very ancient.

A Roman signet-ring, now in a British collection, is 2 inches long by 1 inch broad, is made of bronze, and covered with the *ærugo*, or peculiar oxidation, which gives the character to the antique medals. It has the inscription in raised letters: —

CAIUS JULIVS
CÆCILIVS HERMIAS

The letters rise flush to the level of the border, and at the back is a ring for the finger. It was evidently inked on the face, and then impressed on the letter or document.

Hand-stamps are made of several kinds for various purposes: —

Canceling.	Address.	Embroidering.
Dating.	Official.	Eyeleting.
Post-office.	Embossing.	Monograms.

See Figs. 1055, 1056, 2389.

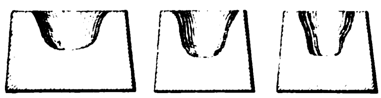
2. (*Bookbinding.*) A brass tool for embossing or gilding. Some are hand-stamps, others are arranged on a foundation plate and used in a press.

3. An instrument for cutting out objects, such as wads, planchets, blanks for making various objects.

4. (*Metal-working.*) A tool or machine by which sheet-metal is molded into form by a blow or simple pressure. See STAMPING-MACHINE; STAMPING-PRESS.

Deep vessels are stamped by a series of successive molds, from sheets of metal, whose width is equal to that of the width and depth of the finished article. The first mold is comparatively

Fig. 5534.

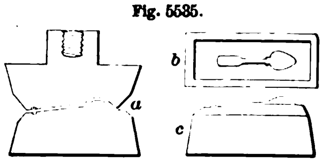


Sections Showing Progression.

shallow, the succeeding ones are deeper and narrower. The metal is forced into the molds by corresponding dies, and burnished after each stamping upon a revolving tool with a frusto-conical head. Only three molds are shown, but a larger number is frequently employed, the object being to gradually bring the metal to the required shape without rupturing or wrinkling it.

In making spoons, forks, etc., with the fly-press, it was formerly customary to stamp the handles and the bowls at two different operations. The dies (Fig. 5535), having curved surfaces and beveled edges, produce the spoon at a single impression, leaving only a slight fin at its edges. *a* represents a section of the counterpart dies; *b* is the face of the upper die, and *c* an elevation of the lower one.

Fig. 5535.

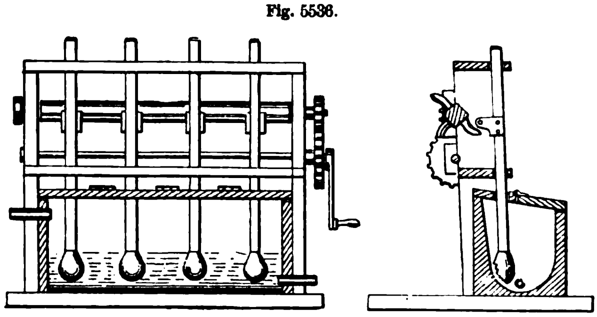


Stamp.

5. (*Mining.*) *a.* One of the pestles or vertically moving bars in an ORE-STAMPING MILL (which see).

b. A mark cut in the roof or side of the mine, as a point of reference to show the amount of work done.

Fig. 5536.



Stamping-Machine for Treating Hides, Skins, and Leather.

6. (*Leather.*) A machine for softening hides, etc., by pounding them in a vat.

7. A label to attach to a letter to prepay postage, signify the payment of a duty, or for other purposes.

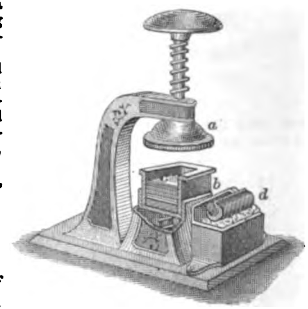
Postage-stamps, after being printed under the hydraulic press, in sheets each containing 200, are gummed by placing each sheet separately, back upward, on a flat board, its edges being protected by a metallic frame, and a paste composed of dextrine is applied with a whitewash-brush. They are again pressed, and each sheet cut in half.

The perforation is effected by passing the sheets between two cylinders, one above the other, and provided with a series of raised bands, which are adjusted to a distance apart equal to that required between the rows of perforations. Each ring on the upper cylinder has a series of cylindrical projections, which fit corresponding depressions in the bands of the lower cylinder; by these the perforations are punched out, and by a simple contrivance the sheet is detached from the cylinders to which it has been conducted by an endless band; the rows running longitudinally of the paper are first made and then, by a similar machine, the transverse rows. The sheets are then pressed to remove the roughness caused by the punching operation.

Stamp-af-fix'er. A device for attaching stamps to letters, etc.

It consists of a stand having an arm carrying the spring-presser head *a*; a box *b* having an interior spiral spring pressing against the movable bottom of the stamp receptacle *c*, and a trough *d*, containing sponge or other absorbent.

Fig. 5537.



Stamp-Affixer.

The stamps, gummed side upward, are placed in the receptacle, successively moistened with a roller, and attached to the object, placed between them and the presser-head, by forcing the latter down.

Stamp-bat'-ter-y. (*Metallurgy.*) A series of stamps in a machine for comminuting ores. See Fig. 596. See also STAMP-MILL.

Stamp-book. One whose pages are arranged with little squares, with the names of countries and the various values of the stamps of each country appended thereto.

Collectors of postage-stamps might read "Cornelius O'Dowd upon Men and Women and other Things in General," "Blackwood's Magazine," Vol. XCVII. pp. 67–69.

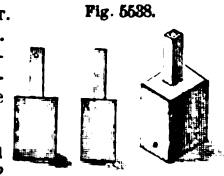
Stamp-can'cel-er. A hand-stamp for defacing postage or internal-revenue stamps. It is said that the double hand-stamps for canceling stamps and post-marking letters by the same stroke of one hand saved the government in 1866 the salaries of two hundred and fifty-four clerks at from $700 to $900 each, or more than two hundred thousand dollars per annum.

Stamp'er. (*Porcelain.*) A mill with heavy, iron-shod stamps, which comminute calcined flints for porcelain. From the *stamper* the dust is removed to the GRINDING-VAT (which see). See STAMP-MILL.

Stamp'er-press. A press for stamping sheet-metal. See STAMPING-PRESS.

Stamp-head. The iron block at the end of a vertical stamping-bar.

Fig. 5538.

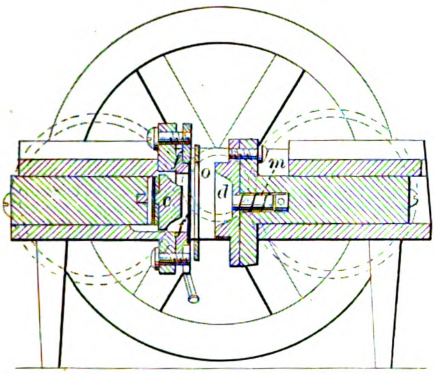


Stamp-Heads.

Stamp'ing-ma-chine'. (*Metal-working.*) A machine for swaging sheet-metal between dies to the requisite form.

In Fig. 5539, a sheet of metal is inserted between the ring *o* and the fixed annular die *f f'*,

Fig. 5539.

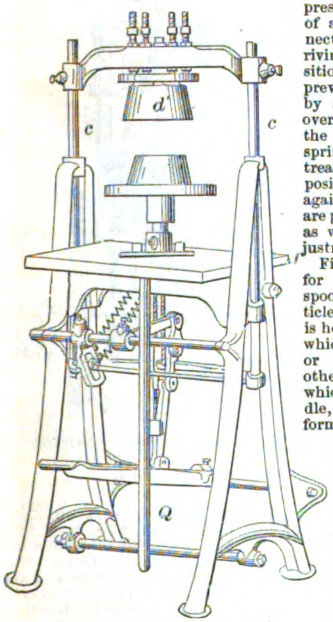


Machine for Forming Sheet-Metal Basins, etc.

the intaglio die d then advances, and its edge acting against $f f'$ cuts out a blank, which is then struck into the die d by a forward movement of the cameo die c; as d recedes the article is forced out by a follower m.

In Fig. 5540, the intaglio die d' is attached to a yoke connected with the two rods c c, through which it is depressed by the operation of a treadle and connecting devices; on arriving at its lowest position it is temporarily prevented from rising by a rod Q engaging over the treadle; when the rod is pushed aside springs restore the treadle to its normal position, and the die again rises. The dies are provided with lateral as well as vertical adjustment.

Fig. 5540.



Stamping-Machine.

Fig. 5541 is designed for stamping forks, spoons, and similar articles. One die, as B, is hollowed at the part which forms the bowl or prongs, and the other, A, at the part which forms the handle, the object being to form as small a burr as possible, and that at the angles instead of centrally.

The lower die is vertically adjusted upon wedges operated by set-screws. The die-holder is used in connection with an ordinary fly or other press. See also STAMPING-PRESS.

2. (*Shoemaking.*) For stamping finished goods. The shoe is readily jacked upon the post, and, being guided by the hand, is forced up against the stamp by the depression of the treadle.

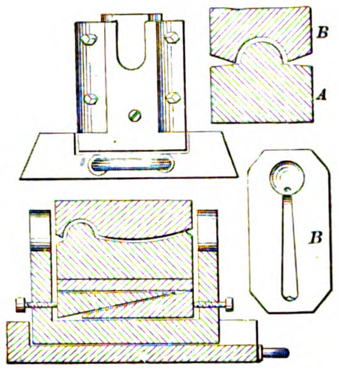
Stamp′ing-mill. A machine for breaking ore. See STAMP-MILL.

Stamp′ing-press. Another name for the STAMPING-MACHINE (which see also).

Machinery for making seamless articles from sheet-metal by stamping was devised in France as early as 1840. The first attempts, which were partially successful, were made with the drop-press. This, however, it was thought, did not allow sufficient time for the metal to assume the required form without tearing, and the screw-press was substituted for it, giving better results. The cam-press has also been generally used in France, which has long maintained a pre-eminence in wares of this kind.

Vessels are manufactured from sheet-iron, the depth being

Fig. 5541.



Machine for Stamping Forks, Spoons, etc.

given at several successive pressings, depending on the depth of the article. The metal is annealed after each pressing, and is finally turned.

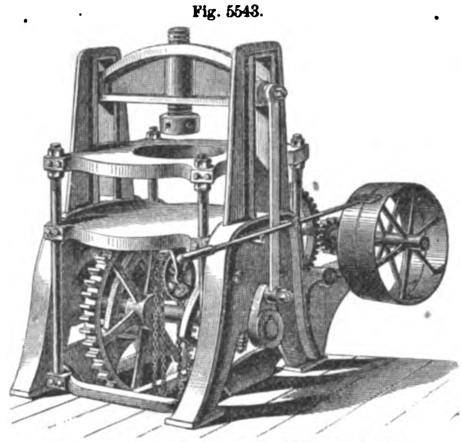
Such articles are now manufactured in this country from tin-plate, annealing being dispensed with, and the goods are prepared ready for market without re-dipping.

Fig. 5542.

Stamping-Machine (Shoe Machinery Manufacturing Co.).

Fig. 5543 illustrates a machine for forming pans or kettles from blanks. There are several molds for each pan, the operation being a progressive one; deeper and deeper molds being used successively so as to stretch the blank more and more, to avoid the tearing which would result from the attempt to stretch the thin sheet-metal at a single impulse, even though very moderately and gradually performed. The hollow mold is placed on the flat table, shown in the view, and upon it is laid a blank of sheet-metal, or a pile of blanks when several are to be stamped at once. The under side of the blank rests upon the flat upper surface of the hollow die, and the holder (shown with a round opening through it) is brought down upon the blank so firmly that, when the upper die descends, the metal has to expand into the hollow die, stretching out into a smooth seamless pan or kettle, without buckling or corrugating the margin. The upper

Fig. 5543.



Howard's Stamping-Press for Sheet-Metal Ware.

or salient die is fastened to the headed screw (which is shown above), and is operated when the cross-head descends by means of the pitmen and cranks on the sides of the machine, forcing the blanks into the hollow die as far as the ductility of the metal will permit. The holder is clamped down upon the blanks by means of cams beneath the table.

Metallic cartridge-cases are made in the same way.

Fig. 5544 is a machine for shaping sheet-metal. The plate to be shaped or stamped is placed upon the die, and the attendant depresses the treadle connected with the valve-rod of the chest *c*, whereupon, the water being admitted above the pistons of the four cylinders, the clamp *b* is forced downward and fastens the circumferential portion of the plate between its own lower surface and the flat upper surface around the die. The other treadle is then depressed, and causes the central piston to descend and force the follower or stamp downward, so that the

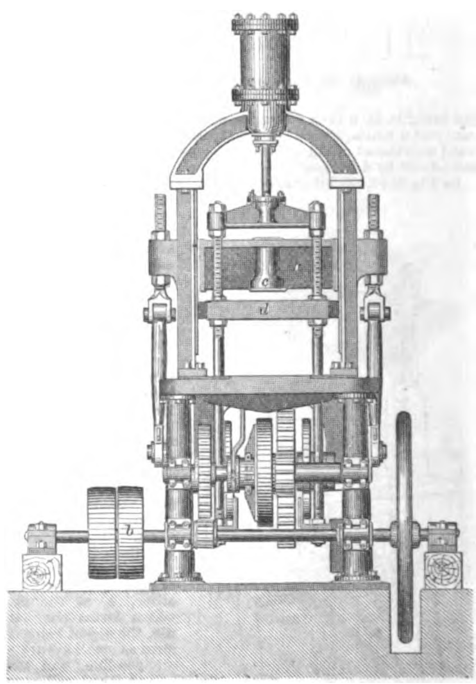
Fig. 5544.

Grimshaw's Machine for Shaping Sheet-Metal.

sheet-metal is pressed into the die and made to receive a corresponding form. As the sheet-metal is thus forced into the die by the pressure of the follower or stamp, its circumferential portions are drawn out from under the clamp, and the strain or tension thus exerted upon the metal effectually insures smoothness in the completed article, and also enables a deeper dish or similar piece of ware to be produced at a single operation. *a* is a casting with four cylinders, and *e* the top plate on which the receiving-chests are placed.

The press (Fig. 5545) for stamping hollow articles for sheet metal has a cross-head *a* reciprocated by connecting-rods from crank-arms on a horizontal shaft rotated by gearing driven from the fast-pulley *b*. The cross-head receives a convex die *c*, which works into a counterpart concave die held by the table *d*, which is suspended by a yoke and rod from a piston in the cylinder above. The latter has a cushion of air in its lower part, so as to give a certain degree of elasticity to the blow, the table and lower die receding slightly before the pressure of the upper die.

Fig. 5545.



Stamping-Press for Hollow Ware.

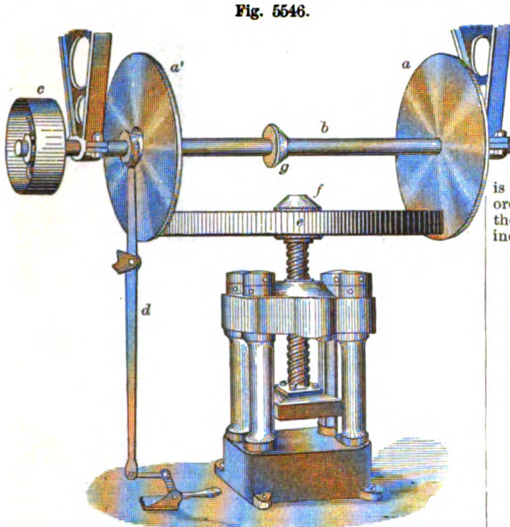
Debeauvais' press (Fig. 5546) is operated by two friction-wheels *a a'* attached to opposite ends of a shaft *b*, rotated by a belt turning the pulley *c*. When it is desired to depress the platen or stamp, the shaft *b* is, by means of a treadle operating a connecting-rod *d*, thrown to the left, bringing the face of the wheel *a* in contact with the periphery of the horizontal wheel *e* keyed on the head of the screw. On releasing the treadle a spring, which throws the shaft *b* to the right, is permitted to act, bringing the wheel *a'* in contact with *e* and causing a reverse movement of it and the screw, lifting the platen until the cone *f* at top of the screw strikes a cone *g* on the shaft *b*, throwing the two wheels out of contact. The rapidity of movement of the platen progressively increases, as the wheel *e* recedes from the centers of the wheels *a a'* either in the ascending or descending movement of the screw.

Fig. 5547 is for striking ornaments on metal or leather, or for cutting disks or planchets from sheet-metal. The punch or upper die is brought down by pressure of the foot on the treadle, the plunger being actuated by a lever which is vibrated by toggle motion set in operation by the treadle. The lower and upper dies bear the relation required by the work, whether for mere impression of a raised ornament or the severance of pieces of metal.

Fig. 5548 is a stamping-press for cutting wads, washers, or planchets from sheet-metal strips.

A swivel-step is seated in the annular base, and a swivel die-chuck connected with the lower end of the slide, or to the stem thereof. A spring-dog is applied to the chuck by means of a screw to engage with the stem of the slide, the hook end entering a socket made in each side of the stem to prevent the slide

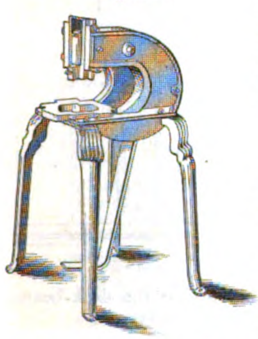
Fig. 5546.



Stamping-Press.

from turning when set for operation. A similar dog holds the swivel-step. See also COINING-PRESS.

Fig. 5547.



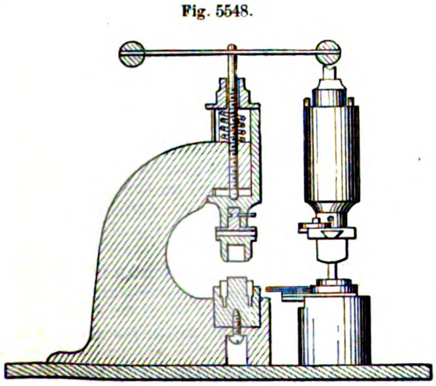
Stamping-Press for Ornaments and Jewelry.

Fig. 5549 is a fly-press for stamping monograms on letter-paper and envelopes; also, by change of dies, for embossing paper, leather, or other materials. The plunger is depressed by the revolution of the fly and returned by the spring.

Stamp-mill. 1. (*Metallurgy.*) One in which the rock is crushed by descending pestles which are lifted by water or steam-power.

The ordinary form consists of a row of vertical stamps lifted by cams upon a shaft, which rotates in bearings in the standards of the frame. The shaft is driven by steam or water power, and the cams are arranged upon it in a spiral series, so as to lift the stamps consecutively instead of simultaneously. This makes the draft upon the power of the engine more uniform, as one or more of the stamps are constantly being lifted while others are descending.

Fig. 5548.

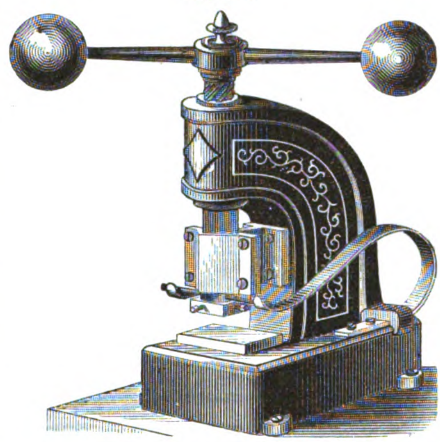


" *Fly* " *Stamping-Press.*

In the accompanying cut the upper platform is that from which the broken rock is fed to the stamps, which descend into a box whose perforated sides retain it until it is of sufficient fineness to pass through the meshes. It is then discharged by a spout to the amalgamator or other machine, by which the valuable portions are separated from the earthy.

Another form of stamp-mill is that in which the stamp is directly connected to the piston-rod of a steam-engine, in the manner of the steam-hammer, both the blow and the recoil being by the force of the steam in the cylinder above. Such is that in the illustration, Fig. 5551, next page. The broken ore is fed into the bell mouth of the chute and conducted to the stamp-box; the ascending and descending rods work the induction and eduction valves of the engine.

Fig. 5549.

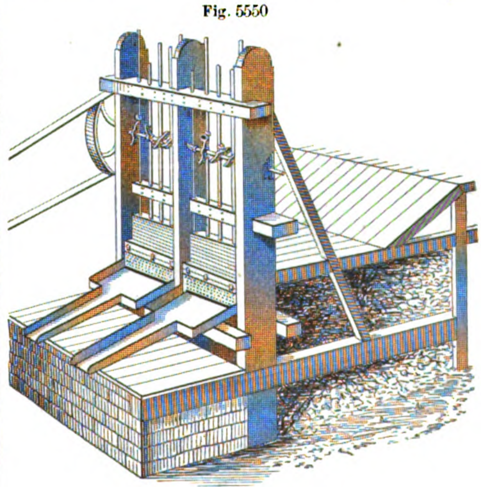


Monogram-Press.

Cosgriff's stamp-mill (Fig. 5551) has four stamps *a a*, surrounded by a screen *b* (the front is not shown in the illustration), and attached to the rods of pistons working in cylinders, which, with the steam-jacket *c* and sole-plate *d*, are cast in one piece; the whole is adjustable to different hights upon the pillars *e e* by means of nuts, so that it may be lowered as the stamps wear away. Steam is admitted alternately above and below the pistons by slide-valves working horizontally in the chests *f*, and operated partly by the steam and partly by the conical upper ends of the piston-rods rising and falling in the caps *g g*, through levers *h h* and connecting-rods. Each piston and its stamp may be worked independently.

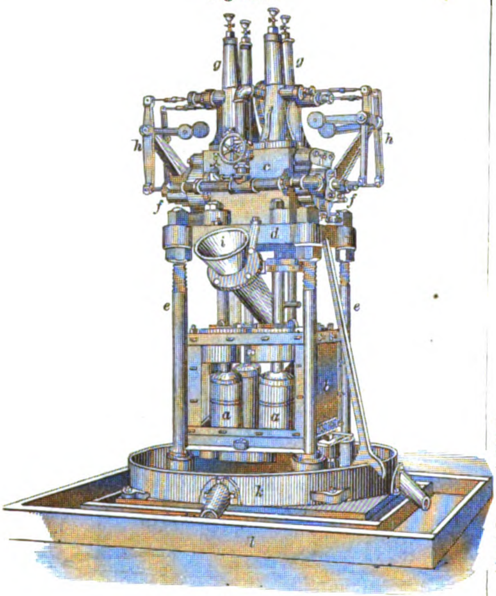
The stamping is done wet; the ore is fed into the hopper *i*, and, falling centrally between the stamps, is equally distributed to each. The crushed material passes through the screen into

Fig. 5550



Stamp-Mill.

Fig. 5551.



Stamp-Mill.

the annular trough *k*, into which a constant stream of water flows; the finer particles are carried off by spouts into the exterior trough *l*.

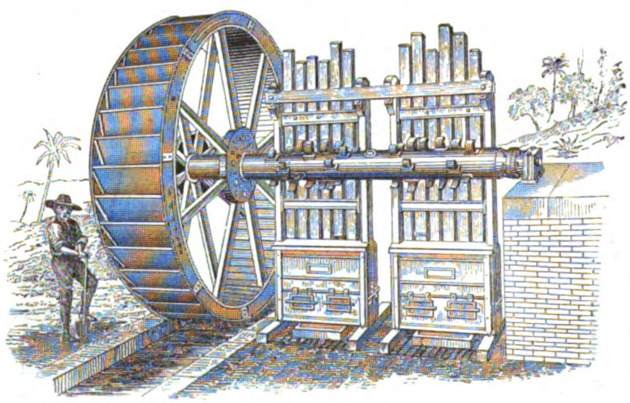
Fig. 5552 shows a mill of two batteries of six stamps each, worked by an undershot water-wheel.

2. (*Oil.*)

The stamping-mill for the trituration of oleaginous seeds, nuts, and fruit does not differ substantially from those used for the comminution of ores. The mortars are arranged in a row beneath the stamps, the latter sliding in guide-bars as they are alternately lifted by the wipers on the horizontal shaft, which is driven by gearing. Each stamp makes two blows at each revolution of the shaft.

At the ends of the machine are two wedge-presses, wherein the oleaginous magma is pressed after the pounding of the stamps. See OIL-MILL.

Fig. 5552.

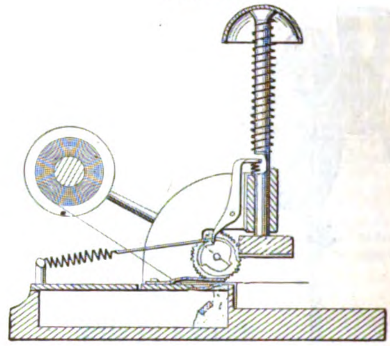


Stamp-Mill.

Stamp-moist'en-er. A wet pad for moistening the gummed side of postage and internal-revenue stamps.

Stamp-press. One for attaching stamps to letters, envelopes, or other articles. A postage-stamp affixer; or one for attaching internal-revenue stamps to dutiable articles.

Fig. 5553.

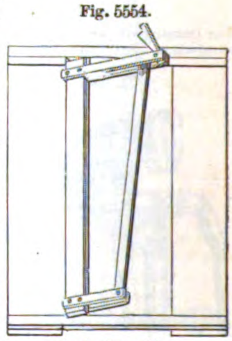


Instrument for Affixing Stamps.

The descent of the affixer causes the spring connecting with the feed-wheel to be tightened, and by releasing the spring-pawl holding the feed-wheel, the latter is rotated by means of the resilient power of the spring, and feeds a stamp forward ready to be cut off and affixed on the descent of the latter.

Stanch. A flood-gate for accumulating a head of water in a river to float boats over shallows, when it is allowed to escape.

Fig. 5554.



Cattle-Stanchion.

Stan'chion. 1. (*Architecture.*) A post, pillar, or support.

2. (*Machinery.*) A principal post of a frame; especially one giving lateral support.

3. (*Nautical.*) *a.* A post, to which man-ropes are attached at a gangway or stairs.

b. Posts which support the quarter-railing, netting, awning, etc.

4. (*Shipwrighting.*) *Stancheon; stanchel.* A post for supporting the deck-beams of wooden and iron vessels.

In iron ships they are generally applied to the alternate deck-beams, and in large ships are made about three to four inches diameter. They consist of simple round bars, to which is welded at each end a small cross, to form the head and foot, having two holes in each, by which they are bolted to the beams or keelsons above and below.

5. The vertical bars of a stall for cattle.

In the example, the stanchion-post is pivoted so as to swing horizontally; the movable stanchion-bar is pivoted to the lower arm and locked in the upper one.

Stan'chion-gun. 1. A small cannon mounted on a pivot.

2. A boat-gun for wild-duck shooting, mounted on the gunwale.

Stand. 1. (*Microscope.*) The table on which the object is placed to be viewed.

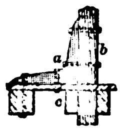
2. A piece of furniture on which an object is to be placed; as a *wash*-stand, a *flower*-stand, a *sewing-machine* stand, etc.

Stand'age. (*Mining.*) Space for water to accumulate in.

Stand'ard. 1. (*Shipbuilding.*) A knee-timber *a* above deck, having one erect and one prone arm,

bolted to the bitt *b*, or other object, and to the deck *c* and its beams.

Fig. 5555.



Deck-Standard.

2. A flag. The standard of the United Kingdom of Great Britain and Ireland quarters the ensigns of England, Scotland, and Ireland. It lost the horse of Hanover when William IV. died; the horse has of late been quartered at the "Prussian Arms."

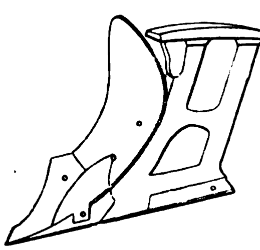
3. (*Carpentry.*) A post or vertical piece in a truss. A strut.

4. (*Machinery.*) A vertical principal post of a machine-frame.

5. (*Vehicle.*) An upright rising from the end of the bolster to hold the wagon-body laterally.

6. (*Husbandry.*) The *sheth* of a plow, projecting downward from the beam and affording a place of attachment for the mold-board and land-side.

Fig. 5556.



Plow-Standard and Attached Portions.

7. A measuring device for men or horses; the first expressed in feet and inches, the latter in hands and inches.

8. The determinate legal fineness and weight of coin, or the fineness of metal in other forms, so far as controlled by law. See also under COIN, page 591.

The standard of gold and silver at the United States Mint is 900 parts pure metal, 100 alloy.

Pure gold, 23.22 grains = $1.00. Hence the value of an ounce is $20 67.183+.

Pure silver, 357.03 grains = $1.00. Hence the value of an ounce is $1 36.166+.

Standard gold	= $ 18 60.465+	per ounce.
Standard silver	= $ 1 22.5	per ounce.
Gold double eagle	= 516	troy grains.
Gold eagle	= 258	troy grains.
Gold dollar	= 25.8	troy grains.
Silver dollar	= 412.5	troy grains.
Silver half-dollar	= 192	troy grains.
Copper cent	= 168	troy grains.
Nickel cent	= 72	troy grains.
Bronze cent	= 48	troy grains.

Silver coin less than one dollar is issued at the rate of 384 grains to the dollar.

The nickel cent contains 88 parts of copper and 12 of nickel.

The new bronze cent contains 95 parts of copper and 5 of tin and zinc.

The British standards are: Gold, $^{22}/_{24}$ of a pound, equal to 11 parts pure gold and 1 of alloy; silver, $^{222}/_{240}$ of a pound, equal to 37 parts pure silver and 3 of alloy.

A troy ounce of standard gold is coined into £3 17*s.* 10*d.* 2*f.*, and an ounce of standard silver into 5*s.* 6*d.*

Copper is coined in the proportion of 2 shillings to the pound avoirdupois.

The relative value of gold and silver has been variable.

Herodotus mentions it as	13 to 1.
Plato mentions it as	12 to 1.
Menander mentions it as	10 to 1.
Livy, B. C. 189,	10 to 1.
Julius Cæsar exchanged at	9 to 1.
Early Emperors (average),	12 to 1.
From Constantine to Justinian,	14 to 1.
Modern times, from	14 to 1 to 17 to 1.

9. A unit of value. See UNIT.

Stand'ard-gage. A gage for verifying the dimensions, or any particular dimension, of articles, or their component parts, which are made in large numbers, and required to be of uniform size. The practice of making each corresponding part exactly similar was first adopted with government small-arms, and has since been generally applied to fire-arms, sewing-machines, machine-made watches, and many other articles. By this means every part fits accurately in place when assembled with its fellows to form the complete article, without the necessity of trimming or filing. See list under GAGE. See also ASSEMBLING, page 171.

Stand'ard-knee. (*Shipbuilding.*) *a.* A bent timber, having one branch fastened against the upright side of a beam, and the other against the ship's side. One fayed vertically to the vessel's side, beneath or above a beam, is a *hanging* knee. See STANDARD.

Stand'ard-piles. (*Hydraulic Engineering.*) In a coffer-dam. Piles placed at regular intervals apart and connected by runners.

Stand'ing. A term applied to a relatively stationary portion of an object which has several parts, one or more of them moving. As, —

The *standing leaf* of a hinge; that attached to the post.

The *standing* part of a rope; the main portion around which the end is hitched.

The *standing* pulley of a compound system; that attached to a permanent object: the *runner* moves, shifts its position as the object moves, etc.

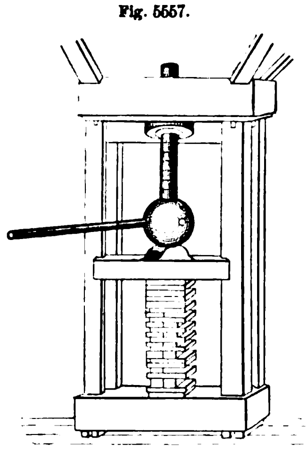
Stand'ing-block. (*Nautical.*) That block of a tackle or purchase which is attached to a stationary object, in contradistinction to the block which moves as the fall is hauled in or paid out. The latter block is called the *running*-block.

Stand'ing-bud'dle. (*Mining.*) A trough filled with water, in which pieces of lead ore are placed and stirred with a shovel.

Stand'ing-part. (*Nautical.*) *Of a hook.* The part attached to a block or chain, by which power is brought to bear upon it; the part opposite to the point.

Of a rope or tackle. The part made fast to the object; in contradistinction to the *fall* or part pulled upon.

Fig. 5557.



Standing-Press.

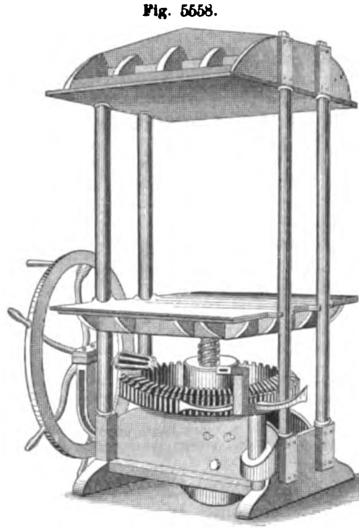
Stand'ing-press. A heavy press for book-binders or other trades. It is named from its being a heavy fixture, in contradistinction to copper-plate, hand printing-presses, and the large variety of portable presses.

The books are put in thin cases and placed between wooden boards, with their backs outward and projecting. The upper bed of the press is screwed down by means of a nut and lever, and allowed to remain for several hours, when they are ready to receive the covering. This may be either of cloth or leather, and the process for both is nearly the same.

Fig. 5558 is a press for smoothing the impression left by the type on printed sheets. The platen is lifted by a screw with an exterior thread, working within a hollow screw in the axis of a bevel gear-wheel turned by a pinion on the shaft of a large hand-wheel, to which the power is applied. A pawl, entering between two of the adjacent teeth on the periphery of the gear-wheel, prevents the latter from turning backward under great pressure.

Stand'ing-rig'ging. (*Nautical.*) The fixed ropes and chains whereby the masts and bowsprit are stayed securely. The term is used in contradistinction to *running*-rigging, which is rove through blocks and pulled upon. It includes, —

Fig. 5558.



Hoe Standing-Press.

Flemish-horses.	Parrals
Foot-ropes.	Pendants
Gammoning.	Ratlines.
Guys.	Shrouds.
Heel and crupper chains.	Slings.
Horses or ridge-ropes.	Stays.
Man-ropes.	Stirrups.
Martingales.	Trusses.

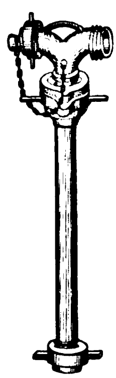
See RIGGING.

Stand'ing-vise. See BENCH-VISE.

Stand'ish. A tray for pen and ink.

Stand-pipe. 1. (*Steam-engine.*) A boiler supply-pipe of sufficient elevation to enable the water to flow into the boiler, notwithstanding the pressure of the steam.

Fig. 5559.



Stand-Pipe.

2. Stand-pipes are also used on the eduction-pipes of steam-pumps to absorb the concussions arising from pulsations and irregularities, caused by the unavoidable employment of bends and change in the direction of pipes. Stand-pipes for this purpose are erected on the eduction-pipe, as near the pump as possible.

3. (*Hydraulic Engineering.*) A curved vertical pipe, arranged as a part of the main in water-works to give the necessary head to supply elevated points in the district, or to equalize the force against which the engine has to act.

To avoid the expense of tall structures and the exposure to freezing in winter, the use of compressed air-vessels has been recommended.

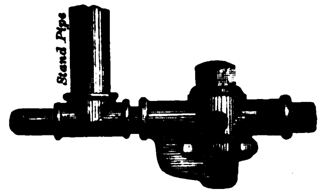
An open-ended safety-pipe may be placed above the bend of the siphon, and rising 20 or 30 feet to allow the water to rise when the pressure is excessive. When the water passes through the discharge leg at a slower rate than it is injected, it forms a column in the pipe on the apex of the siphon, and eventually runs over the top, if the disparity between the supply and demand be maintained.

The stand-pipe of the West Philadelphia Water Works, erected by Henry Howson in 1854, is a tube of boiler-iron 5 feet in diameter and 130 feet high, forming an ornamental column, with a base of cut stone and a spiral staircase terminating in a platform.

The stand-pipes of the London Water Works are of the following hights: —

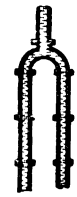
New River	84 to 145 feet.
Chelsea	85 to 135 feet.
West Middlesex	122 to 188 feet.
Grand Junction	100 to 151 feet.
Lambeth	185 feet
East London	60 to 107 feet.

Fig. 5560.



Stand-Pipe for Steam-Pump.

Fig. 5561.



Stand-Pipe.

The combined engine power is equal to 4,000 horses: delivery, 17,000,000,000 gallons annually. The horse-power is in excess; a reserve being kept. 8,500,000 gallons are raised by each horse-power annually, to hights varying from 60 to 188 feet; mean hight, 100 feet. Daily supply, 90 gallons per house. The New River Company supplies daily 700,000 persons with 40 gallons of water per head, at an expenditure of 4 cents per 1,000 gallons.

At Wolverhampton, England, water from a well 140 feet deep was pumped over a stand-pipe 180 feet in hight, making a lift of 320 feet. This was done to give the necessary pressure in the mains, there being no summit reservoir.

At the Erie, Pa., Water Works is a stand-pipe 220 feet in hight, resting on a rock elevated 14 feet above the water, making a total elevation of 234 feet. It is 5 feet in diameter, and is made of boiler-iron, the uppermost sections being 3/16 inch, and the lowermost 7/16 inch thick. It was erected by commencing with the top section and adding the lower ones in regular order, the whole being hoisted as each section was added, by means of a derrick and pulleys.

Hights to which Water may be projected through Engine-Pipes under Pressure.

Pressure per Square Inch.	Equivalent Head of Water.	Hight of Jet.	Ratio of Compression of Air in Air-Chamber.	Pressure per Square Inch.	Equivalent Head of Water.	Hight of Jet.	Ratio of Compression of Air in Air-Chamber.

75	170	132	.2	150	340	297	.1

4. (*Gas.*) .The vertical pipe leading from the retort to the hydraulic main.

Stang-ball. (*Projectile.*) Two half-balls united by a bar. A *bar-shot.*

Stan'hope. (*Vehicle.*) A sporting phaëton.

Stan'hope-lens. A lens of small diameter, with two convex faces of different radii, and inclosed in a metallic tube.

Fig. 5562.

Stanhope-Lens.

Stan'hope-press. A form of hand printing-press. A great improvement in its day. See Fig. 3948.

Stan'na-ry. (*Mining.*) A tin-mine, or tin-works.

Stan'no-type. (*Photography.*) A picture taken upon a tinned iron plate. A *tin-type.*

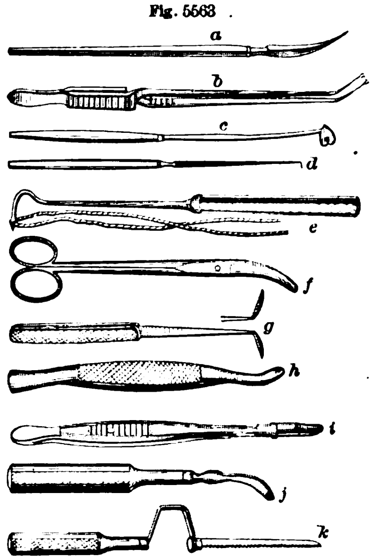
Stapes. (*Surgical.*) A bandage for the foot, making a figure-of-8 round the ankle.

Staph'y-lo-plas'tic Op'er-a'tion. (*Surgical.*) That for cleft palate. See STAPHYLORAPHIC INSTRUMENTS.

Staph'y-lor'a-phic In'stru-ments. (*Surgical.*) Instruments for operating for cleft palate. The edges of the cleft are pared, ligatures are passed through them, and they are brought together.

Uraniscoplastic instruments are allied to the former, being

Fig. 5563.



Tiemann's Staphyloraphic and Uraniscoplastic Instruments.

used in operations for engrafting in cases of deficiency of the soft palate.

a, double-edged staphyloraphy knife.
b, seizing forceps.
c, Sims' adjuster, for wire sutures.
d, tenaculum, for pulling the velum aside, holding the edges of flaps, etc.
e, Whitehead's spiral needle, for sutures.
f, curved scissors, for dividing the muscles.
g, Whitehead's knives, for paring the edges.
h, Sayre's periosteotome.
i, Sims' wire-twisting forceps.
j, Goodwillie's periosteum-levator.
k, Goodwillie's oral saw.

Staph'y-lo-tome. (*Surgical.*) A knife for operating upon the uvula or palate.

Sta'ple. 1. A bow of metal for holding a hook, ring, or lock-bolt.

2. (*Foundry.*) One of the pieces of nail-iron, a few inches long, on one end of which flat disks of thin sheet-iron are riveted. They do the work of *chaplets* in steadying and *holding down* a core, but differ from them in having the sharper end thrust into the sand till the distance of the plate, set by a gage, gives the required thickness of metal.

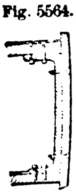
3. Fiber for manufacture: cotton, flax, wool.

4. (*Mining.*) *a.* A shaft uniting workings at different levels.

b. A small pit.

Sta'ple-knee. (*Shipbuilding.*) An iron knee with two arms, one bolted to the under side of a deck-beam, the other to the top of a hold-beam; the middle portion to the ship's side. A *staple-ledging* knee, or deck-standard knee.

Fig. 5564.



Staple-Knee.

Fig. 5565.

Staple-Punch.

Sta'ple-punch. The staple-punch has two points, and is used to prick blind-rods and slats for the reception of the staples which connect them.

Star. (*Pyrotechny.*) 1. A small piece of inflammable composition, which burns with a colored flame, depending on the character of the ingredients employed.

They are usually formed by pressing the composition, while wet, into a cylindrical mold, and afterward dredging with mealed powder. Sometimes the composition is formed in a large cake, which is afterward divided into cubical pieces.

They are used as ornaments for rockets, for filling wooden shells, and in Roman candles.

The following recipes are given for different colored stars: —

White. 4 niter, 2 sulphur, 1 mealed powder; or 9 niter, 3 sulphur, 2 antimony.

Yellow. 1 charcoal, 1 sulphur, 6 nitrate of soda; or 20 chlorate of potassa, 10 bicarbonate of soda, 5 sulphur, 1 mastic.

Red. 5 chlorate of potassa, 20 nitrate of strontia, 4 gum dammar; or 20 nitrate of strontia, 12 chlorate of potash, 11 sulphur, 2 charcoal, 2 antimony, 1 mastic.

Blue. 2 chlorate of potassa, 1 ammoniated sulphate of copper, 1 gum dammar; or 20 chlorate of potassa, 14 carbonate of copper, 12 sulphur, 1 mastic.

Green. 12 chlorate of potassa, 24 nitrate of baryta, 8 sulphur, 1 lamp-black; or 12 nitrate of baryta, 28 chlorate of potassa, 15 sulphur, 1 mastic.

Violet. 9 chlorate of potassa, 4 nitrate of strontia, 6 sulphur, 1 carbonate of copper, 1 calomel, 1 mastic.

Proof spirit, in which gum benzoin has been dissolved, is used for giving consistency to the mass.

2. The series of radial spokes, forming handles, on the roller of a copperplate or lithographic printing-press.

3. (*Printing.*) A reference mark (*) used in printing. An *asterisk.*

Star'board. (*Nautical.*) The right-hand side of a vessel, looking from aft forward; in contradistinction to *port*, which was formerly called *larboard.*

Starch. Starch and cotton goods originated in the East. The institutes of Menu, 800 B. C., refer to the stiffening action of starch on fabric.

Pliny informs us that starch was prepared from wheat by the inhabitants of Chio. The method of starching linen was publicly taught in England in the year 1560 by a Dutch woman, a Mrs. Dingham, the wife of Queen Elizabeth's coachman. She charged £ 5 for showing the process, and £ 1 extra for showing how to manufacture the starch. This was 260 years before Beau Brummel, who made his grand début in starched cravats.

Starch is found in the cells of all plants except fungi, in the form of minute granules, varying in diameter from $^1/_{240}$ to $^1/_{4000}$ of an inch. It is composed of 24 parts carbon and 20 each of oxygen and hydrogen, being nearly identical in composition with cellulose, into which it is charged by heat or the action of sulphuric acid. Its color is changed to a deep blue by iodine, which thus serves as a delicate test of its presence.

The granules are separated from the gluten and other principles by washing, and form an insoluble precipitate, being only mechanically suspended in the water. When dried and examined through the microscope, they are found to be made up of concentric layers, and appear beautifully colored under the influence of polarized light. Though constructed on one general type, the granules obtained from each kind of plants have in general peculiar characteristics, by which their origin may be readily determined.

Those from the potato are among the largest, while those of the cereals generally are much smaller. The granules of arrow-root resemble those of the potato, but are somewhat smaller.

Treated with dilute sulphuric acid, or heated to 300° Fah., starch is converted into dextrine, or British gum, which is largely employed as a cheap substitute for gum-arabic. By farther ebullition with the dilute acid, this substance is transformed into glucose or grape-sugar. See DEXTRINE; SUGAR.

The same process occurs in the germination of seeds by the action of the peculiar substance called *diastase*, into which the albumen of the seed is converted under the influence of warmth and dampness. The same action takes place in the process of malting.

In England, wheat is generally used for making starch, the ordinary process being as follows: —

The grain, crushed between rollers, is thoroughly wetted and allowed to stand for 4 or 5 days, until fermentation takes place; it is then removed to a vat, where more water is added, and allowed to ferment for from 2 to 3 weeks, when the mass is transferred to a stout basket, where it is washed by a continuous stream of water, and at the same time stirred with a shovel until the starch is completely separated from the bran.

It is received in a *back* or vat beneath, from whence it is taken and strained through hair-sieves into cisterns, where it is allowed to settle for 24 hours, after which the water above is decanted by tap-holes at different levels in the side. The upper part of the deposit, termed *slimes*, is removed, and the lower and impure starch is again agitated with fresh water and passed through a finer sieve; when the starch has subsided again from the strained liquid, the latter is drawn off, the second *slimes* are removed, and the remainder is again agitated with water and passed through the sieve. It is now allowed to become solid by evaporation, a little smalt or artificial ultramarine added to give it the required bluish tint, and any trace of acid removed by the addition of an alkali; while still moist it is shoveled into boxes lined with fine canvas, and having perforated bottoms When tolerably dry it is cut into pieces 5 or 6

inches square, partially dried, and finally stoved to render it completely so.

In this country, Indian-corn and also potatoes are very generally used for making starch: potatoes are prepared by thoroughly washing and then crushing in clear cold water; the resulting starchy matter flows into vats beneath, where it is allowed to settle, and is afterward washed one or more times, dried in stoves and packed; the refuse of the potatoes, the pomace and skins, being carried off by a current of water. These factories are small, and only operate during the latter fall and early winter, requiring as they do plenty of cold water, fermentation in this case being inadmissible.

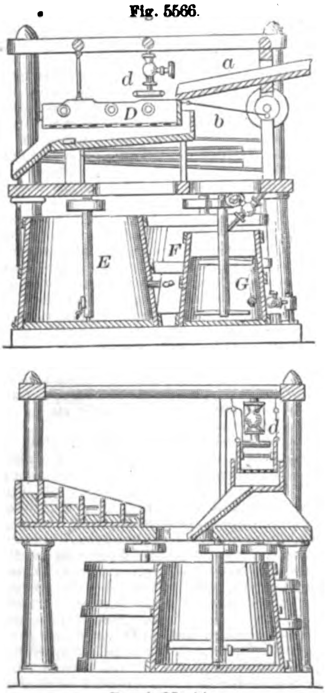
The application of maize to this purpose was patented by James Coleman in 1841, and was successfully practiced in the ensuing year at Oswego, N. Y., by Thomas Kingsford. The Kingsfords at present have probably the largest starch factory in the world, having bins five stories in depth, capable of holding 2,000,000 bushels of corn, and turning out annually some 4,000 tons of starch.

From the bins the grain is passed through fanning-mills, which remove impurities, and is then conducted to large vats, where it is macerated and softened to facilitate the separation of the albumen and gluten. After this process it is ground and pulped by a series of burr stones and heavy iron rollers, and is next transferred to drums or sieves, where the starch is washed out by the action of water, the non-farinaceous portion remaining within the sieves being finally allowed to escape through openings at their ends and conducted away to receptacles, whence it is taken and used as food for cattle.

The starch is received in vats, where it is agitated by means of stirrers operated by water or steam power, and is supplied with water and chemicals to purify it. When the superfluous water has been partially withdrawn, and it is in a semi-fluid state, it is run into molds, where it settles into solid cakes, which are broken into square cakes; these are placed in a kiln and dried at a low heat, and the cakes are scraped to remove impurities, which appear as a yellow crust on the surface. They are now again dried, causing them to fall into little pieces, which assume the peculiar forms so well known. They are then packed into barrels or boxes, according to quality. The highest grades, as corn-starch for puddings, or *maizina*, being ground fine, measured, and automatically put up and pressed in the packages by an arrangement of devices which prevent wastage and obviate the production of dust.

Various forms of apparatus are used for washing out and drying the fecula; the general principles of all, however, being similar.

Fig. 5566.

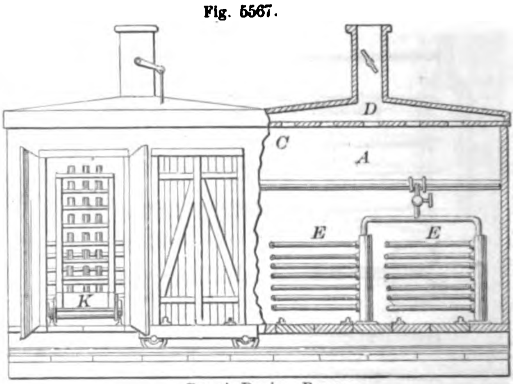


Starch-Machine.

In the apparatus (Fig. 5566), the pulpy mass passes from the trough *a* to the vibrating separator *D*, having at bottom a bolting-cloth, and supplied with water from a pipe *d*; the feculous matter is received in a vat, as *E F*. After settling, the water is drawn off and caustic alkali added. The contents of the vat are then agitated and transferred to a winding, inclined trough *b*, where the starch is deposited while the gluten is dissolved by the alkali. The starch is then transferred to another vat, as *G*, agitated and washed with water, after which it is again allowed to settle, drained and dried.

The drying-room (*A*, Fig. 5567) is provided with a series of racks *K*, has ventilating openings *C D*, and is heated by pipes *E E*. The cakes of starch are conveyed to the chamber by trucks running upon tracks and transferred to the shelves.

Fig. 5567.



Starch Drying-Room.

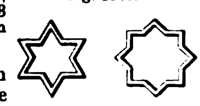
An incombustible starch, according to Hager, is made by pouring 50 parts hot water upon 10 parts pulverized burned bones, and adding gradually 6 parts sulphuric acid. The mixture is kept in a warm place, and occasionally stirred for two days, when 100 parts distilled water are added and the solution filtered; to the filtrate, a soluble phosphate of lime, are added 5 parts sulphate magnesia in 15 distilled water, and enough ammonia stirred in to impart an ammoniacal odor. The precipitated double phosphate of ammonia and magnesia is filtered, dried, and pulverized. Two parts of the powder are mixed with 1 tungstate of soda and 6 wheat starch, and a little blue carmine added. For use, it is mixed with twice its quantity of cold water, and sufficient boiling water stirred in to form a slimy liquid, in which the goods are immersed.

Star-fort. (*Fortification.*) Inclosed works having alternate *salient* and reëntering angles; the *faces* form with the *flanks* angles greater than a right angle.

A *star-fort* may be constructed either on a triangle or a square; in the former case it has 6 salient angles, and in the latter case it has 8.

Each face may be 90 yards long, and in construction is divided into 8 equal parts. On the middle one an equilateral triangle is erected.

Fig. 5568.



Star-Forts.

Star-gage. (*Ordnance.*) An instrument for measuring the diameter of the bore of a cannon at any part of its length. It consists of a graduated brass tube carrying four steel points at one end; two of these are movable, and are pushed outward by means of a tapering slider in the tube, enabling small variations in the caliber of the piece to be accurately measured.

Star'ling. (*Hydraulic Engineering.*) An inclosure consisting of piles driven closely together into the bed of a river, and secured by horizontal pieces at the top. The space between the rows of piling, being filled with gravel or stone, forms an effectual protection for the foundation of a pier. A *sterling.*

The starlings of the piers of the bridge erected across the Euphrates by Semiramis (1944 B. C.), to unite the two portions of the city, are distinctly described by Diodorus Siculus (B. C. 40).

Start. 1. (*Hydraulics.*) One of the partitions which determine the form of the bucket in an overshot wheel. *Strut.*

2. (*Mining.*) The lever of a crab or gin, to which the horse is attached.

Start'er. An apparatus for giving an initial motion to a machine, especially such as may be at rest on a dead-center. Used in sewing-machines, steam-engines, etc.

Start'ing-bar. (*Steam-engine.*) A hand-lever for starting the valve-gear of a steam-engine.

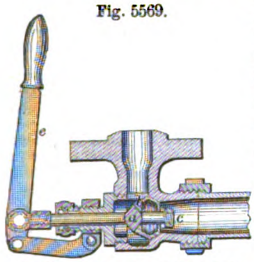
Start'ing-bolt. One used to drive out another. A *drift-bolt.*

Start'ing Steam-cyl'in-der. (*Steam-engine.*) A small low-pressure engine, used for starting a large marine engine.

Start'ing-valve. (*Steam-engine.*) *a.* A device introduced by Bourne in 1852. A small valve used in starting the main valves of large steam-engines when setting the engine to work.

Bourne, in 1836, introduced small cylinders to move the link motion which controls the action of the valves of the main engine.

Fig. 5569.



Starting-Valve for Gifford Injector.

b. A valve adapted for the Giffard Injector. It has an interior valve *a* and a larger valve *b*. The range of the former relatively to the latter, in which is its seat, is regulated by the play allowed by the nut *c*. Opening of the valve *a*, by pulling the lever *e*, allows a small but sufficient body of steam to pass, to raise the water.

Another pull opens the valve *b* and starts the injector.

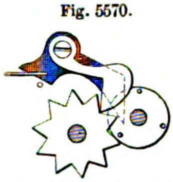
Start'ing-wheel. (*Steam.*) A wheel operating the valves in starting the engine.

Starting-bars and *starting-gear* have a similar purpose.

Star-wheel. (*Horology.*) A wheel having radial projections, which engage with a pin on the hour-wheel, employed in repeating-clocks. Also used in meters and registers.

The drop and attached pawl are carried by a spring, and are lifted by pins on the disk. The pins escape first from the pawl, which drops into the next space of the star-wheel. When the pin escapes from the drop, the spring throws down the drop, whose pin strikes the pawl; this acts against the side of a tooth, and gives the star-wheel a partial revolution.

Fig. 5570.



Star-Wheel (from Mechanical Movements).

State-room. 1. (*Nautical.*) A small cabin, usually for two passengers, on a steamer.

2. (*Railway.*) An apartment on a sleeping-car. In the example, the rooms open into a side passage, and the doors of the rooms, when swung open 90°, cross the passage, cutting off access to the room, and giving space for disrobing.

Sta'tion. 1. (*Shipbuilding.*) A long measuring-rod, also called a *room-and-space staff*, whereby the positions of the timbers of the frame are regulated.

2. (*Railway.*) A regular stopping-place for trains.

3. (*Surveying.*) The position of an instrument at the time of an observation.

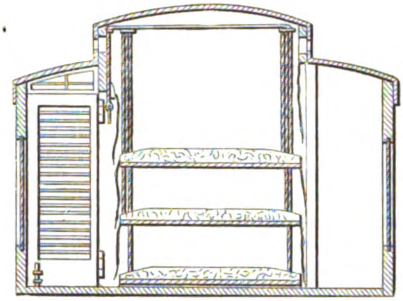
Sta'tion-a-ry En'gine. (*Steam-engine.*) *a.* One permanently placed, as distinguished from a locomotive or portable engine.

Fig. 5572 is a perspective view of an engine manufactured by Woodbury and Booth, Rochester, N. Y.

b. A form of engine for drawing carriages on railroads by means of a rope.

Until 1829, or thereabout, the question of the comparative economy and efficiency of stationary engines and locomotives was still undeterminate. The success of the

Fig. 5571.



State-Room on Car.

"Rocket" and the counsels of experts determined the question. See Rope-railway.

Stationary railroad-engines were long used on the inclined planes of the Alleghanies when the Pennsylvania Railroad followed the Holidaysburg route.

They are also used on the Morris and Essex Canal, State of New Jersey, in raising the boats from one level to another. See Inclined Plane.

For a number of years the incline of the London and Birmingham Railway of England, between the out-town and city termini, 1¼ miles, was ascended by means of a rope wound upon a cylinder by two stationary engines, at Camden Town.

The railway over a part of the Andes to Santiago is operated by a rope and stationary engines.

Sta'tion-bill. (*Nautical.*) A list containing the appointed stations of all the officers and crew of a vessel.

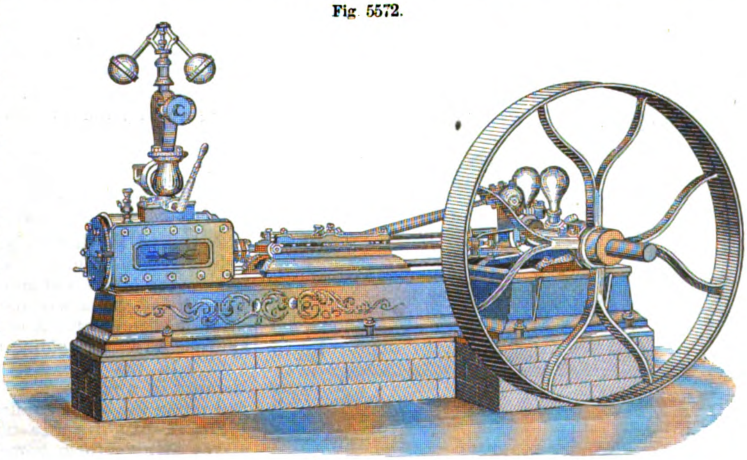
Sta'tion-cal'en-dar. A device for indicating a railway-station. They are of two general descriptions.

1. A dial or bulletin-board at a railway-station, to indicate the hours of starting of trains for given destinations; or the time of starting of the next train for a given place.

2. A device on board a car, consisting of an endless ribbon or map, which unrolls as the car proceeds, and exposes the names of the stations in order at a slit as the train approaches the stations, one after another. The map of the route, or the list of stations, is wound and unwound from a pair of rollers, which receive motion from some part of the car, say one of the axles.

Sta'tion-point'er. A circular plotting instrument, having a standard radius and two movable ones. By laying off two observed angles right and left from a central object, and laying it over the

Fig. 5572.



Stationary Engine.

objects on a chart, the position of the observer is indicated.

Sta'tion-staff. (*Surveying.*) An instrument for taking angles.

Stat'u-a-ry-brass. An alloy of copper, zinc, and tin, used for statuary, generally known as bronze. The proportions of the metals used are indefinite. Analyses of Keller's statues at Versailles give copper, 91.4 ; zinc, 5.53 ; tin, 1.7 ; lead, 1.37. Gun-metal, containing copper 9, tin 1, is frequently employed. See BRASS ; BRONZE ; ALLOY.

Stat'u-a-ry-cast'ing.

Herodotus and Diodorus Siculus refer to massive statues set up in the temple of Belus, in Babylon, at a date supposed to be about 2230 B. C. The massive statues of Memnon, Osymandyas, and other Egyptian kings, are of stone, and attest a great degree of skill, so that it becomes impossible to determine when the arts of modeling and sculpture were invented in or introduced into the land of the Nile. The Egyptian statuettes are frequently of metal.

The Roman Colossus set up by Nero, being a figure of himself, was placed before his Golden House, near the site of the temple of Venus, at Rome. It was of bronse, the work of Zenodorus, and Pliny gives its hight as 110 feet, — larger than that of Rhodes.

About 1491 B. C., "he [Aaron] received them [the golden ear rings of the people] at their hand, and fashioned it with a graving tool, after he had made it a molten calf." — Exodus xxxii. 4.

"The smith with the tongs both worketh in the coals, and fashioneth it [an idol] with hammers, and worketh it with the strength of his arms." — Isaiah xliv. 12 (712 B. C.).

In the year 120 B. C., a Chinese general brought back from a country north of the desert of Gobi a golden statue of Buddha as a trophy.

"The magnificent statues of brass and iron, which issue from the foundries of Tolon-Noor, are renowned not only throughout Tartary, but even in the most distant countries of Thibet From its vast workshops all the countries which profess the religion of Buddha receive their supply of idols, bells, vases, and other utensils employed in their idolatrous service The large images are cast in several pieces, and afterward soldered together During our stay at Tolon-Noor we saw a single statue of Buddha which made in its various pieces the load of 80 camels. It was intended as a present to the Tale Lama." — ABBÉ HUC'S *Travels in Tartary*, 1844-46.

The great statue of Buddha in Nirvana — that is, in a state of utter annihilation of external consciousness — is at Kamakura, half a day's march from Yokohama, in Japan. The statue represents Buddha sitting in the Oriental manner, upon a lotus. The statue is of bronze, is 50 feet high and 96 in circumference at the base. It is hollow, and the interior is fitted up as a temple, with images. It was cast about 600 years ago, in sections of a few feet square and an inch or more in thickness. The joints were so well fitted, that after the lapse of centuries they are only to be detected by discoloration arising from the weather. It is placed on a pedestal 5 or 6 feet high, and the head is covered with small knobs representing the snails which, tradition says, came to protect Buddha from the heat of the sun.

Fig. 5573.

The Daibutz. Buddha in Nirvana (Kamakura, Japan).

This statue was received many centuries ago from a far western country, doubtless Tolon-Noor, which is yet the great foundry for the lands over which the religion of Buddha prevails.

Schwanthaler's colossal bronze statue of the feminine genius "Bavaria," is 54 feet high, and erected on a pedestal 30 feet in hight, in front of the "Ruhmeshalle," at Munich. A winding staircase in the interior leads to the head, wherein is a chamber large enough to contain 28 persons. Openings are afforded among the curls for viewing the prospect.

The casting was made at five different times, commencing with the head. This was in 1844. The bust was the largest portion, and for it 20 tons of bronze were melted.

The present system of casting statuary from wax patterns is as follows: —

1. Take a cast in plaster sections, which together form a matrix.
2. Cover the inside of the sections with a shell of wax.
3. Place the sections in position to form a mold.
4. Fill the inside with clay or *slush*, to form a core, with supports to sustain it independently of the mantle.
5. Remove the plaster sections, the wax adhering to the clay.
6. Work up the wax surface into complete form, by hand.
7. Coat with porous clay composition to form a mantle.
8. Bake in a furnace, melting or burning out the wax.
9. Run the metal into the baked clay mold.

Figures of large size have been made by the deposition of copper by electro-metallurgy upon a core or model of clay.

The church of St. Isaac at St. Petersburg is decorated with a large number of statues and figures in relief obtained by this process.

Stat'ue. A sculptured figure in stone, or a casting in metal from one molded in clay.

Stat-u-ette'. A small statue. Statuettes and other artistic forms in plaster are made very closely to resemble silver in appearance by being covered with a thin coat of powdered mica. This powder is mixed with collodion and then applied to the objects in plaster with a brush, after the manner of paint. The mica can be easily tinted in various colors. It can be washed in water, and, unlike silver, is not liable to become tarnished by sulphureted gases.

Stau'ro-scope. A kind of polariscope invented by Von Kobell, of Bavaria, about 1855, and particularly designed for investigating the effects of polarized light upon crystals belonging to different crystallographic systems. — POGGENDORF, Ann. 95-320.

Stave. 1. (*Coopering.*) One of the strips which compose the sides of a cask, tub, or bucket.

The undressed strip, as riven or sawn from the block, is also called a stave.

Staves are made by machinery, different machines being used for the several operations of

Sawing.	Bilging.	Howeling.
Riving.	Dressing.	Crozing.
Chamfering.	Shaving.	Setting.
Cutting.	Planing.	Finishing.
Bending.	Jointing.	

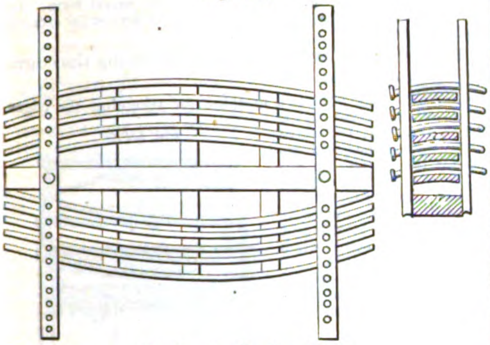
2. One of the boards joined laterally to form a hollow cylinder, curb for a well or shaft, the curved bed for the intrados of an arch, etc.

3. One of the bars or rounds in a lantern-wheel.

Stave-bend'er. A device for bending steamed stuff for staves, or holding them in shape after being bent. In the example, the steamed staves are clamped in a rack and kiln-dried, so as to assume and retain the shape required.

Stave-bilg'ing Ma-chine'. One for bending staves to give them bow-shape at the bilge ; also their hollowing shape. See STAVE-BENDER.

Fig. 5574.

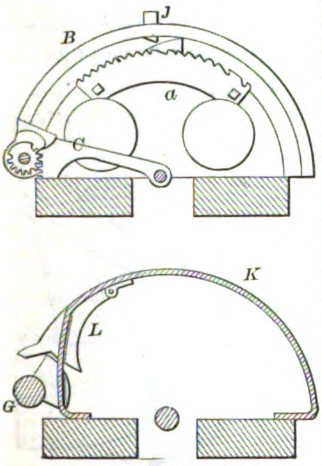


Machine for Bending Staves.

Stave-cham'fer-ing Ma-chine'. One for beveling the ends of staves at the chine.

Fig. 5575 is a machine for chamfering the ends of and crozing barrel-staves at the same time. A stave is inserted in the machine, held by two ribs *B* at the ends, and clamped between them and a central curved bar *K*, by means of two vibratable clamps *L*, operated by segment rack-levers *C* and pinions at each end of the shaft *G*. The croze is formed by a toothed cutter *a*, and the ends are chamfered by upper and lower cutters seen at *J*. Each stave, as it is inserted, pushes the preceding one forward, they occupying the same relative position as in the completed barrel, uniformity is secured, and splitting off the wood at the edges of the staves is prevented. See also STAVE-CROZING MACHINE.

Fig. 5575.

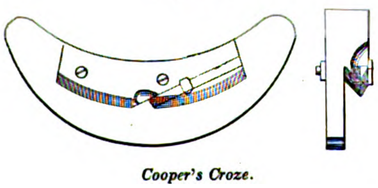


Chamfering and Crozing Machine.

Stave-croz'ing Ma-chine'. The *croze* of a cask is the *kerf* on the inside, into which the edge of the barrel-head is inserted. The cooper's *croze* is a kind of toothed plane with a curved face to cut the *kerf* in the cask. The previous rounding of the inside of the barrel to make a fair surface to work on is done by the *howel*. The *howel* may also make the *chamfer*, which is the bevel at the end of the stave forming the *chine*.

In *stave-crozing* machines the kerf is usually cut by a saw; in barrel-crozing machines the staves, after being set up, are subjected to the action of the crozing-saw. In some cases two saws and a cutter croze, cut off, and chamfer the stave simultaneously. Wilde, August 12, 1862; Cutter, June 14, 1870.

Fig. 5576.



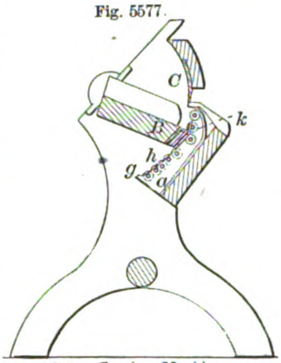
Cooper's Croze.

Stave-cut'ter. A machine for cutting staves from the bolt.

In the machine (Fig. 5577), the stave-bolt is held upon the swinging-bed *B*, and presented to the action of the curved knife *C*.

A series of curved ribs *a* on the fixed bed carry alternating rollers *g h*, which prevent the side of the block from coming in direct contact with the ribs, and permit the chips and splinters to pass between them. When the stave is completely severed, it is caught by a spring *k* and prevented from falling back as the table descends.

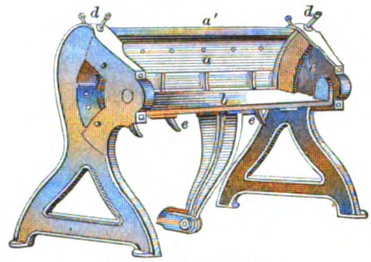
Fig. 5577.



Stave-Cutting Machine.

In Crossett's stave-cutter, Sept. 24, 1861 (Fig. 5578), the bar *a'* with the fixed knife *a* is adjusted as to hight in segmental grooves in the heads *c c* by screws *d d*, and held by set-screws behind. The table *b* is pivoted at each end, and is tilted upward, in order to present the block from which the staves are riven to the action of the knife; its rear edge is slotted to receive a series of curved vertical guides *e e* attached to the front of a bar connecting the ends of the machine; chips fall through the interspaces between the guides. See also Crozier and Currier's patent, March 29, 1859.

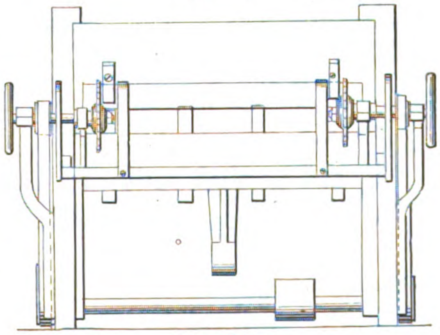
Fig. 5578.



Crossett's Stave-Cutter.

Fig. 5579 is a machine designed to slice from a block, and at the same time saw the staves to an exact length. As soon as the stave is sliced off, two adjustable circular saws cut the stave to the desired length, it being held in place by two circular springs until the next succeeding stave is cut.

Fig. 5579.

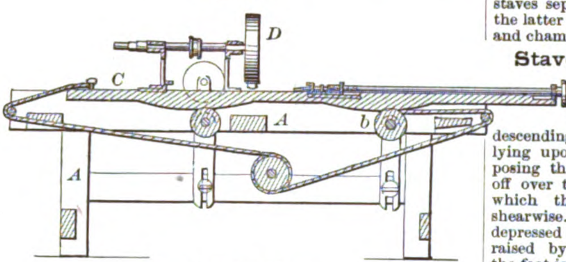


Stave-Cutter.

Stave-dress'ing Ma-chine'. The machine (Fig. 5580) is designed for dressing the inside of staves of uniform size, as those for beer-barrels.

These are held upon a table *C*, which is traversed back and forth upon rollers *b* journaled in the bed *A*, so as to present them to the rotary-cutter *D*. The bottom of the bed has a

Fig. 5580.

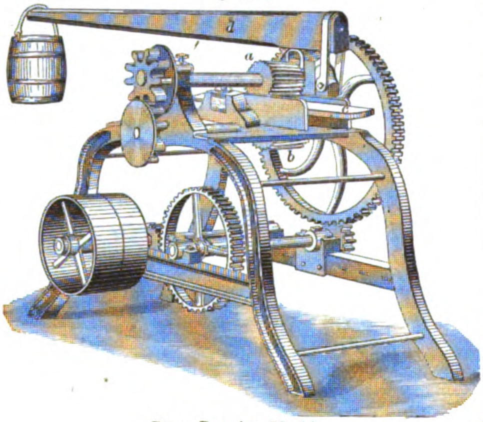


Stave-Dressing Machine.

curve corresponding to that of the staves to lift them up to the cutter in proportion as their curvature tends to cause them to recede from it. The staves may be held down by upper rollers or other suitable means.

In Fig. 5581, the rived stave *c* is drawn in between the two

Fig. 5581.



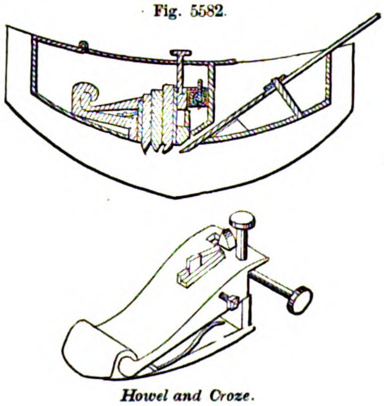
Stave-Dressing Machine.

fluted rollers *a b*, and presented to the action of convex and concave faced revolving cutters, which *hollow* and *back* the stave in the direction of its length, dressing the inside and outside of the stave respectively. A weighted lever *d* regulates the pressure on the upper feed-roller.

Stave-how'el-ing Ma-chine'. The cooper's *howel* is a plane for smoothing the insides of staves or of barrels about where the croze comes.

Fig. 5582 is a tool in which the *howel* and *croze* are combined. The crozing portion, shown in the lower figure, is removable from the case carrying the howeling bit when the former is not needed.

Fig. 5582.



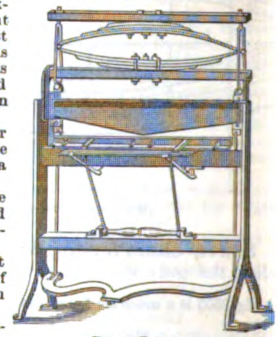
Howel and Croze.

In howeling-machines the work is performed either on the staves separately, or after they are set up in barrel form. In the latter case it is frequently associated with devices for crozing and chamfering.

Stave-joint'er. A machine for truing the edges of staves.

Fig. 5583 is a machine for trimming the edges of staves by a descending cut, the stave lying upon a bed and exposing the part to be cut off over the edge, against which the cutter works shearwise. The cutter is depressed by a treadle and raised by a spring when the foot is withdrawn.

Fig. 5583.



Stave-Jointer.

In Crozier's stave-jointer the stave is held in a frame and dressed by knives on a revolving head.

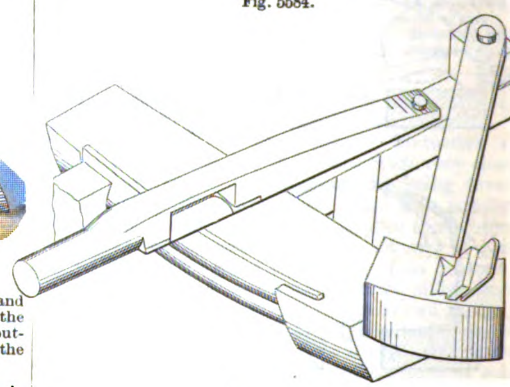
In Seymour's machine the stave lies upon a bed and is jointed by a guillotine knife.

In Doane's machine it passes between a pair of saws set at an angle with each other.

Fig. 5584 is a bench attachment. The staves are clamped in their bent position on a frame, to which are pivoted a double-acting knife and a swing plane.

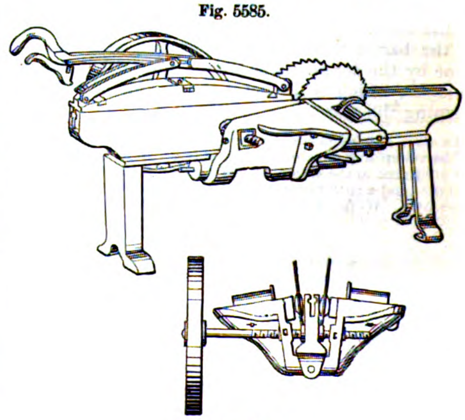
In Fig. 5585, the stave is clamped upon the curve-topped carriage, and is passed between the saws, which are carried upon inclined adjustable arbors. See also STAVE-SAWING MACHINE.

Fig. 5584.



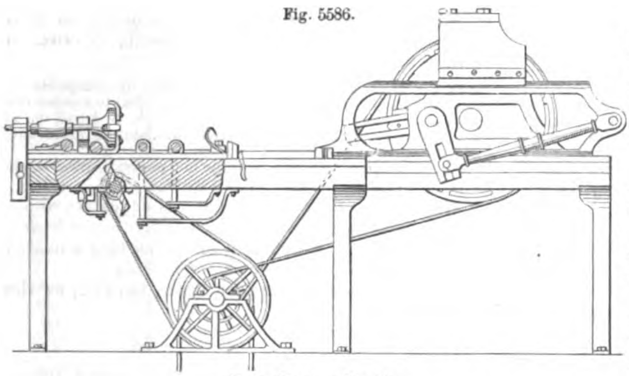
Stave-Jointer.

Fig. 5585.



Jointing-Saw.

Fig. 5586.



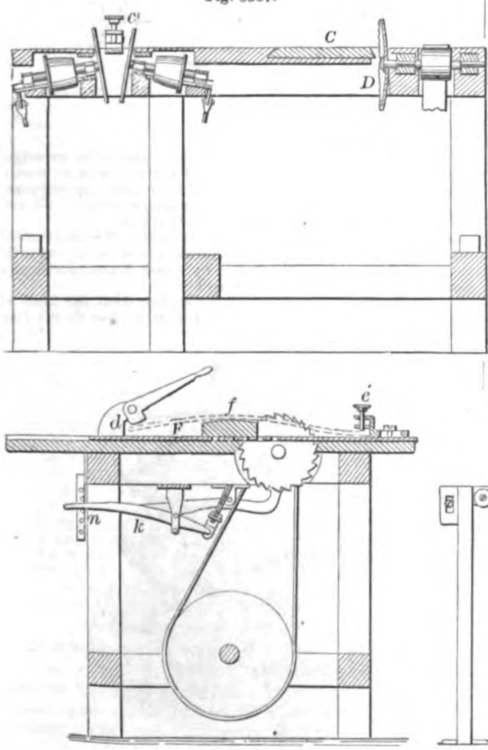
Stave-Planing Machine.

Stave-plan'ing Ma-chine'. A machine in which staves are faced by a plane.

In Fig. 5586, the stave is pushed beneath a stationary plane-bit to shave the outer face, and its lower surface is dressed by the revolving cutter. The pusher consists of a sliding-frame, which is reciprocated by a pitman connected to a radially adjustable wrist on a rotating bell-crank, whose other arm has a slot traversed by a pin on the driving-wheel. The driving-wheel and rotating crank-shaft are journaled eccentrically, so that the movement of the pin along the slot will cause a slower motion in the feeding than in the return motion of the pusher.

Stave-riv'ing Ma-chine' One for splitting balks of timber into slabs suitable for making staves. The slab of rived timber undergoes treatment for bending, sawing to a length, hollowing, backing, dressing, chamfering, crozing; some of these operations, however, are performed after the staves are set up.

Fig. 5587.



Stave Sawing and Jointing Machine.

The riving of staves is usually by frow and mallet (see Fig. 2108). Dorr's riving-tool has a set of knives in a frame, so as to check the end of the balk for a number of staves (or shingles) at once. The knives are not quite parallel, but have divergence answering to the radial marks in the timber; for instance, the medullary rays in oak and some other woods.

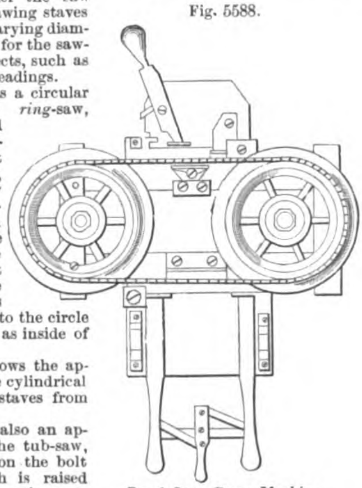
Stave-saw'ing Ma-chine'. (*Coopering.*) *a.* One for sawing staves from the log, bolt, or balk.

b. One for sawing the edges of staves, otherwise known as *jointing*. See STAVE-JOINTING MACHINE.

The machine (Fig. 5587) is designed to saw staves from the bolt and *joint* or impart the required bevel to their edges. The bolt is placed on the sliding-table *C*, which is advanced while the stave is cut to the required circular form by the dished saw *D*. The stave is then transferred to the other end of the table, where it is held and bent between the two clamps *d e'*, the center being supported by the block *f*. The table *F* is then advanced, presenting the stave to the action of two circular saws, which are suitably inclined to impart the desired radial bevel to each edge. The saws may be brought nearer together or separated, without altering their inclination, by means of a lever *k*, which is engaged with a rack *n* to hold it in fixed position, and actuates a bell-crank arrangement which moves frames carrying the saw-spindles.

Fig. 5588 shows a stave machine using a band-saw, which works upon pulleys in connection with adjustable feed-tables, so as to render the saw available for sawing staves for vessels of varying diameters, and also for the sawing of flat objects, such as shingles and headings.

Fig. 5588.



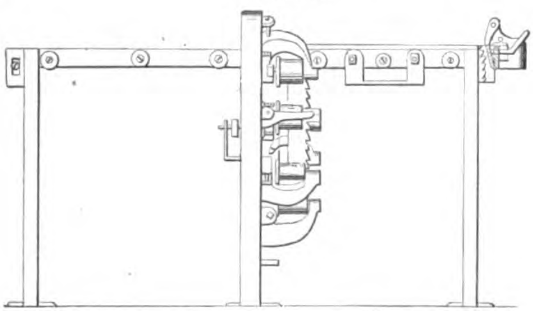
Band-Saw Stave-Machine.

Fig. 5589 has a circular band-saw, or *ring*-saw, hung upon and between friction-rollers set in a true circle, so that the saw is put in motion and driven by one of the rollers. These rollers are set in adjustable brackets, so as to be adjusted to the circle outside as well as inside of the saw.

Fig. 5590 shows the application of the cylindrical saw to sawing staves from the bolt.

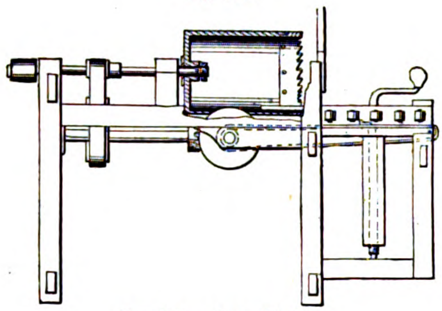
Fig. 5591 is also an application of the tub-saw, which acts upon the bolt of wood which is raised against it, the reciprocating, vibratory table, with its head-block, being pivoted at such a point as to cause the saw to cut a transverse circle on the outside of the stave to conform to the outside diameter of the barrel when completed. The cams and flanges *Q R* act against rollers on the

Fig. 5589.



Ring-Saw Stave-Machine.

Fig. 5590.



Barrel-Saw Stave-Machine.

arms of the feeding-table, giving the same the necessary vibration.

In Hurlbut's stave-machine (Fig. 5592), the saws are capable of being so adjusted as to give the required bevel to the edges of the staves as they are presented to the action of the saws by the forward movement of the carriage. The angle at which the saws are set varies according to the dimensions of the barrels for which the staves are designed.

Stave-set'ter. (*Coopering.*) A device to hold staves as they are consecutively set up, in order to form a barrel or cask.

In Fig. 5593, the chine hoop is suspended by clamps over a concave table, which holds the head in position to receive the staves which form the barrel. When the hoop is driven on to hold the staves in place on the head, the clamp is withdrawn and the barrel removed from the table.

Fig. 5594 shows by a plan view the independent spring-heads which hold the staves against the truss-hoop.

Stav'ing. 1. A casing of staves or planks which forms a *curb* around a turbine or similar water-wheel.

2. (*Forging.*) Shortening or compacting a heated rod or bar by endwise blows. *Upsetting.*

Stay. A lean-to, support, brace, tie, etc., as the case may be.

Of an *axle-tree.*

Of the *splinter-bar.*

Of a *chain-cable;* the transverse piece in a link.

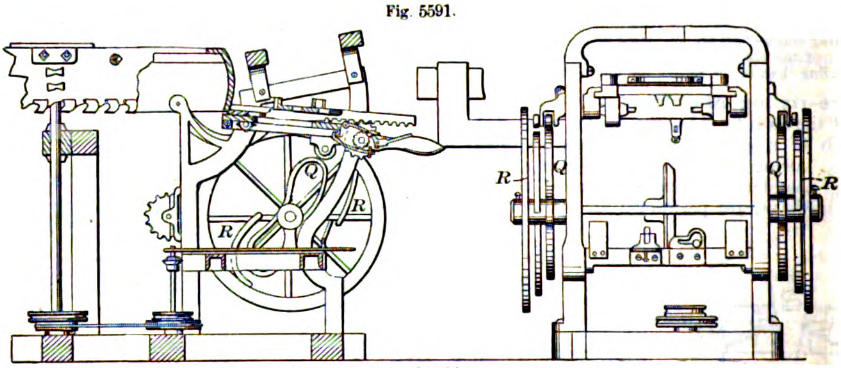
Of a *core-box;* the spindle that supports the core in some kinds of hollow castings, as shells.

Of a *crane;* the prop or strut which supports the jib.

Specifically: —

1. (*Nautical.*) A strong rope which stiffens and

Fig. 5591.



Stave Machine.

supports a mast in its erect position, by connecting its head to some part of the hull, or to a part stayed from the hull.

a. The *fore-and-aft* stays lead forward in the vessel's line amidships.

b. The *back* stays pass somewhat abaft the shrouds, and are attached to the side of the vessel, at the *channels.*

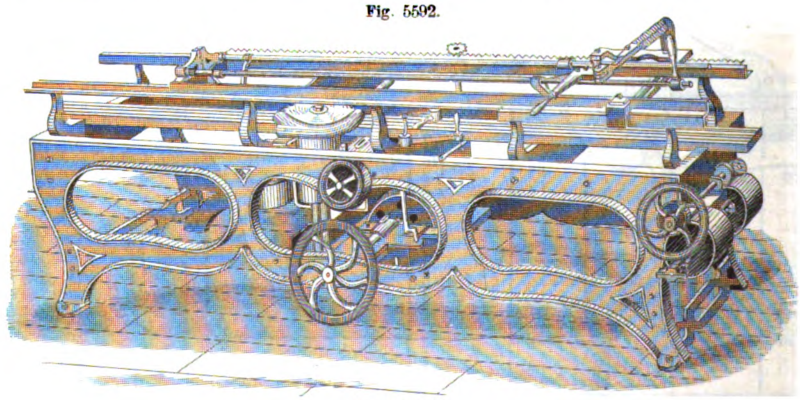
c. The *breast* and *standing* stays lead from the mast-heads down to the gunwale on each side.

d. Spring stays are *preventer* stays to assist the principal ones. The *fore-and-aft* stays support the *staysails* by means of *hanks.* The stays are named from the masts they support; as the *fore*-stay, *foretopmast*-stay, *maintopmast*-stay, *jib* and *flying-jib* stay, the *bob*-stay, etc. See Staysail.

e. The *triatic stay* is connected at its ends to the heads of the fore and main masts, and has a thimble spliced to its bight for the suspension of the *stay-tackle,* by which boats, machinery, and heavy freight are hoisted aboard.

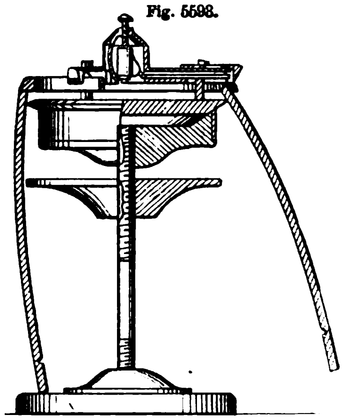
f. A *jumper-stay* is a movable stay leading from the head of a mainmast to a pair of eye-bolts in the deck close to the after

Fig. 5592.



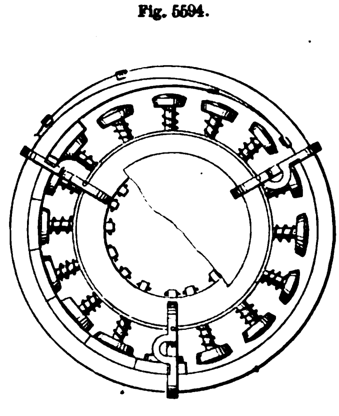
Stave-Machine.

Fig. 5593.



Stave-Setter.

Fig. 5594.



Stave-Setter.

part of the fore-rigging; the weather jumper-stay alone being set up.

g. A *short stay* refers to the position of the anchor when it is nearly *under foot*, in heaving in.

h. To *stay* a vessel is to tack her. To *miss stays* is to fail in tacking. To *heave in stays* is to put a vessel about by tacking.

2. (*Steam.*) *a.* A *rod*, *bar*, *bolt*, or *gusset* in a boiler, to hold two parts together against the pressure of steam, as the *tube-stays*, *horizontal*, *vertical*, and *water-space stays*, etc.

b. Sling-rods (*sling-stays*) connecting the locomotive boiler to its frame.

c. Rods beneath the boiler supporting the inside bearings of the crank-axle of an English locomotive.

3. A bar in a frame to prevent lateral deviation of another bar. See TRUSS.

4. A *guy* supporting the mast of a *derrick*, etc.

5. (*Mining.*) A piece of wood used to secure the pump in an engine-shaft.

6. (*Apparel.*) A corset.

The garment with busk and stiffening slips of metal, wood, or whalebone is a comparatively modern invention. The ancient Greeks and Romans had belts and cinctures, but no female cuirasses. In the time of Galen, under the Antonines, the physicians wrote against these bands, which interfered with the vital functions, but their protests were received then, as now, with indifference. The ladies of the time of Louis IX. of France, like the "first gentleman in Europe" of nearly six centuries later, had their dresses stitched upon them to secure a tight fit without creases. Lord Alvanley's "fat friend" would stand for two hours like a royal Turveydrop, while the wrinkles were cut out of his coat and the seams taken up by *fine-drawing*.

The introduction of bones and metal into the female breastplate is credited to the court of Isabel of Bavaria, about 1417, and the illiberal chronicler has suggested that the device was padded to conceal deformity, and stiffened to act as a *scoliosis brace*. Catharine de Medici introduced the fashion into France.

The Emperor Joseph II. proscribed the corset and tried to discourage its use by arraying malefactors in it, much as the English authorities endeavored to set a seal of condemnation upon cotton goods by hanging criminals in cotton shirts.

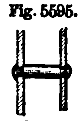
The dresses in one loose length, girdled at the waist and secured by brooches at the shoulders, was substituted by the separate waist and skirt in the fourteenth century by Queen Philippi, wife of Edward III. of England, and Queen Jeanne of Bourbon.

With the moral and hygienic features of the question this *Mechanical Dictionary* has nothing to do. The tortoise seems to get along safely in his carapace, which is the most straitly laced armor now extant among vertebrates. The armadillo is another notable instance, but his strait-jacket is open all down the belly, and allows of expansion, whether the increase in girth arise from emotion, sufflation, or overeating.

"Let me not stay a jot for dinner." — LEAR.

Stay-bolt. (*Steam.*) A bolt connecting two plates, so as to make them mutually sustaining against internal pressure. It is much used in the water and steam-jackets of locomotive and other boilers. Ostrander's stay is tubular; it has a solid head outside, but inside is open into the fire-box, so that a breakage is revealed by the leakage of water into the fire.

Fig. 5595.



Stay-Bolt.

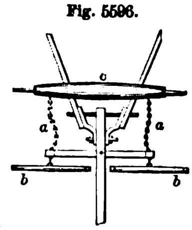
Stay-busk. (*Wear.*) A stiffener in a corset.

Stay-chain. (*Vehicle.*) One of the chains which connect the ends of the double-tree with the fore-axle, so as to limit the sway of the former. *a a* are the *stay-chains*, *b* the *double-tree*, *c* the *fore-axle*. In carriages, straps effect the same end.

Stay-foot. (*Sewing-machine.*) An attachment to the presser-bar of a sewing-machine to guide a seam-stay in some kinds of ladies' and children's shoes.

Stay-gage. (*Sewing-machine.*) An attachment to the cloth-plate to guide a strip over the goods or leather, so as to be laid upon and sewn over a seam to cover and strengthen (stay) it. Used also as a guide in sewing or trimming.

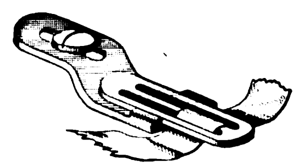
Fig. 5596.



Stay-Chains.

It is attached to the cloth-plate with the flat-headed screw accompanying it, and adjusted so that the needle will strike the binding as desired. Insert the binding as in the seam stay-foot, but pass the seam to be stayed above the gage and under the presser-foot, and guide the seam so as to stitch the binding as near the seam as is desired.

Fig. 5597.



Seam-Stay Gage.

Stay-hole. (*Nautical.*) The grommet or hole in a staysail through which the *hanks* pass; by the latter the sail runs on the stay.

Stay-lace. A braided strip to fasten a corset.

Stay-pile. (*Hydraulic Engineering.*) A pile driven into a bank and affording an anchor for the main piles which form the face of the quay, to which it is connected by *land-ties*. See PILE.

Stay-rod. 1. (*Steam-engine.*) *a.* One of the rods supporting the boiler-plate which forms the top of the fire-box, to keep the top from being bulged down by the pressure of steam.

Fig. 5598.

Staysails

b. Any rod in a steam-boiler which supports plates against internal strain by connecting parts exposed to rupture in contrary directions.

c. A tension-rod in the frame of the marine steam-engine.

2. A tie-rod in a truss or building, which prevents the spreading asunder of the parts connected.

Staysail. (*Nautical.*) A *fore-and-aft* sail supported by a *stay* of a vessel.

a, foretopmast staysail.
b, fore-staysail.
c, maintopmast staysail.
d, main top-gallant-mast staysail.
e, mizzen-staysail.
f, mizzen-topmast staysail.
g, main-royal staysail.
It is usually three-cornered.
The parts and appliances are known as, —
The *head*, — the upper corner.
The *tack*, — the lower forward corner.
The *clew*, — the lower after corner.
The *leech*, — the after edge.
The *sheet*, — a rope for hauling aft the *clew*.
The *halyard*, — for raising.
The *down-haul*, — for lowering the sail.

Stay-tack'le. (*Nautical.*) Tackle suspended from the triatic stay, and used for hoisting in heavy butts of water, freight, boats, blubber, etc.

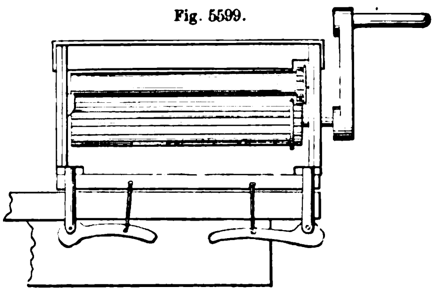
Stay-wedge. (*Locomotive.*) One of the wedges fitted to the inside bearings of the driving-axles, to keep them in their proper position in the stays.

Stead. 1. A frame, as of a bed.

2. A building, as a *homestead*. The *steading* is the collection of buildings, say the house, stables, barns, and other out-houses of a farm.

Stead'y-pin. 1. (*Founding.*) One of the pins — generally three or four, in one flask — which, by fitting into holes in the *lugs* of another, enable the two parts to be restored to their original position after the pattern is *drawn*. This term is also applied to the dowels or pins which hold patterns together when the whole is made in two or more parts, for convenience in molding.

Fig. 5599.



Steak-Crusher.

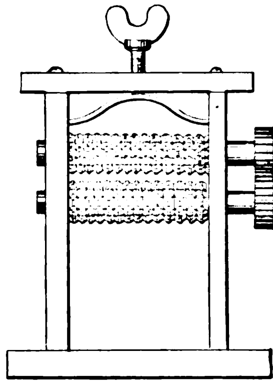
2. A dowel-pin in a sectional structure.

Steak-crush'er. A household implement to mash tough steaks before cooking.

The instrument is clamped to the table and the steak passed between the rollers, the upper one of which is smooth and the lower one corrugated.

Steak-mash'er. In Fig. 5600, the top roll tends to roll the steak in one direction, while the other roll acts upon it in like manner in the opposite direction; the fibers are thus twisted and rolled while being mashed.

Fig. 5600.



Steak-Masher.

Steal'er. (*Shipbuilding.*) The endmost plank of a *gore-strake*, which stops short before reaching the stem or stern.

Steam. The elastic aëriform condition of water heated to the boiling-point.

A steam-boiler from which a hot-air blast or an air-blast mixed with steam is blown into the fire to urge the combustion is shown in Hero's "Spiritalia." See folio edition "Veterum Mathematicorum," Parisiis, MDCXCIII., a copy of which is in the Patent-Office Library.

Applications of Steam.

Name.	Nationality.	Invention.	Date.
Hero	Greek	Rotary steam-engine (*recoil principle*)	B. C. 150
Hero	Greek	Cylinder and piston in pumps	150
Hero	Greek	Water fountain caused by pressure of steam	150

	English	"*Great Britain*," screw, Atlantic	1843
Nasmyth	English	Steam-hammer	1845
Collins	American	Line of mail packets, "*Pacific*," "*Baltic*," etc., Atlantic	1850
	English	"*Great Eastern*," Atlantic	1858
	French	"*La Gloire*," armor plates, government vessel	1859
	English	"*Warrior*," armor plates, government vessel	1860
Winans	American	Cigar steamers	1860
Ericsson	American	"*Monitor*" (Timby's turret), government vessel	1862

* Watt also introduced, at various periods, the rotary-ball governor, which he devised from the old windmill governor; the throttle-valve; floating water-gage; steam-gage; steam indicator and register; packing the piston with lubricant instead of water.

Terms used: —

Pressure, the elastic force expressed in pounds per square inch.

Temperature, the heat indicated by a thermometer.

Density, the weight of a unit of its volume compared with that of water.

Relative volume, the space occupied by a given volume compared with that of the water which produced it.

Pure steam; in which the water is perfectly vaporized, none being held in mechanical suspension.

Wet steam; in which portions of water have passed off with the vapor, and are held in mechanical suspension.

Saturated steam; same as *wet* steam.

Dry steam; steam without water mechanically suspended therein.

High-pressure steam; steam at a pressure considerably above the boiling-point.

In England, a pressure above 25 pounds to the square inch is often spoken of as high pressure. In America, above 50 pounds to the square inch. The customs vary.

Low-pressure steam; below 25 or 50 pounds pressure to the square inch, as the case may be. See previous definition.

Superheated steam; that which has been brought to a temperature higher than the boiling-point corresponding to its pressure, so as to be in the condition of a permanent gas. Also known as *surcharged* steam, *anhydrous* steam, or *steam-gas*.

In the following table and calculations, the unit of measure is 1,700 cubic inches.

Elastic Force, Temperature, Volume, and Density of Steam.

From a Temperature of 32° *to* 387.3°, *and from a Pressure of* .2 *to* 408 *Inches of Mercury.*

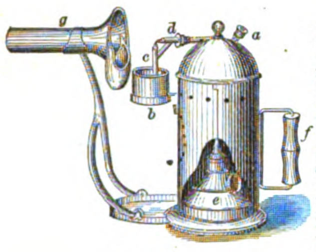
Steam-at′om-iz-er. (*Surgical.*) An instrument in which steam is employed for generating spray from a medicinal liquid when applied locally in that form.

Fig. 5601.

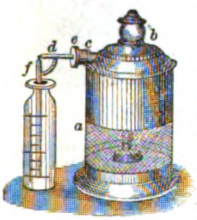


Steam-Atomizer.

Fig. 5601 consists of a sheet-metal case provided with a wooden handle *f*, and having a dome-shaped boiler at top for containing water. For use, the safety-valve *a* is removed, the boiler half filled with water, and the lamp *e* lighted. The spray-tube *c* is inserted in the cup *b* which contains the liquid, and the spray-tube *d* inserted in its socket. The blast of steam from the tube *d* causes the fluid to rise in the tube *c*, and be finally ejected in a shower at its top. The combined face-shield and drip-cup *g* serves to direct the jet of spray upward or downward, and as a receptacle for any fluid which is not forced through it. See Atomizer.

In Fig. 5602, *a* is the holder, containing a spirit-lamp, over which is the boiler *b*, provided with a safety-valve and a wooden ring, so that it may be removed without burning the hand; *c* is a tube leading from the boiler, into which the blunt-pointed canula *d* is inserted and packed with perforated pieces of india-rubber or leather, by means of a screw *e*. The sharper-pointed canula *f* is inserted in the bottle containing the liquid, and when steam is generated in the boiler, it, issuing from the canula *d*, first exhausts the air from the bottle, and then the liquid, rising in the canula *f*, is dissipated in the form of spray.

Fig. 5602.



Steam-Atomizer.

Steam and Smoke En′gine. The name given to a form of engine in which the expansive force of the heated gases from the fire is combined with that of the steam.

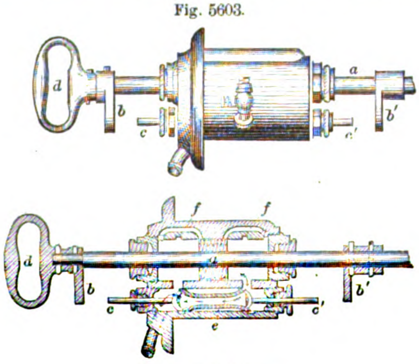
Oliver Evans' *volcanic* engine was of this class.

Bennett's also, U. S. patent, 1838. See Aëro-steam Engine, pages 20–23.

Steam Bell-ring′er. (*Railway Engineering.*) A device for ringing the bell of a locomotive by steam pressure from the boiler.

In Fig. 5603, the piston-rod *a* is attached directly to the crank of the bell, which is caused to ring automatically by opening the cock of the induction-pipe and moving the piston until one of the tappets *b b′* strikes the end of one of the valve-stems *c c′*. To stop the bell, hold the handle *d* so as to leave the bell in a perpendicular position. It is not necessary to shut off steam. The valve *e* receives steam in the center, and exhausts at the ends; relief-passages *f f* allow the air or vapor in the ends of the cylinder to escape around the piston, and, by removing the resistance, permit the piston to yield to the momentum of the bell until it stops. It may also be rung by hand by means of the handle *d*.

Fig. 5603.



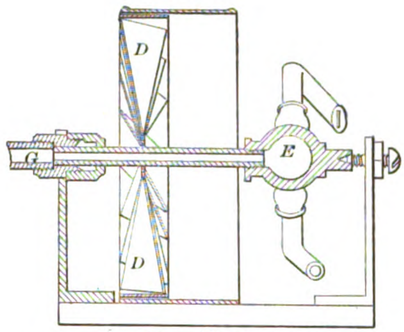
Steam Bell-Ringer.

Steam-blow′er. 1. A blower driven by a steam-engine.

2. A blower in which steam is mingled with the air-blast.

In Fig. 5604, *D* is a fan placed in a chamber adjoining the furnace. Steam from the boiler is admitted through the pipe *G* to the hollow shaft of the fan, and serves to turn the reaction-wheel *E* which rotates the fan. The current of air produced by the fan is mingled with the escaping steam and forced into the furnace beneath the grate.

Fig 5604.



Steam-Blower.

Steam′boat. A name applied to a vessel propelled by steam. The term especially belongs to steam river-craft; ocean-going craft being called steamers, steamships, etc.

The problem of the application of steam to the propulsion of vessels occupied many minds before the design was accomplished. Some had even gone so far as to make plans and test them.

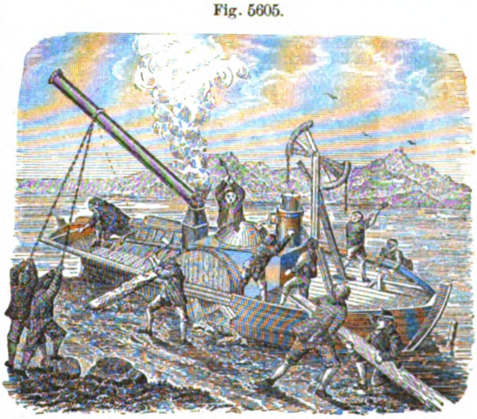
Blasco de Garay, 1543, the Marquis of Worcester, 1655, Denys Papin, 1695, Savery, 1698, and others, had prophesied, proposed, or tried steam navigation.

The modes of propulsion were applied in the following order as to date: —

Hydraulic propeller	1730
Stern paddle-wheel	1737
Artificial fins	1757
Screw	1785
Side paddle-wheels	1787
Duck's-foot side paddle-wheel	1788
Middle paddle-wheel	1789
Sets of reciprocating paddles	1789

See list under Steam. See also Propeller, pages 1808, 1809.

Fig. 5605.



Destruction of Denys Papin's Steamboat in 1695, *by the Bargemen of the Seine* (*by Figuier*).

Fig. 5605 shows a view of Papin's boat as it existed in the imagination of M. Figuier. It is next to impossible to exaggerate the merits of M. Denys Papin of Blois, but it will not be safe to warrant the illustration given by his lively countryman. The device of using wheels instead of oars, the propelling power being men or animals, was employed by the Egyptians and Romans in their war-galleys. When the Romans passed over to Sicily they were transported thither in ships moved by wheels, set in motion by oxen.

Dr. John Allen, of England, in 1730, suggested the use of the backwardly discharging pump, now known as the *hydraulic propeller*.

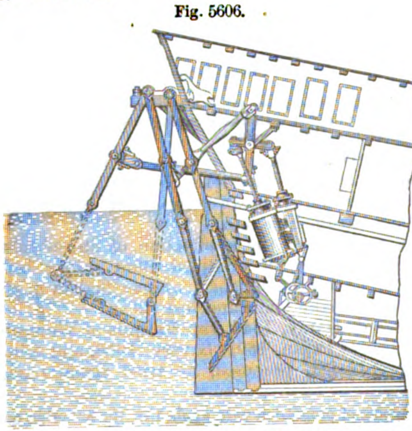
In 1737, Jonathan Hulls published a pamphlet in England describing a method of propelling a vessel by steam, for which he had secured a patent. He proposed placing the wheel at the stern, that being the proper place for it, because water-fowl pushed their web feet behind them. He used an atmospheric steam-engine, and obtained a rotary motion by an arrangement of cords and pulleys. This was before Watt's application of the crank to the steam-engine. See CRANK.

In 1757, Bernouilli (French) and Genevois (Swiss) experimented with steamboats, the first using a kind of artificial fin, and the latter the duck's-foot propeller.

In 1775 we are informed that M. Perier navigated a small steamboat on the Seine.

In 1781 the Marquis Jouffroy constructed and ran a steamboat on the Saone. Fig. 5606 shows the peculiar features of the engine and the mode of propulsion of the boat. The duck's foot seems to have formed the type. The boat was 140 feet long, 15 feet beam.

Fig. 5606.

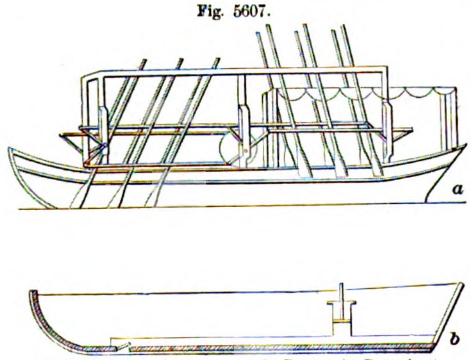


Marquis de Jouffroy's Mode of Propelling Boats.

In 1782, James Rumsey, of Sheppardstown, Va., made a public experiment on the Potomac with a boat about eighty feet long, and propelled by a steam-engine working a vertical pump in the middle of the vessel, by which the water was drawn in at the bow and expelled through a horizontal trunk at the stern. She went at the rate of four miles an hour when loaded with three tons in addition to the weight of her machinery, one third of a ton more. The whole machinery, including boiler, occupied a space but little over four feet square (see *b*, Fig 5607).

In 1786, Benjamin Franklin and Oliver Evans suggested substantially the same mode of propulsion, namely, the power of steam upon a column of water received at the bow and ejected at the stern on a line with the keel. The plan has been lately

Fig. 5607.



a, Fitch's Steamboat. *b, Rumsey's Steamboat.*

revived, and several vessels have been built in England to test it. See HYDRAULIC PROPELLER.

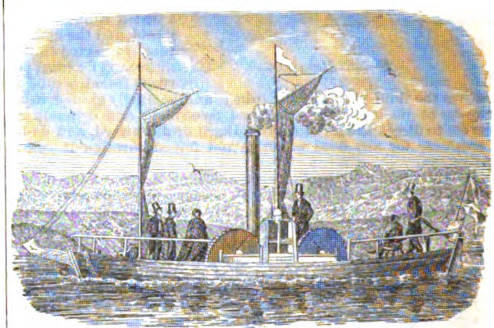
In 1786, John Fitch, a watchmaker of Philadelphia, made public his plan of paddling a ship by steam, the device resembling vertical paddles, six on each side, working alternately. His vessel was launched on the Delaware in 1788, and performed her trip of 20 miles to Burlington, where she unfortunately burst her boiler, and whence she floated back to the city. She was repaired, and made several subsequent trips. The cylinder was 12 inches diameter, had 3 feet stroke (*a*, Fig. 5607).

In 1796, he tried a steamboat, 18 feet long, 6 feet beam, on the Colleet Pond, New York City, where the "Tombs" prison now stands. The screw and paddle-wheel are said to have been used coactively in this vessel.

Fitch went West, died suddenly in 1799, and was buried at Bardstown, Kentucky.

William Symington, in 1788, applied a steam-engine to the

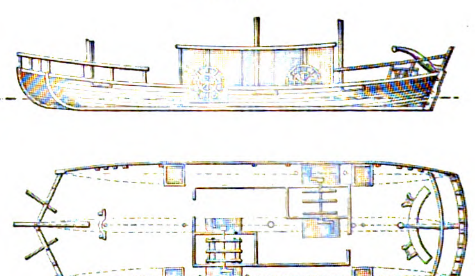
Fig. 5608.



Patrick Miller's Steamboat (1788).

pleasure-boat of Patrick Miller, of Dalswinton. This boat was furnished with side paddle-wheels, and was laid up in the winter. In 1789 a boat 60 feet long was propelled on the Forth and Clyde Canal at the rate of 7 miles an hour. Patrick Miller published an account of the invention in the year 1787.

Fig. 5609.



Miller's Boat, Dalswinton, Scotland (from his Plan in 1787).

Symington's steam-vessel, constructed in 1789, had a central space running lengthwise between the two boats, which were placed side by side and decked over. Each boat was 25 feet long and 7 feet beam, and the engine was placed on a platform. The engine had 4-inch cylinders, and drove a couple of paddle-wheels, fore and aft of the engine, which was placed amidships. The engines were atmospheric, and their pistons were connected below to an oscillating lever, or beam, much as in the present manner. Chains proceeding from the upper sides of the pistons passed over a pulley above, and the motion of this pulley, made continuous, was transmitted by an endless chain and pulleys to pulleys on the shafts of the wheels. This was substantially the same contrivance for changing the reciprocating to a rotary motion that involved the use of a ratchet and was adopted by Hulls, 52 years before.

In Symington's second boat ("Charlotte Dundas"), 1802, Fig. 5610, we find that he still kept the trough extending from stem to stern of the boat, but abandoned the wheel forward of the engine, and also Hull's chains and pulleys, adopting instead the double-acting steam-engine, connecting-rod, and crank invented by Watt some years previous to the time of the trial-trip of Symington's single-wheel steamboat.

Fulton called to see Symington, and took a trip with him.

Symington designed his boats for passenger or freight trans-

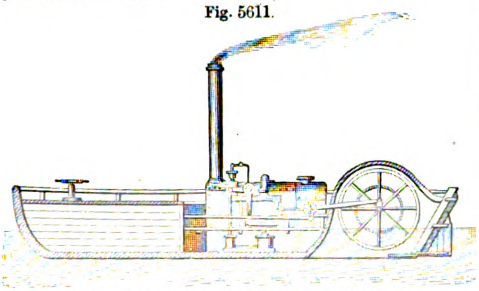
Fig. 5610.

Symington's Steamboat, "Charlotte Dundas."

portation on canals, or for towing other boats on canals, and does not seem to have used them in river, much less in ocean navigation.

His boat was used to convey passengers rather as a curiosity than as a regular business. Boats were towed by it in the canal at the rate of $3\frac{1}{2}$ miles an hour. It was abandoned from the fear (that still attends their use) that they would wash and injure the canal banks.

Fig. 5611.



The Machinery of the "Charlotte Dundas."

Oliver Evans' dredging-machine was built in 1789, by order of the Board of Health of Philadelphia. It was a flat scow, with a small steam-engine on board for working the mud-raising machinery, and propelled itself $1\frac{1}{2}$ miles on wheels to the Schuylkill, and then, by means of a stern paddle-wheel, navigated the river to its junction with the Delaware, and up that stream to Philadelphia.

Oliver Evans was a very ingenious man, and Jefferson remarked in regard to his patented *hopper-boy*, that it was "too valuable for any man to have an exclusive right to it." A curious reason truly. Jefferson, in the liberality of his own heart, carried the anti-monopoly idea to an extreme.

In 1802, Oliver Evans agreed to build a boat to run between New Orleans and Natchez on the Mississippi. The high-pressure engine was built in Philadelphia, the boat in Kentucky, but the boat was destroyed by a hurricane before the engine arrived, and the latter was used to run a saw-mill for a long period.

In 1804, John Stevens, of Hoboken, N. J., built a steamboat at his own foundry and shops, the motive-power of which was a screw-propeller with an engine supplied by a flue boiler.

In August, 1807, Fulton's boat (the "Clermont") started from New York for Albany. The Legislature of that State had promised to any persons who would accomplish the distance by a steam-vessel in 36 hours the exclusive use of the waters of the Hudson for steam-navigation. The "Clermont" performed the trip in 32 hours. Mr. Stevens built the steamboat "Phœnix," but was precluded from using it on the Hudson by the monopoly of Fulton. It was then placed on the water between New York and New Brunswick, when Mr Stevens conceived the project of sending it around to Philadelphia by sea, which he successfully carried out.

In 1808 it left New York for Philadelphia, in charge of his son, Robert L. Stevens. On the passage a storm arose, but the "Phœnix" made a safe harbor at Barnegat, whence it proceeded to Philadelphia, and plied for many years between Philadelphia and Trenton. This steamer was the first to navigate the ocean, and accomplished the distance between New York and Philadelphia in three days.

After the monopoly of the waters of the Hudson by Livingston and Fulton had ceased, Robert L. Stevens built the steamboat "New Philadelphia," and it started off at the speed of $13\frac{1}{2}$ miles an hour. The increase of speed was due to the false bow, making a sharp cut-water.

In 1827, R. L. Stevens completed and placed upon the Hudson the double-engine, large steamer "North American," which accomplished the distance between New York and Albany in about nine hours.

In 1834, Mr. Stevens established the Camden ferry line in connection with the Camden and Amboy Railway, and subsequently invented the present usual system of connections between pistons and cranks, and also the division of the paddle-board into portions arranged like steps, so as to prevent too great jar on the water.

The machinery and boat of Stevens' screw-propeller is shown in Fig. 4747, page 2071. The machinery is still preserved in the Stevens Institute of Technology in Hoboken, N. J.; in 1844 it was again placed on a boat, which it propelled at the rate of 8 miles per hour.

Mr. A. L. Holley claims for the Messrs. Stevens of Hoboken that they were the originators of many, if not most, of the improvements in modern naval warfare. He claims that the Messrs. Stevens, father and son, either originated, or first developed, the following important features of modern naval warfare: Twin screw, 1805; armor plating, 1812; inclined armor, 1812 and 1841; training guns by rotating the vessel, 1812 and 1862; engines and screws below water in war-vessels, 1841; large engines to work expansively at ordinary times, and with maximum power in action, 1841; concentrated fuel, (working to petroleum?) 1841; iron hulls for war-vessels, 1841; wrought-iron rifled gun, 1841; the Armstrong lead-coated elongated shot, 1841; concentrated protection, a central battery, a belt of armor at the water line, and a shell-proof deck, 1843 to 1854; protecting the hull by immersion to fighting-draft, by means of water let into compartments for the purpose, 1843 to 1854; wrought-iron engine-framing, and a wrought-iron ship of 420 feet length, 1843 to 1854; loading a gun below deck by steam power, 1862.

We now come to a man whom success crowned, *Fulton*. Perhaps in the fullness of the meed of praise the claims of others have been not fully regarded. He had the benefit of the previous experiences of Hulls, Jouffroy, Ramsey, Rumsey, Symington, Evans, and Fitch, and the choice of six different modes of propulsion, each of which had been used by one or other of his predecessors. He was not slow to acknowledge his indebtedness (see his letters to Bell), worked faithfully at his boat and machinery, and achieved success.

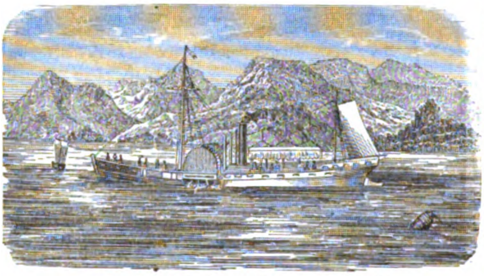
Much unnecessary acrimony has been shown in Great Britain in reference to the respective claims of the American trio, Rumsey, Fitch, and Fulton (stated in order of date), and those of Symington and Bell. The hard words have been principally bestowed upon Fulton, because he was manifestly the most practical and successful. The ungenerous and untruthful remarks seem frivolous to one who has read the pleasant and confidential correspondence that took place between Fulton, Bell, and Miller, the latter being the person that bore the expense of the Symington experiments.

Had it been possible, it would have been better for the British journalists to have written the "History of Steam Navigation," leaving out the name of Fulton. A parallel experiment has been made by the same parties in writing the "History of Electric Telegraphs," leaving out the names of Henry, Draper, Morse, Farmer, and others. Of course they have not heard of Hughes, Phelps, Edison, Stearns, Little, Anders, Pope, and House. One such treatise(?) is before the writer, and its complacent appropriation of all the glory is amusing.

Fulton visited Symington about 1801 or 1802, and they had a pleasant chat and a trip together eight miles up the Forth and Clyde Canal. Fulton spoke highly of his host's boat, and referred to the value of steam-vessels on the vast rivers of the United States. After the death of the Duke of Bridgewater, and the abandonment of Symington's plans as unsuitable *for canals*, the inventor ran his boat into a creek, where she rotted away, and the ingenious mechanic died a disappointed and impoverished man. He was faithful in his day and generation, and will not be forgotten in the history of steam-navigation. Mr Bell visited the boat in its desolate condition.

Robert Fulton was born in Little Britain, Lancaster County, Pa., in 1765, and studied as a watchmaker. He afterward studied as a painter with Benjamin West. He brought forward his ideas of steam-navigation in 1793, and corresponded with Lord Stanhope on the subject in 1794. He took out three British patents, — a double-inclined plane to be used in transportation, a flax-spinning machine, and a rope-machine. He submitted his plan for improving canal navigation to the British government in 1796, and patented it in 1797. He pursued the subject in correspondence with Earl Stanhope during his stay in France, which continued seven years. During this period he made experiments with his submarine and torpedo boat. Chancellor Livingston had designed to avail himself of the conditional grant in 1798 of the State of New York for navigating the Hudson by steam, and being U. S. Ambassador in Paris during the period of Fulton's residence there, they became mutually interested in the projects for steam-navigation. Experiments on the Seine were instituted, and in 1803 a paddle-boat 60 feet long was launched on the river. A previous boat had been broken in two by the weight of machinery. Fulton returned to the United States in 1806, and, in concert with the Chancellor, commenced the building of the "Clermont," of 160 tons. This vessel was launched on the East River, and was fitted with the Boulton and Watt steam-engine, purchased for the purpose in England.

Fig. 5612.



Fulton's Steamboat, "Clermont," 1807.

Fulton's boat, the "Clermont," ran in 1807, and had the following proportions: —

Length, 133 feet.
Depth, 7 feet.
Breadth, 18 feet.
Burden, 160 tons.
1 cylinder, 2 feet diameter, 4 feet stroke.
Paddle-wheels, 15 feet diameter, 2 feet dip, 4 feet broad.
Boiler, 20 feet long, 7 deep, 8 broad.
Speed, 5 miles per hour, up stream.
She reached Albany in 32 hours.

Fulton invented the outside bearing of the paddle-wheel shaft, and the paddle-box as a guard for the wheel. He was the first to proportion the sizes and strengths of the parts, and to bring the combination of engine and boat to a system. To him more than to any other one man is due the credit of the introduction of steam-navigation. The verdict of his countrymen is about right after all. It is not always that the general voice blends so harmoniously with the facts.

Charles Brown had built for Fulton, between 1806 and 1812, six steamboats of lengths varying from 78 to 175 feet, and tonnage 120 to 337, prior to the practical working of any steamboat in Europe.

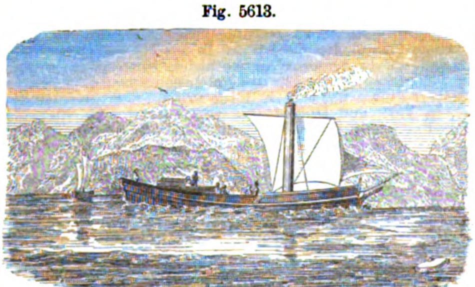
Fulton built the first steamboat on the Western rivers, at Pittsburg, in 1811. The "Orleans," of 100 tons, was a sternwheeler, took her first freight at Natchez for New Orleans, and plied for three or four years on the river between those points. She made her first trip from Pittsburg to New Orleans in 14 days. The next vessel was the "Comet," of 25 tons, in 1814. She made three or four trips, was taken to pieces, and the engine set up in a cotton factory. The third was the "Vesuvius," in 1814. She made a number of trips, but eventually exploded.

Fulton afterward devoted his attention to a submarine battery, for which he obtained a patent in 1813. In 1814 a steam man-of-war was launched under the name of "Fulton the First."

He died in 1815.

Bell's steamboat, the "Comet," was built in Greenock, and plied in 1812 between Glasgow and Greenock. It had 40 feet keel, 10½ feet beam, was fitted with a portable engine of 3 horsepower, and was propelled by paddle-wheels. He lost money by the operation, but had a safe, practical boat which made trips all round the coasts of the British Islands.

Fig. 5613.

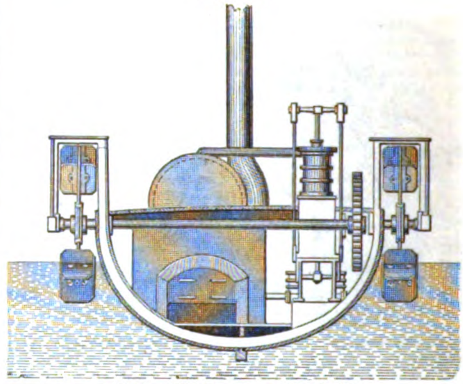


Bell's Boat, "Comet."

In 1814, there were 5 steamers making regular passage in Scottish waters, and none in England or Ireland In 1820, England had 17; Scotland, 14; Ireland, 3. In 1840, it stood thus: England, 987; Scotland, 244; Ireland, 79.

The "Majestic" was navigated from Glasgow to Dublin in 1814, by Dodd. In 1817, 7 steamboats plied on the Thames under Dodd's direction. A Parliamentary commission of 1817 stated the necessity of steam as a marine and river motor, and

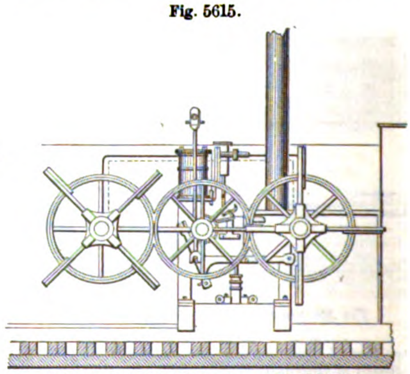
Fig. 5614.



"Comet" (Transverse Section).

cited the extensive use of the same in America, "which preceded by some years the establishment of practical steam-vessels carrying passengers in any part of Europe." (TEMPLE)

Fig. 5615.



"Comet" (Side Elevation of Machinery).

In 1818, Mr. Scarborough, of Savannah Ga., purchased in New York a ship of about 350 tons burden, which was then on the stocks, to settle the question of the ability of a steam-vessel to navigate the ocean. This ship was the "Savannah." He engaged as engineer Captain Moses Rogers, who had been familiar with the experiment of Fulton. Captain Stevens Rogers, of New London, Conn., was employed to navigate the vessel. Under his command the "Savannah," having been duly equipped with engine and machinery, steamed out of New York Harbor on the 27th day of March, 1819, bound to Savannah on her trial trip, which was successfully made.

On the 26th of May in the same year she left Savannah for Liverpool, making the trip in 22 days, during 18 of which she was propelled by steam-power From Liverpool the "Savannah" went to Copenhagen, Stockholm, St. Petersburg, Cronstadt, and Arundel, and from the latter port returned to Savannah, making the passage in 25 days.

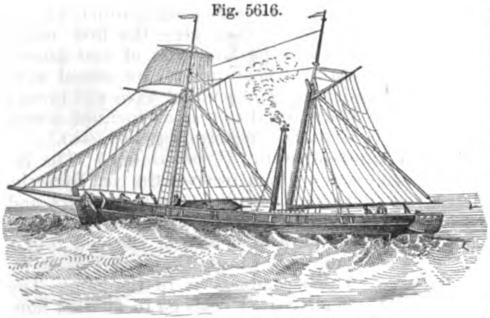
The log-book of the "Savannah" was sent to the Navy Department in 1848. Captain Stevens Rogers died in New London in 1868. The "Savannah" was built by Crocker and Ficket in New York, and her engines made at Elizabethtown, N. J.

In 1824, the "Enterprize," under Captain Johnson, made a voyage to India, doubling the Cape of Good Hope.

The "Curaçoa," in 1829, made several voyages between Holland and the West Indies.

The screw-propeller, after being several times suggested, and well proved by John C. Stevens, of Hoboken, was more distinctly noticed when brought forward by Ericsson in 1836. Ericsson's propeller, the "Francis B. Ogden," was tried on the Thames in 1837. The same year the propeller of Francis P. Smith was also tried. The latter put the screw in the deadwood. Ericsson's second vessel, the "Robert F. Stockton," was launched on the Mersey in 1838; she crossed to the United States in 1839, and was purchased by the Delaware and Raritan Canal Co. Captain Ericsson subsequently built the "Enterprize." He was the first to couple the engine directly to the propeller-shaft. He did for England and America with the screw-propeller what Fulton did in America and Bell in England for the paddle-wheel. The "Archimedes," English gov-

Fig. 5616.

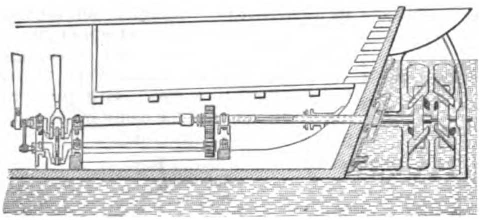


The "Robert F. Stockton" Propeller.

ernment vessel, was built in 1838, and fitted with a propeller; the "Rattler," in 1842.

In 1838 the "Sirius" and "Great Western" crossed the Atlantic from Bristol to New York, the former in 19 and the latter in 18 days.

Fig. 5617.



Machinery of the "Robert F. Stockton."

In the same year the "Archimedes," an English government vessel, was fitted with a screw.

In 1840 the famous Cunard line of Transatlantic steamers was established. The first steamer of the line was the "Britannia," which sailed from Liverpool, July 4, 1840. The company commenced with four ships, having an aggregate of 4,602 tons; the service has now grown to a fleet of 60 vessels, some of nearly 5,000 tons, and an aggregate tonnage of 120,000 tons. For 35 years the service has been regularly maintained; at first once, then twice, and more latterly thrice a week, in each direction, without the loss of a vessel, a passenger, or a mail-bag. This immunity from accident is extraordinary when we consider that the ships of the company have made over 4,000 voyages and carried 2,000,000 passengers.

The dimensions of one of the later vessels may be given. Like all the vessels belonging to the line, the "Scythia" was built on the Clyde, and, like many others of them, constructed and engined by Messrs. J. & G. Thomson, of Glasgow. This steamer is 482 feet in length between the perpendiculars, 42 feet 6 inches in molded width, and 36 feet in depth, and has a builders' measurement of 4,556 tons. The "Scythia" is propelled by compound direct-acting engines of 600 horse-power nominal, but capable of being worked up to five times that amount. The cylinders of these engines are respectively 60 and 104 inches in diameter, and the piston has a stroke of 4 feet 6 inches. The vessel is divided into seven water-tight compartments by six strong iron bulkheads, which extend from the keel up to the main deck, which latter, it may also be stated, consists of strong plated iron covered with wood. The iron plating, being securely riveted to each of the beams and ribs of the ship, adds greatly to its general strength and security. The "Scythia" is provided with twelve lifeboats of large size, all constructed on the self-righting principle, and all fitted with lowering appliances by which they can at once and safely be lowered into and placed in the water, while there is an abundant supply of life-buoys in every part of the ship. She is fitted to accommodate 1,500 individuals, including her crew. Of that number there is ample accommodation for 300 first-class and 1,000 second and third class passengers. The vessel lately made her trial trip on the Clyde, an average speed of 15 knots per hour.

The Collins line was started soon after the Cunard, but was not so successful, a number of the vessels being lost.

The rate of speed has been gradually increased, the figures being approximately as follows: —

"Savannah"	1819	26 days.
"Sirius"	1838	19 days.
"Great Western"	1838	18 days.
"Pacific" and "Baltic"	1851	9 days, 19 hours.
"Arabia" and "Persia"	1851 to 1861	9 days, 12 hours.
"Scotia" and "City of Paris"	1863 to 1866	8 days, 12 hours.
"City of Brussels" and others	1866 to 1873	7 days, 20 hours.

The following are some of the fastest trips on record: —

The "Daniel Drew" ran from Yonkers to New York, a distance of $14\frac{1}{2}$ miles, in 35′ 45″, or at a rate of over 25 miles per hour.

The "Chauncey Vibbard" ran from New York to Albany, 160 miles, in 6 hours and 40′. In deep water she averaged 24 miles an hour.

The "Mahroussee," built in England by Samuda, designed by Lang; oscillating engines by Penn, — obtained a speed on her trial trip of $21\frac{1}{2}$ statute miles an hour. Length, 360 feet; breadth, 42 feet; depth, 29 feet; wheels, 33 feet diameter; tonnage, 3,141; horse-power, 800.

An Indian dispatch-boat for the Orissa canals, built by Thornycroft, London, has a length of 87 feet; beam, 12 feet; draft of water, 3 feet 9 inches. The speed contracted for was 20 statute miles per hour. The hull, the working parts of the engines, and the propeller are of Bessemer steel, and the woodwork is of teak. The trial trip of the boat gave the following results: With tide, 25.08 miles per hour; against tide, 24.15 miles per hour; a mean speed of 24.61 miles per hour. In another official trial it was shown that the boat could keep up a speed of 22 miles per hour without losing steam.

The regularity of passage is extraordinary, as may be seen by a statement of the passages of the Inman steam-ships "City of Chester" (4,566 tons) and "City of Richmond" (4,607 tons), covering the whole of the year 1874: —

"CITY OF CHESTER." Voyage.	d.	h.	m.	"CITY OF RICHMOND." Voyage.	d.	h.	m.
First	8	1	38	First	8	11	58
Second	8	5	58	Second	8	2	38
Third	8	11	28	Third	8	9	48
Fourth	8	2	8	Fourth	8	18	23
Fifth	8	4	33	Fifth	8	7	18
Sixth	8	6	8	Sixth	8	21	48
Seventh	8	8	38	Seventh	8	2	48
Average	8	5	47	Average	8	10	38

The six largest steam-ships in the world, excepting naval vessels, are the "Great Eastern," owned by the International Telegraph Construction and Maintenance Company, 674 feet long, 77 feet broad, 22,500 tons; the "City of Pekin," belonging to the Pacific Mail Steam-ship Company, 6,000 tons, 423 feet long, 48 feet broad; the "Liguria," of the Pacific Steam Navigation Company, 4,820 tons, 460 feet long, 45 feet broad; the "Britannic," of the White Star Line, 4,700 tons, 455 feet long, 45 feet broad; the "City of Richmond," of the Inman Line, 4,600 tons, $453\frac{1}{2}$ feet long, 43 feet broad; and the "Bothnia," of the Cunard Line, 4,500 tons, 425 feet long, $42\frac{1}{2}$ feet broad. See Ship, Fig. 5001, page 2154.

Taking the largest of these, we may give the details.

PARTICULARS OF THE "GREAT EASTERN" STEAM-SHIP.

Material. *Iron.* Builders. *J. Scott Russell & Co.*

Gross tonnage	22,500 tons.
Nominal horse-power, total	2,600 H. P.
Length between perpendiculars	680 feet.
Length on deck	691 feet.
Breadth, extreme	83 feet.
Depth of side	58 feet.
Estimated draft, light	20 feet.
Estimated draft, laden	30 feet.

Screw engines. *James Watt & Co., makers.*

Nominal horse-power of screw engines	1,600 H. P.

Description. *Horizontal direct-acting (ungeared).*

Number of cylinders. *Four.*

Diameter of each cylinder	84 inches.
Length of stroke	4 feet.
Number of strokes of engine per minute	55

Kind of boilers. *Tubular.*

Pressure of steam	25 lbs.

Kind of screw-propeller. *Four blades, ordinary.*

Diameter of screw	24 feet.
Pitch of screw	44 feet.

Paddle-wheel engines. *J. Scott Russell & Co., makers.*

Nominal horse-power of paddle-wheel engines	1,000 H. P.

Description. *Oscillating.*

Number of cylinders. *Four.*

Diameter of each cylinder	74 inches.
Length of stroke	14 feet.

Kind of boilers. *Tubular.*

Pressure of steam	25 lbs.

Kind of paddle-wheels. *Common.*

Diameter of paddle-wheels	56 feet.
Length of floats of paddle-wheels (*reefing*)	13 feet.
Depth of floats of paddle-wheels	3 feet.
Total coals carried	10,000 tons.

In a recent number of the Statistical Society's "Journal," a table was given showing the number of vessels, tonnage, etc., of all the mercantile navies of the world for 1870 and 1873. It appears that in 1873 sailing-vessels had decreased — as compared with 1870 — in number by 5.44 per cent; in tonnage by 11.57 per cent; in average size by 6.67 per cent. Steamers had in the same time increased in number by 24.59 per cent; in tonnage by 54.94 per cent; in average size by 24.41 per cent. The total number of sailing-vessels was, in 1870, 59,518, with a tonnage of 16.042,498 tons; in 1873, 56,281, with a tonnage of 14,185,836: the average size being, in 1870, 270 tons; in 1873, 252 tons. Of steamers, the total numbers were, in 1870, 4,182,

with 2,793,532 tons, average size 676 tons; in 1873, 5,148, and 4,328,193 tons, averaging 841 tons each. In 1870, Great Britain carried 6,993,153 tons in 23,165 sailing-vessels, and 1,651,767 tons in 2,426 steamers; in 1873, 5,320,089 tons in 20,832 sailing-vessels, and 2,624,431 tons in 3,061 steamers.

Fig. 5618 is a transverse section through a steamer whose hold is fitted with racks for holding sides of meat for Transatlantic transportation. Such are proposed to carry the surplus meat of Texas or Buenos Ayres to a European market. The proposition has been many times made, but the instance illus-

Refrigerating-Steamer (Section through the Steamer and Barge).

trated is that of the steamer "Frigorific," 900 tons, intended for the La Plata and Paris trade. The barge shown alongside is intended for the river Seine transportation between Havre and Paris. Both ship and barge are fitted with the Tellier refrigerating apparatus, in which a low degree of temperature is imparted to an air-blast which passes around large plates cooled by the expanded vapor of methylated spirit. See ICE-MAKING, pages 1164-68, and Plate XXVI. Some of these refrigerating devices employ ice, and others cool the air by the expansion

of previously condensed vapor. See also REFRIGERATOR, pages 1910, 1911.

Steam'boat-ing. (*Bookbinding.*) Cutting simultaneously a pile of books which are as yet uncovered, that is, are *out of boards.*

Steam'boat-roll'ers. (*Coal-mining.*) The large coal-breaking rollers at the mines. The *lump* coal is dropped through holes in the platform into a hopper, thence between a pair of heavy rollers known as *steamboat-rollers,* as they give the first rough breakage and produce the large size of coal known as *steamboat coal.* These rollers are armed with steel teeth, and revolve on parallel axes and toward each other. The coal falls on to an inclined screen known as the STEAMBOAT-SCREEN (which see).

Steam'boat-screen. (*Coal-mining.*) The inclined barrel-screen which receives the coal from the first set of breakers, known as *steamboat-rollers,* and sorts it. The meshes hold the large size, known as *steamboat coal,* and pass it out at the end into a chute known as the *steamboat-chute,* which conducts it to the bin. The smaller-sized coals go to another hopper, and thence to a second pair of crushing-rollers, known as the *breaker-rolls;* thence to the long screen which sorts it into various sizes, — *pea, chestnut, stove, egg, furnace,* and *broken,* which is next below the steamboat.

Steam-boil'er. A vessel in which water is converted into steam for the purpose of supplying steam-engines, lard-tanks, pulp-digesters, cooking-vessels, dye or bleaching vats, tanks for impregnating wood with preserving solutions, and for many other purposes. A *steam-generator.*

Boilers are known by names indicating *shape,* as, —

Cylindrical. Spherical.
Hay-stack. Wagon.
Kettle.

Or *position,* as, —

Horizontal. Stationary.
Portable. Upright or vertical.

Or *use,* as, —

Locomotive. Marine.

Or *construction,* as, —

Flue. Sectional.
Drop flue. Multiflue. Return flue. { Instantaneous generators. Flashers.
Sheet flue. Internal fire.
{ Tubular. Water tube. Two-stack. Turn-over.
Drop tube. Superheaters.

Or the *inventor,* or *locality of invention,* —

Cornish. Smeaton.
{ London. Small Cornish.

The following is the official classification of steam-boilers: —

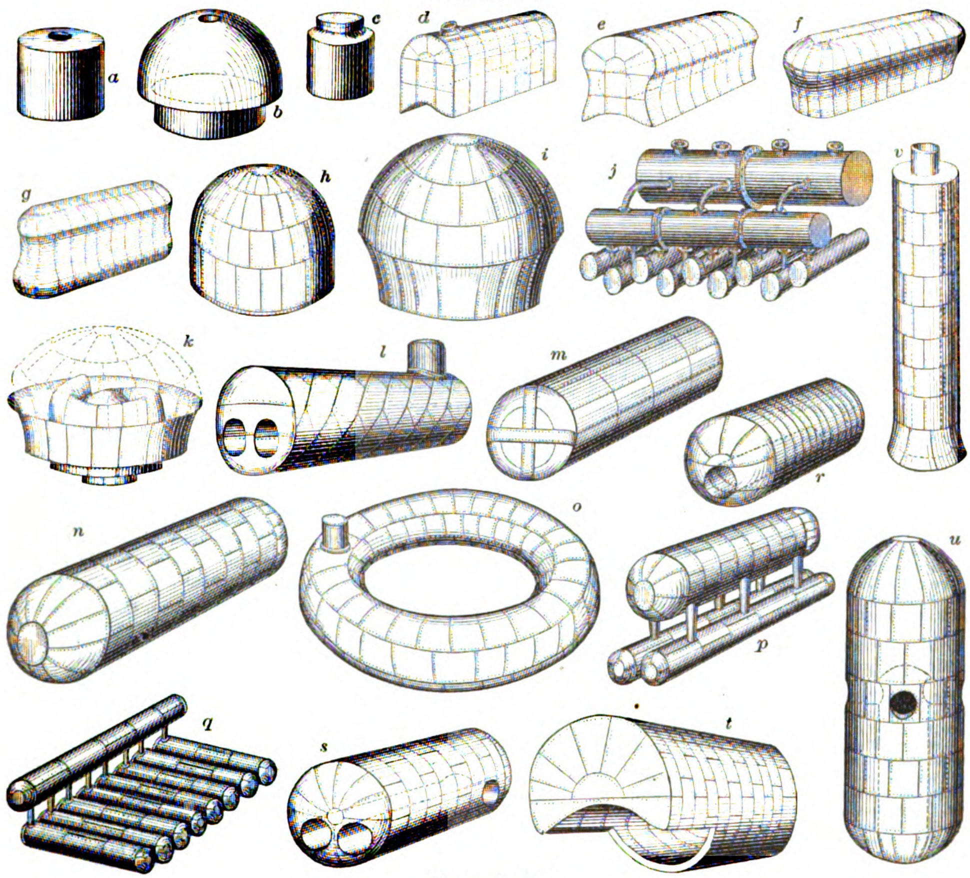
Boiler attachments.
Chemical vapor-boilers.
Cleaners.
Circulation.
Condensers.
Coverings.
Draft-regulators.
Fire-tube boilers.
Flashers.
Flue and tubular.
Furnaces.
Furnaces, hydrocarbon.
Grates and grate-bars.
Heaters and feeders.
Incrustation.
Indicators.
Sectional.
Spark-arresters.
Superheaters.
Tubes and flues.
Water fire-boxes.
Water-tube.
Miscellaneous.

The early form of steam-generator was a sphere, as seen in the Æolipile of Hero; the boilers of Worcester, Papin, and Savery. The flue wound spirally around the outside.

For this was substituted a boiler with a hemispherical top and flat or arched bottom; as in those of Newcomen and Leupold.

The wagon-boiler — so called from its shape, resembling a wagon with a tilt — was used by Watt, and continues to be used to the present day. It has some variation in its forms, and the sides are sometimes strengthened by stays against collapsing or bulging. It is only used with low pressures.

Fig 5621.



Forms of Boilers.

Fig. 5621 shows 22 forms of steam-boilers, from a report by Mr. Marten, of the Midland Steam-Boiler Inspection and Assurance Company of England.

a was the *Savery* boiler.

b, the *tun* boiler.

c, the *flange* boiler.

d e f g are forms of *wagon* boilers.

h, *haystack* boiler.

i, *balloon* boiler.

j, a boiler of nine cast-iron pipes, a transverse larger connecting-pipe, and an upper one forming a steam dome.

k, an improved *haystack* boiler, with a central dome-like fireplace and helical flue.

l, *cylinder* boiler with flues and boiler-plate head.

m, *cylinder* boiler with cast-head banded.

n, *cylinder* boiler with hemispherical ends.

o, *ring* boiler.

p, the *elephant* boiler, or French boiler.

q, the *retort* boiler.

r, the *cylinder* boiler with single flue.

s, the *cylinder* boiler with two flues opening at the front and at the sides near the rear end.

t, the *Butterley* boiler, fired internally and uniting the *wagon* and cylindrical forms.

u, *upright* boiler with hemispherical ends. *v*, *chimney* boiler.

Plate LXI. shows a variety of steam-boilers.

In Fig. 5622, *A* represents a transverse section, and *B* a longitudinal section of the wagon boiler, so termed from its resemblance in shape to the tilt or cover of the old-fashioned road wagon.

a is the fire-grate; *b b*, the flue surrounding the boiler; *c*, feed water-pipe; *d*, steam-pipe; *e*, external safety-valve; *f*, internal safety-valve; *g g'*, gage-cocks.

The feed water-pipe *c* descends in the boiler to a point below that at which the surface of the water should stand; the steam pressure within the boiler supports a column of water in the pipe, at a hight dependent on the amount of the pressure. A float *h* in the pipe is connected by a chain *i* passing over two pulleys, with a rod *j*, which supports the flue-damper. When there is an undue steam pressure on the boiler, the float *h* rises, causing the damper to fall, partially closing the flue-opening, diminishing the draft, and moderating the heat of the furnace until the evaporation within the boiler is reduced to its proper amount. If, on the contrary, the steam pressure is too low, the float *h* falls, opening the damper and increasing the evaporation.

The float *k* rests on the surface of the water within the boiler, and is attached by a wire *l* which passes steam-tight through a collar in the top of the boiler to the extremity of a lever *m*, having a weight *n* at its other end; a rod is connected at *o* to this lever, and has a valve *p* fitting a seat in the bottom of the hot-water cistern *q*. As the float *k* rises and falls, it, through the medium of the rod *l*, opens or closes the valve *p* more or less, so as to maintain the water in the boiler at a nearly uniform level. The hot-water cistern *q* is supplied from a reservoir which receives the water of condensation by means of a pump operated by the action of the engine.

The external safety-valve *e* is a lever of the third kind, whose weight may be adjusted so as to blow off at different degrees of pressure. The waste steam may be discharged into the open air or utilized for heating the feed-water. The internal safety-valve *f* is a lever of the first kind, its weight being so adjusted as to admit air to the *boiler* when the steam pressure falls below that of the atmosphere. See SAFETY-VALVE.

Fig. 5623 is a perspective view of a wagon-boiler, one half the top being removed to show the interior.

Steam-boilers, before the invention of Smeaton (1740 – 1770), were *globular*, or segments of spheres, and were *heated from the exterior exclusively*. Smeaton invented flue-boilers, so that the fire might reach the interior. He devised the horizontal, lengthened cylindrical boiler, traversed by a flue.

Oliver Evans, of Philadelphia, used a flue-boiler with his engine, which was alternately a steam-

dredge, steam-scow, and stone-saw. Patented February 14, 1804. Extended by Congress February 7, 1815.

Captain John Stevens, of Hoboken, had a flue-boiler on his boat in 1804. See SCREW-PROPELLER, pages 2070, 2071.

Trevethick had a flue-boiler in his locomotive of 1802 - 1805. It had two flues, one direct and the other reverting, the chimney being over the fire-box.

Several of the locomotives tried at the Liverpool and Manchester Railway, 1829, were similarly furnished.

The cylindrical steam-generator is a strong form, economical of material.

In one English form the fire passes underneath the boiler longitudinally, thence turns and passes alongside of the boiler, traversing a brick flue; it then crosses in front and returns along a flue on the other side; reaching the chimney after traversing three times the length of the boiler.

In the form invented by Smeaton, and usual in the United States, there are no brick flues at the side, but two or more tubular longitudinal flues in the boiler, through which the caloric current returns to the front end, and then is conducted to the chimney.

Woolf's steam-boiler, patented in England in 1803, and very successful at the Cornish mines, was an extension of the cylindrical system, a large number of cylinders of comparatively small diameter being connected together and to an upper cylindrical steam-chest.

One of his boilers having 8 tubes of cast-iron may be taken as an illustration. These tubes are, say, 6 inches in diameter, and are connected to each other by bent tubes at their extremities, having communications to a larger cylinder above, employed as a reservoir for the steam. The furnace is divided by a wall longitudinally into 2 parts, and the 8 tubes are fixed horizontally across both these.

Steam-generators with interior furnaces have been made to assume a number of forms.

Fig. 5624, Plate LXI., illustrates some of these, — *a*, section, and *b*, elevation, of oval boiler; a very old form.

c, plan, and *d*, elevation, of an old boiler with spiral flue.

e, section of cylindrical boiler with central flue, in which is the fire-space and two smaller return flues.

f, wagon-boiler, with central cylindrical flue.

Fig. 5625 shows three usual forms of boilers, —

a, the portable-engine boiler.

b, the vertical stationary boiler.

c, the single-flue cylindrical boiler with steam dome.

The boiler with *numerous small flues* was first introduced upon George Stephenson's locomotive, the "Rocket," in 1829. It was mainly by the heating surface thus obtained that it was enabled to beat Braithwaite and Ericsson's "Novelty," and Hackworth's "Sanspareil." The inventor of the small boiler-flues was Henry Booth, the Secretary of the "Liverpool and Manchester Railway Company." Flues on a larger scale had been used by Smeaton 79 years before. Linings and diaphragms used to aid circulation were invented by Jacob Perkins, and used by him and several of his pupils, and by others.

Galloway's boiler, English (Fig 5626), had a double furnace, and combines the tubular and flue construction. The main flue is supported by a series of hollow legs, around which the flame plays, and through which the water circulates. These water-legs are placed zigzag. The furnaces, being distinct, may be fired alternately, so that one will consume the smoke of the other.

Tippet's boiler (Fig. 5627), English patent, 1828, was a large cylinder with a smaller interior cylinder, which formed the fire-place and flue. From the external cylinder *a*, which contains water, proceed three rows of open vertical pipes *b b b*, which support a semi-cylindrical steam-chest *c*. At the rear of the main boiler *a* is a short pipe *d*, communicating with a short cylinder *e*, which receives the direct impact of the flame as it comes from the main flue, and from which the flame proceeds upward, enveloping the vertical tubes and coursing along the under side of the semi-cylinder, whose bottom is covered with water. The flue dives in front, passes under the main boiler *a*, beneath and back of chamber *e*, and over the top of the chamber *c* to the chimney.

In Fig. 5628, *A* is a front elevation, *B* a transverse, and *C* a longitudinal section of Horton's boiler. The upper and lower parts *a b* are cylindrical and connected by a space *c* with vertical sides, through which the transverse flues *d d* pass. The fire-spaces are in the lower flues *e e*, and the heated products of combustion after passing through these are reverted through the small flues *f f*, which expose a proportionately greater area of surface to the water above, in order to compensate for the heat lost in passing through the lower flues.

Field's boiler, *A* (Fig. 5629) has a number of vertical tubes *a* fitted into the crown sheet *b* over the fire-space. These are closed at their lower ends, but open into the boiler above, as shown at *B*, and contain smaller tubes *c*, open at both ends and funnel-shaped at top. The application of heat causes the water in the outer tubes to expand and rise through the annulus between the two tubes, while the cooler water in the upper part of the boiler flows downward, causing a rapid circulation in each direction and preventing incrustation. The upright boilers of the dummy locomotives of the Hudson River Railway, built in 1858 and 1859, had cylinders around the tubes to separate the downward from the upward currents; the down flow of solid water is between the shell and the insulating cylinder, and the up flow of foam is among and around the tubes.

Montgomery's boiler (Fig. 5630) has a series of vertical tubes *a a* passing through the central longitudinal flue *b*, and connecting the upper and lower water-spaces *c c*; a diaphragm *d*, through which the tubes pass, serves to divide their length into two portions, the flame in its hottest condition coming in contact with the portion of the tubes above the diaphragm; on reaching the back part of the flue the flames are reverted, and pass under the diaphragm to the front of the boiler, in order to reach the chimney; the object is to keep the upper ends of the tubes at a constantly higher temperature, so as to create a continuous ascending current in the tubes and down through the water-ways at the sides and ends. The steam generated in the tubes sweeps upward with the water instead of through it, and carries with it the sedimentary impurities, which tend rather to accumulate when the current descends and is relatively quiet. *e* is a steam-drum, *f* the grate.

Sectional Steam-Boilers. — Steam-boilers made in detachable portions, which are fastened together by packed or screw joints. They admit of renewal of portions as they may become worn, also of removal for scaling off the incrustation, also of building up of such number of sections as may give the heating surface and capacity desired. Such are Harrison's, Root's, etc. See *infra*. See also TUBULOUS BOILER.

Hancock's sectional boiler, English patent, 1827, consisted of vertical and parallel flat rectangular chambers, which were connected at bottom and top to preserve equality of contents, and were separated by vertical fillets which divided the intervening space into flues. The chambers are of sheet-iron, and extend across the furnace-chamber. The tendency of the flat chambers to bulge by the pressure is counteracted by the vertical bars.

Hemispherical bosses were projected from the surfaces of the plates to increase the heating surface.

Perkins' sectional boiler was intended for generating steam of high intensity, say a temperature of 700° to 1000° Fah. A series of cast-iron bars 5 inches square, perforated throughout longitudinally with holes of 1½ inches diameter, were arranged in 3 tiers, across a furnace, their ends projecting through the furnace walls, where they were connected so as to form them in continuity. Water was injected by a pump into the upper two tiers, which were kept full, and passed from thence to the lower tier. The water in the two upper tiers, at a temperature of say 700° to 800° Fah., was discharged by a valve-box into the lower tier, which was maintained at about 1000°, where it was flashed into steam, and passed to a strong steam-drum, whence it was drawn for the use of the engine.

See also Payne, English patent, No. 555, November 12, 1736 "Throwing water upon hot iron, which is immediately rarefied into elastic impelling force, to be applied to give motion to hydroulo-pneumeticall, or other engines and machinery."

Such steam-boilers are technically known as flashers. See INSTANTANEOUS GENERATOR, pages 1190, 1191, Figs. 2685, 2686.

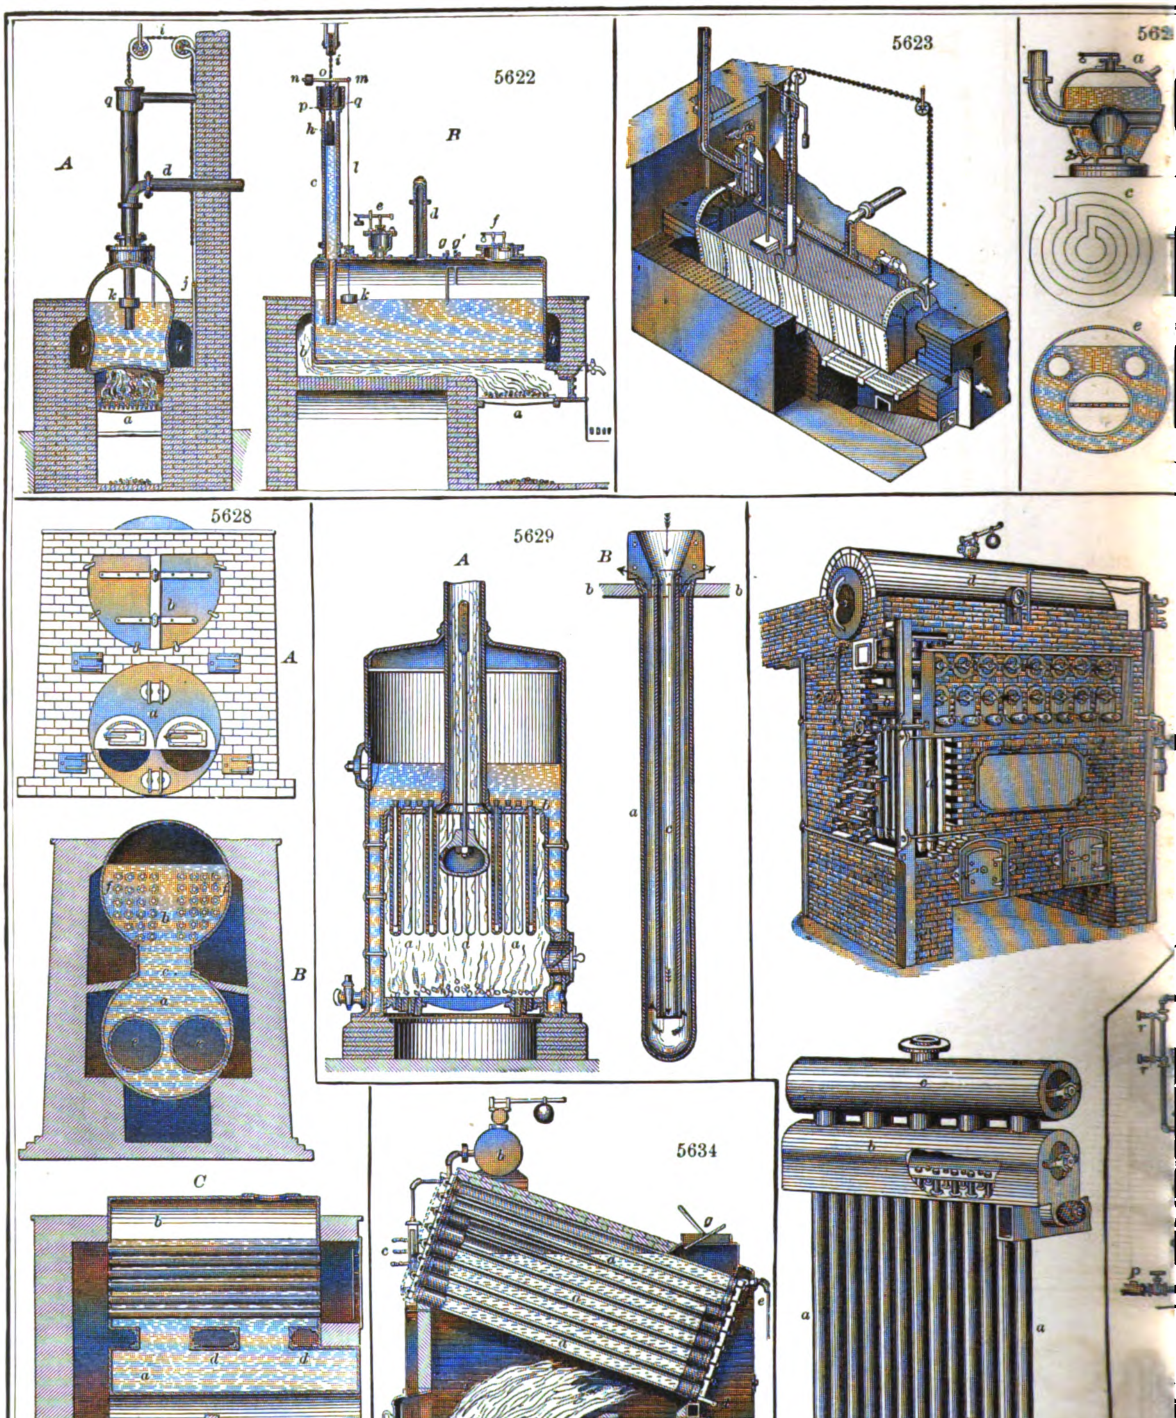
McCurdy's sectional boiler consisted of a pyramidal pile of horizontal tubes, within each of which was a tube closed at each end, and maintained by a coil of wire at a given distance from the inclosing tube. The object was to expose a thin film of water to the action of the fire. The tubes were connected by other pipes, and the water was pumped through the pipes consecutively.

Howard's sectional boiler (Fig. 5631) consists of a series of horizontal pipes *a*, from which arises a system of vertical tubes *b*. The flame of the furnace impinges against the bottom of the pipes *a*, and is diverted toward the front of the boiler, being prevented by a diaphragm *c c* from coming in contact with the upper part of the tubes *b* until, after passing through a flue at front, it is redirected backward, heating the upper portions of these tubes before entering the exit flue *d*. Within the upright tubes *b* are smaller tubes, for the purpose of causing a continuous upward and downward circulation of water.

Hancock's boiler for road locomotives, 1838, was composed of communicating sections provided with hemispherical projections on each side, and held together by stay-bolts.

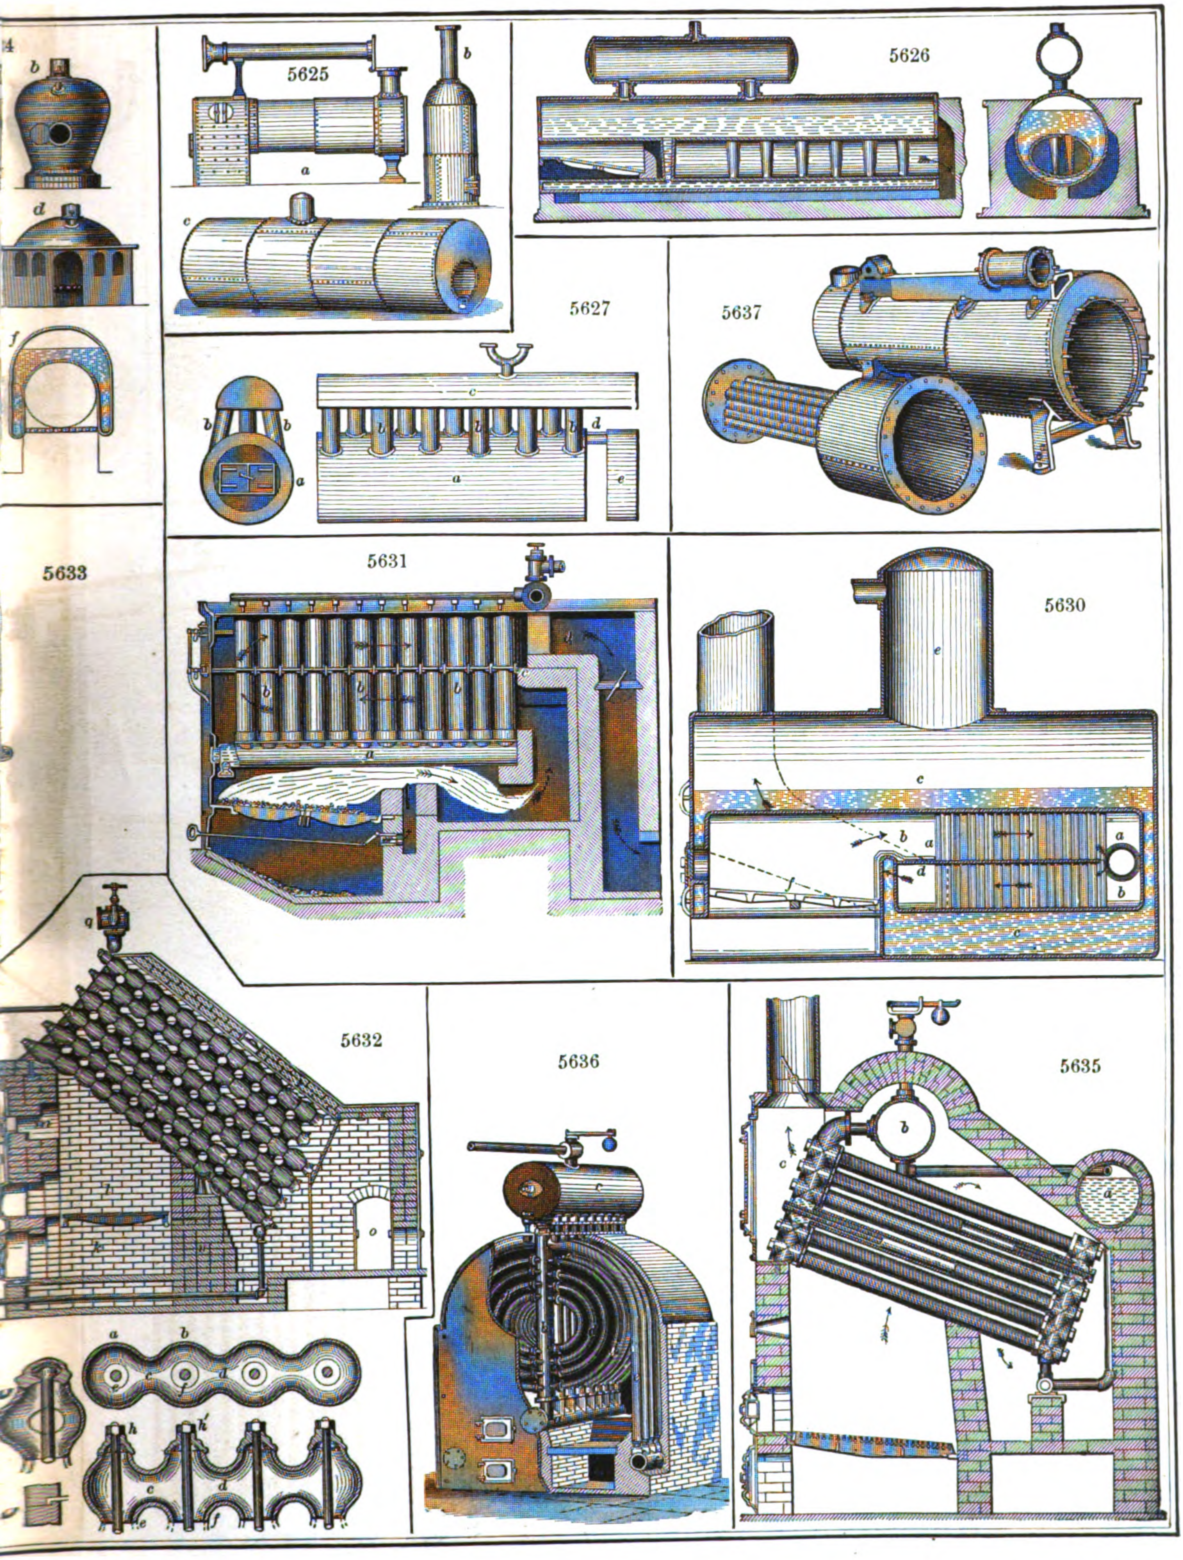
In English patent No. 111, of 1856, small retort-boilers were connected together, so that the various parts of the apparatus might be replaced, or increased steam capacity obtained by an increase of their number; and in English patent 2047, of 1857, small bottle-shaped chambers, each separately heated by gas, were connected by pipes to a common steam-receiver.

In Harrison's patent of 1859, however, we first find these general principles embodied in such form as to make the *multilocular* boiler a practical success.



VARIOUS FORMS O

PLATE LXI.



STEAM-BOILERS.

See pages 2327 - 2328.

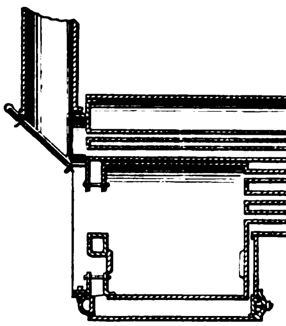


Fig. 5638.

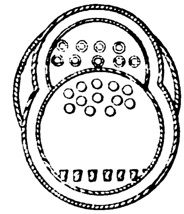


Steam-Generator.

An important feature in the Harrison boiler (Fig. 5632) was that it enabled the employment of cast-iron, and also that boilers of various forms and dimensions might be built up from the same elements, or *units*, as they are termed; these consist of sets of spherical or spheroidal chambers *a b*, etc., united by curved necks *c d*; each set or unit, which may consist of any desired number of these spheroids, is cast in one piece, particular care being taken with the cores so as to insure a uniform thickness to the walls. Other necks *e f* at right angles to the first enable any number of these units to be securely united together, so as to form steam-tight joints by means of circular rabbets *g*; the sections are held firmly together by through bolts extending from end to end of the boiler, and tightened by nuts *h h'*. These bolts also serve to hold in position the caps *i* which close the extreme sections of the boiler, and which are similarly rabbeted.

Fig. 5632 illustrates a Harrison boiler in position. It is set at an angle of about 40° with the horizontal, and properly secured at each end to the brickwork of the furnace. *k* is the ash-pit; *l*, the fire-chamber; *m*, a door through which a steam-pipe is introduced for cleansing the boiler from soot, etc., when necessary. The products of combustion are deflected upward by the bridge wall *n*, not coming in contact with the lower rear portion of the boiler until after they are diverted downward by the inclined roof of the furnace; they finally pass off through the flue *o*. A comparatively small portion of the boiler is exposed to the direct action of the flame. The boiler, when in operation, is kept about two thirds full, the upper portion serving as a steam space. *p* is the water-supply pipe; *q*, safety-valve; and *r r'*, gage-cocks.

Wiegand's sectional steam-boiler (Fig. 5633) is composed of a series of separable sections of uniform size connected to one feed-pipe and one steam-drum. Each section is made up of a double row of pipes *a* entering the bottom of a tank *b*, to which they are secured, and having removable caps *c* at bottom. These contain smaller pipes *d*, extending nearly to their lower ends, the upper ends of the small pipes being secured in a horizontal plate somewhat above the bottom of the tank. Water is supplied to and blown off from the section through the same orifice in the front end of the tank, and the steam passes from the center of the tank into the drum.

The whole apparatus, except the top of the drum, is exposed to the heat of the furnace. The tanks are filled with water to the level of the partition; the heated water ascends through the annular spaces between the larger and smaller pipes, while cooler water descends through the small pipes, maintaining a constant circulation.

Root's sectional boiler (Fig. 5634) consists of a series of wrought-iron tubes *a a a*, inclined from front to rear, screwed into square cast-iron caps, and connected at their ends by elbows. The tubes in each row alternate for convenience of cleaning, etc., and the upper tier have a common connection with the steam dome *b*, to which a safety-valve is attached. This dome and the elevated ends of the tubes serve as a steam space. *A c* are the usual gage-cocks, *d* is the feed-water pipe, and *e* the steam-pipe; *f*, the furnace. The heated gas, after circulating among the pipes, is conducted off by the chimney *g*.

Fig. 5635 is a form of steam-boiler in which the *sections* are formed of tubes united at their ends, so that currents of water are continuously circulating from the cooler to the hotter portions. The feed-water is supplied to the coolest or bottom part of the boiler from a hot-water chamber *a* above, and steam generated in the upper ends of the tubes is collected in the drum *b*. The heated products of combustion follow the course indicated by the arrows, so that the upper ends of the tubes are constantly maintained at the highest temperature, but *baffling-plates* may be provided, causing them to follow a more circuitous course to more nearly equalize the temperature at different parts of the boiler, and finally discharge them by the chimney *c*.

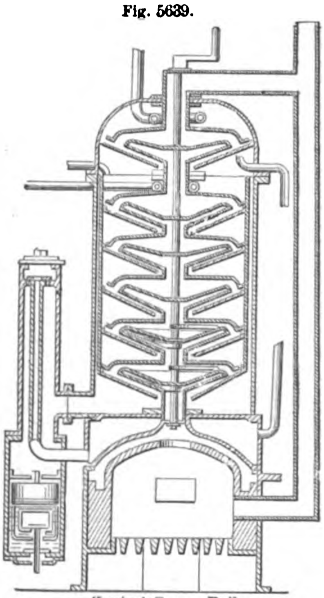
The boiler, Fig 5636, consists of a central pipe *a* resting on the partition-wall of the furnace; from this ascends a series of vertical tubes *b* communicating with the steam-drum *c*, and to which is joined the series of tubular curved sections *d d d*; other curved tubes *e* arising from pipes *f* on either side near the base of the furnace also communicate with the tubes *b* and with the steam-drum. The pipes and sections are united by screw joints, and any one which proves defective may be readily taken out and replaced by a new one. Injury or rupture of any one part leaves the remainder unimpaired. Any sediment which may be deposited is blown off through the base tubes.

A boiler for locomotives and portable steam-engines, specially constructed for being taken apart, is shown in Fig. 5637. It possesses no irregular curves or unbraced flat surfaces, but is everywhere of cylindrical form, which is the safest form for resisting pressure. It is here represented with the fire-box and tubes removed, and lying at its side. The cut shows how, by merely unscrewing a set of nuts from the front and rear ends of the boiler, the whole of the fire-box, fire-sheet, and tubes may be withdrawn. In case any incrustation on the tubes or interior surface of the boiler has taken place, it may be easily removed, after which the tubes and fire-box are replaced and firmly fixed by means of the nuts, which, through the intervention of copper-packing, hold everything together.

Fig. 5638 is a boiler of somewhat similar character, in which the fire-chamber flues, rear chamber, and reverting-flues are attached together, and are removable from the shell which forms the exterior wall of the boiler.

Many unusual forms of steam-boilers have been either suggested or made, intended to secure compactness or economize fuel. The two points are not perfectly attainable in one structure. The Cornish boiler and the locomotive are representatives of the two ends of the scale.

Fig. 5639.



Vertical Steam-Boiler.

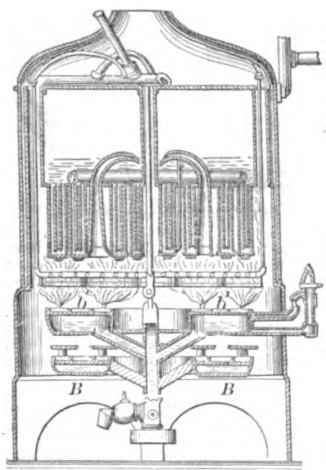
Fig. 5639 is a boiler in which a thin current of water is passed down over heated plates, flowing alternately outward and inward; the caloric current being deflected against the plates. A cold-air chamber is interposed between the arch of the furnace and the superheater. The water is pumped into the heater, which has a perforated distributor over one of the heating vessels, and is drawn therefrom through a pipe, and forced through another pipe to a second distributor that discharges into the upper part of the generator. The steam-generator communicates through a pipe with the lower side of the seat of an annular valve at whose upper side is a chamber communicating through the central opening of the valve with the superheater, so that when the pressure in the generator is in excess of that in the superheater the steam escapes through the valve-ports.

Fig. 5640 is a steam-boiler for using liquid hydrocarbons as fuel. It has a swinging reservoir *b' b'*, which is suspended in the fire-box of the generator, and has immediately below it another reservoir *B B* to contain naphtha, or other light oils, to be used in igniting the fuel in the upper reservoir. The upper reservoir is provided with a fluid-level indicator, which is placed outside the furnace, for the purpose of indicating the hight of the oil in said reservoir. In the top plates of the oil reservoir perforations are made, through which the gas escapes as it is formed, and is ignited by coming in contact with deflectors placed directly above it. Directly over the above-named deflectors are placed a series of cups for receiving and distributing the steam which is conveyed to them through the coiled pipes from the exhaust of the engine, or directly from the generator, for the purpose of being decomposed by the heat, and thus burned as auxiliary fuel.

Fig. 5641 is a coiled pipe mash-boiler for brewers' use. The

supply steam-pipe *b* and the discharge water-pipe *c* enter at the same opening in the boiler, the latter within the former, and each is so coupled with the semicircular sections of coiled pipe *f f* as to form hinges upon which the said coils swing.

Fig. 5640.



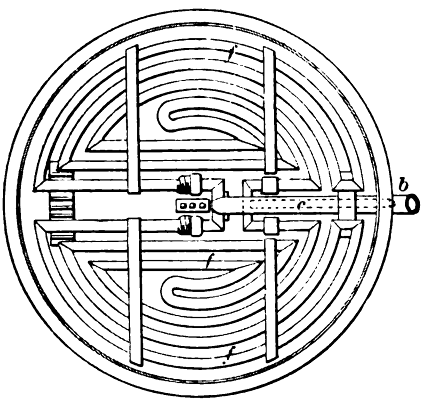
Liquid Carbon Steam-Boiler.

To obviate the destructive effect of the fire upon the boiler-plates, several plans have been proposed.

Manby, English patent, 1821, caused a circulation of hot oil through the boiler. The oil was heated in a close vessel, and conducted by a pipe to a vermicular system of pipes in the boiler, again descending to be reheated, keeping up a continuous circulation.

Alban's English patent, 1825, has a number of vertical tubes, closed below and opening above into a common steam-pipe. These tubes are plunged into a cistern of lead, which is kept in a melted condition by a furnace beneath. The water-pipe traverses the steam-pipe, and has a series of apertures on its lower side, just over the vertical tubes of the generator. The water from the feed-pipe drips into the tubes and flashes into steam. See B, Fig. 2685, page 1190.

Fig. 5641.



Brewers' Boiler.

In the cases cited, the oil and lead respectively are in contact with all the parts exposed to the direct action of the fire, and either of them yields a heat to the water sufficiently great for the generation of steam of any reasonable pressure.

" Some Cornish boilers have not less than 30 feet, or even 40 feet, heating surface to one foot of grate. This appears to be more than is justified by any corresponding gain, and certainly more than would be advisable in any marine or locomotive boiler.

" In boilers burning 13 lbs. coal per hour on each superficial foot of grate a proportion of 18 feet to each foot will be found to give good results. Where slow combustion, however, and extra size are not objectionable, advantage may be found by increasing the amount. In calculating the surfaces, it is usual not to include the bottoms of square flues, and one fourth of the surface of circular flues should be deducted on the same principle.

" Water in rapid circulation absorbs heat more rapidly than iron itself. The circulation of the water also tends to wash off the globules of steam from the surface of the metal, and thus prevents priming and also the formation of calcareous incrustation and deposition of sediment.

" 1 cubic foot of water, converted into steam per hour = 1 horse-power. 4 to 5 feet heating surface is requisite for each horse-power. Boiler should contain 4 or 5 times as much water as it boils off per hour. Steam space should be at least ten times that consumed at a stroke of the engine." — G. H. Knight.

The evaporative capacity of the *steam-generator* is predicated upon the requirements of the engine it is to serve.

The resistance on the piston being estimated, say, equal to 20 lbs. per square inch of its surface, the boiler must be capable of supplying steam at 20 lbs. pressure per square inch in such measure as to drive the piston at that speed.

Assuming the speed to be 200 feet per minute, or 12,000 feet per hour, and that the area of the piston is 5 square feet; then, to enable the piston to advance through 12,000 feet, a column of steam must follow it 12,000 feet in length and 5 square feet in its section, which gives 60,000 cubic feet of steam.

Steam having a pressure of 20 lbs. per square inch bears to the bulk of water which produces it the proportion of 1,281 to 1; therefore, if we divide 60,000 by 1,281, we shall find the number of cubic feet of water which must be supplied in the state of steam, by the generator to the cylinder, in 1 hour.

This division gives 47, nearly. The boiler, therefore, must in this case evaporate 47 cubic feet of water per hour, or, according to the conventional standard of boiler-makers, be a boiler of 47 horse-power.

Steam-boil'er A-larm'. (*Steam.*) An attachment to a steam-boiler to indicate excessive pressure of steam or lowness of water, as the case may be. See High-pressure Alarm; Pressure-gage; Low-water Alarm; Steam-gage, etc.

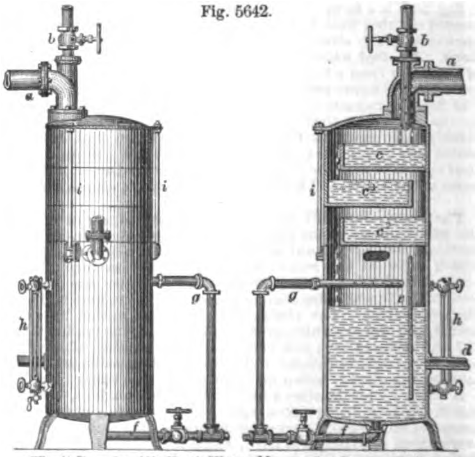
Steam-boil'er Feed'er. An apparatus for supplying water to steam-boilers. See Boiler-feeder; Feed-pump, etc.

In McMurray's apparatus (Fig 5642), the exhaust steam entering through the pipe *a* is met by the feed-water, which is discharged in a spray from the perforated foot of the pipe *b* and is condensed, being received in the pan *c*, and thence overflowing successively into the pans c^1 c^2, gradually depositing its sediment until it reaches the bottom of the apparatus, the purified water being returned to the boiler by the pipe *d*. *e* is a diaphragm extending across the lower compartment of the apparatus from a point just below the line of highest water to a short distance below the pipe *d*, in order to prevent greasy impurities floating on the surface from entering this pipe. *f* is the sediment blow-off pipe, and *g* the pipe by which grease and scum are blown off; *h* is a gage for ascertaining the hight at which the water stands. The several chambers are each in a separate compartment, and are united by bolts *i* passing through lugs on the cover and bottom compartments, so as to be readily detachable for cleaning.

Steam-boil'er Fur'nace. The chamber in which fuel is burnt, beneath or inside of a steam-boiler. Many forms are shown under Steam-boiler. Modifications bearing special names are to be found in the list under Steam-engine.

In Fig. 5643, *A* is an elevation, one side being removed, *B* a transverse vertical, and *C* a horizontal section of Smith's smoke-consuming furnace. *a* is the boiler, *b* the fire-space, *c c d d* longitudinal, and *e e* transverse flues. Air entering the flues *c c* through openings at the rear of the furnace is heated by the walls, and passing through the flues *c c* in the direction shown by the arrows, is admitted beneath the grate through the openings *f f*. The flues *d d* at the front of the furnace are provided

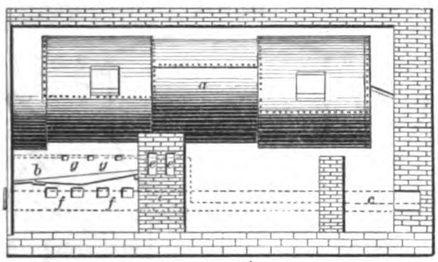
Fig. 5642.



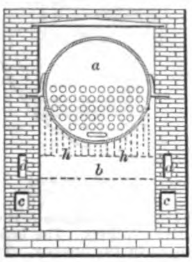
The "Standard" Feed-Water Heater for Steam-Boiler.

with registers; the air entering them is conducted through openings $g\ g$ in the walls, and openings $h\ h$, communicating

Fig. 5643.



A

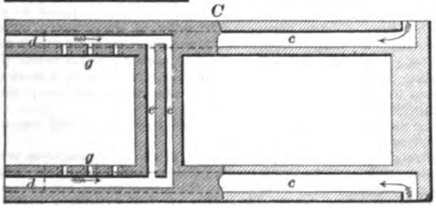


B

with the flues $e\ e$ in the bridge i, into the fire-space above the fuel, having been heated by contact with the furnace walls.

The amount of air chemically required to each lb. of bituminous coal is 150 cubic feet, of which 45 feet are required for the various combustible gases given off, and 105 for the solid carbon; *but combustion will not take place after the carbonic-acid gas bears a proportion of ¼ to the atmosphere*; the factor 150 therefore becomes

C



Smith's Steam-Boiler Furnace.

in practice $105 \times 4 + 45 = 465$ cubic feet atmosphere required in practice to 1 lb. of bituminous coal. In combustion of the gases, the bulk of the products is to the bulk of air required to furnish the oxygen as 11 to 10; the amount is therefore 50 cubic feet (not allowing for increase of temperature).

In perfect combustion of carbon, the resultant gases (carbonic acid and nitrogen) are of exactly the same bulk as the amount of air, that is, 105 cubic feet (not allowing for increase of temperature). The total amount of the products of combustion in a cool state would therefore be $50 + 105 = 155$ cubic feet; but, in practice, to this must be added $105 \times 4 = 420$, the amount of air required to dilute the carbonic-acid gas, $420 + 155 = 575$ cubic feet resultant gases.

The average temperature of a furnace being about 1000° Fah., the products of combustion are increased to about thrice their original bulk. The bulk therefore of the products of combustion which pass off must be $575 \times 3 = 1{,}725$ cubic feet. At a velocity of 36 feet per second, the area to allow this quantity to pass off per hour is about 2 square inches to each pound of coal.

Hence, in a furnace in which 13 lbs. of coal are burnt on a square foot of grate per hour, the area of flue to every foot of grate is $2 \times 13 = 26$ square inches; and the proportion to each foot of grate, if the rate of combustion be higher or lower than 13 lbs., may be found in the same way.

The system of admitting air to the gases in a subdivided form, in whatever part the admission may take place, is very advantageous.

The fires should be kept thin and open, feeding by small quantities at a time, or by *a system of coking the coal, allowing the combustion of it to be slow at first.*

The grate-bars should be as narrow as possible, making up in depth what they want in width; $\frac{1}{2} \times 4$ inch are good proportions.

The spaces between the bars should be as wide as the nature of the fuel will allow; for coal, from $^7/_{16}$ to $^9/_{16}$, according to the kind.

Space in furnace above fire-bars should be about 3 cubic feet per superficial foot of grate.

The area of the entrance of the ash-pit should not fall short of ¼ of the area of the grate, and in order to facilitate the supply to the back part of the grate the bars should incline downward about one inch to the foot; 2½ feet is sufficient depth for an ash-pit cleared out once a day. See also SMOKE-CONSUMING FURNACE.

Steam-box. A box or chest above the boiler to form a reservoir for steam. A *steam-chest.*

Steam-brake. (*Railway Engineering.*) A device for bringing the power of steam under pressure to act upon the car-wheels and stop their motion.

It has been applied in many ways: —

By mechanical devices connected between the cars of a train, and actuated by the power of the engine, or by a supplementary engine.

By a steam-winch on the locomotive winding a rope or chain which passes throughout the length of the train and actuates devices under each car.

By steam conducted by a pipe throughout the train and actuating pistons in cylinders beneath the cars, the pistons actuating the brake-levers.

By air-pipe throughout the train connecting cylinders beneath each car with an air-exhaust or air-pressure pump upon the locomotive. See BRAKE; CAR-BRAKE.

Steam Ca-nal′-boat. The first steamboats used in Scotland were made for canal purposes. Symington's first boat was built at Dalswinton and the second on the Forth and Clyde Canal. The project was abandoned when it was found that the canal-banks were likely to be injured by the swash of the wave produced. When the project was revived by Fulton, Stevens, and Bell, in 1807, it was upon the Hudson, the Delaware, and in British waters. See STEAMBOAT.

In 1871 the Legislature of New York offered a reward of $100,000 for the best practical application of steam-power to the propulsion of boats navigating the Erie Canal. About two thousand propositions were presented to the board of commissioners appointed to investigate the merits of the various plans proposed; and in order to thoroughly test the practicability of the different schemes, the board required that the competitors should place full-sized boats on the canal, which were to make actual trips both ways, carrying full loads of freight, the speed and consumption of fuel in each case being carefully observed and recorded under the supervision of the chief engineer of the board. After two years' experiment, the first prize was awarded to Mr. William Baxter. The trial-boat submitted by him had attained on her last trip an average speed of 3.09 miles per hour, consuming 14.82 pounds of coal per mile, and carrying 200 tons of freight. The nearest competitor made 2.41 miles per hour, burning 75.89 pounds of coal to the mile. The average speed of the horse-drawn boats is 1.5 miles per hour, and the cost of towage 35 cents per mile. The saving in cost of transportation by the use of steam is estimated at $3,000,000 dollars annually, assuming the present business of the canal as a basis. Boats of this kind are now habitually making the round trip from New York to Buffalo and back in two weeks, occasionally in 12 days, and a speed of 6 miles an hour has been attained on the canal without detriment to its banks. These boats are of the propeller class, and employ the Baxter marine engine, a simplified form of surface-condensing engine, which together with its boiler occupies no more room on board than the space allotted for stabling in the ordinary towage-boats. By the use of steam on the canal, it is claimed that grain may be transported from Chicago to Liverpool *via* New York in 20 days.

The Baxter steam canal-boats are about 97 feet long by 17 feet 7 inches wide, and, with a load of 215 tons, draw 6 feet of water. There are two houses on the deck, — one at the bow for the men and another at the stern for the engine. The motive-power is a common upright boiler, a trifle larger than those used for unloading ships on the docks, and a small vertical compound engine. The three cylinders are mounted on a cast-iron frame, having four uprights that serve for supports and bearings. They stand side by side, the two high-pressure cylinders at the sides, and the larger low-pressure cylinder in the center. The slides and ports for all three cylinders are placed in a small horizontal cylinder at the side, and one connection moves them all at once. The feed-pump and the pump for the condenser are connected with the small cylinders, and the rod of the larger cylinder is connected with the shaft, and the three cross-heads are united and move together. The exhaust from the two high cylinders is thrown into the low-pressure cylinder, and its exhaust is thrown into the condenser. This consists of a copper pipe that goes out board at the side, takes a turn under the boat and enters at the opposite side, and finally leads to the tank, heating the feed-water as it goes. There is no exhaust into the smoke-stack, and the water of the river or canal acts as an out-board surface condenser, and there is little waste of water.

Steam-car. A car drawn by steam-power. See STEAM-CARRIAGE; RAILWAY-CAR, etc.

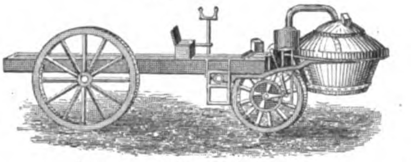
Steam-car′riage. A term of somewhat general import. A steam-driven carriage. It was originally constructed for common roads; afterward for tram

road; then for rails. (See LOCOMOTIVE.) It has now been again adapted to common roads. See ROAD-LOCOMOTIVE; ROAD-ROLLER; TRACTION-ENGINE.

Savery proposed the use of the high-pressure steam-engine for propelling carriages.

Dr. Robinson, in 1759, suggested to Watt the use of steam for the purpose; the latter afterward specified it in general terms in one of his patents, but never practically carried out the idea.

Fig. 5644.



Cugnot's Steam-Carriage.

Cugnot, a Frenchman, constructed a steam-carriage in 1769, and exhibited it before Marshal Saxe. It carried four persons at the rate of 2 to 3 miles an hour, but, owing to the smallness of the boiler, it was necessary to stop every 12 or 15 minutes to get up steam. He made a second carriage, of which several successful trials were made in the streets of Paris, but this, having upset while going at the rate of about 3 miles an hour, was considered as dangerous, and locked up in the arsenal. It is still to be seen in the Conservatoire des Arts et Métiers at Paris. Cugnot was born in 1729, and died in 1804.

In 1769, Moore, a London linen-draper, patented an invention of this kind; and in 1772, Oliver Evans obtained an exclusive right from the State of Maryland for the use of a steam-carriage devised by him.

In 1786, William Symington constructed a model of a steam-carriage, but afterward devoted his attention to steam-navigation.

In 1784, Murdoch, an assistant of Watt, invented a steam-carriage, which he tested on a road in Cornwall; and in 1789, Thomas Allen, of London, proposed a plan for constructing steam-carriages.

Trevethick and Vivian, engineers of Cornwall, patented a high-pressure steam-carriage in 1802. It was a four-wheeled carriage, the wheels of the fore-carriage being small and having a narrower track than the large driving-wheels which sustained the body.

The cylinder was horizontal, and in the rear of the hind axle. The piston-rod was forked to admit the crank, which turned a shaft having a spur-wheel gearing into a similar wheel on the driving-wheel axle. A fly-wheel was placed on the crank-shaft. The boiler was below the cylinder, and fed from the rear.

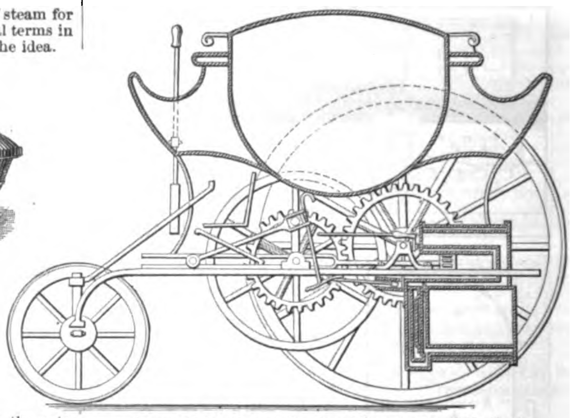
The specification cites bellows for the fire and a feed-water pump for the boiler, with divers accessories, showing a careful attention to the requirements of the case.

A steam-carriage of this description was publicly used for a considerable time previous to the introduction of railways, in the neighborhood of Euston Square, London, the terminus in after years of the London and Birmingham Railway.

Trevethick was a very ingenious and skillful engineer, and is known as the predecessor of Brunel in the construction of a tunnel under the Thames, which he had nearly succeeded in completing when the work was terminated by an irruption of water; as the inventor of a locomotive railway-engine employed in the vicinity of Merthyr Tydvil in 1804; of mining-engines and machinery and coining apparatus for the silver regions of Peru; of ore-refining furnaces; and of various improvements in steam-engines, hydraulic engines, propelling and towing vessels, discharging and stowing ships' cargoes, floating-docks, construction of docks, buoys, steam-boilers, heating apartments, etc.

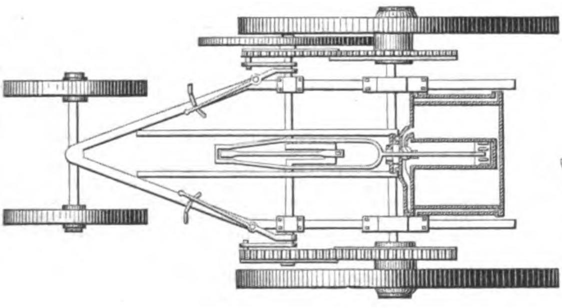
See LOCOMOTIVE.

Fig. 5646.



Trevethick's Steam-Carriage (Longitudinal Section).

Fig. 5645.



Trevethick's Steam-Carriage (Plan of Machinery).

Griffith's steam-carriage, patented 1821. The engine part of the carriage was supported on two driving-wheels. The boiler consisted of tiers of water-tubes arranged in the fire-box. The upper row of tubes, being filled with steam and exposed to the furnace heat, may be compared to some of the modern superheaters. The connection from the piston to the driving-axle was by sweep-rods, the lower ends of which were provided with driving pinions and detents operating upon toothed gear attached to the driving-wheel axle. The engine was suspended by slings inside the frame.

The machine was one of a chain of inventions, but was not otherwise practically useful.

Burstall and Hill's steam-carriage, 1824. This machine bears some resemblance to the former, having the engine and boiler behind the carriage, and applying the power to the hind wheels.

The engine had two double-acting vertical cylinders, and the pistons were connected to working-beams, whose other ends were attached to rocking-standards, which became inclined toward the cylinders as the pistons rose, and allowed the latter to move in a vertical line. At a point on each working-beam, between its connections to the piston and rock-post respectively, was attached the connecting-rod, which was keyed to the crank on the driving-axle. The cranks were at an angle of 90°, and dispensed with a fly-wheel. The machine was not successful.

James, of Birmingham, England, from 1824 to 1832, appears to have constructed several steam-carriages. He caused the engines and their framework to oscillate upon an axis, and connected these engines to the induction and eduction steam-pipes by means of hollow axles moving in stuffing-boxes, which, together with the body of the carriage, were suspended on springs bolted to the axle-trees.

The cylinders were 4 in number, and the crank was a 4-throw, the cranks being arranged at angles of 90°.

The machine was a mechanical success, but was commercially a failure.

Gordon's steam-carriage, 1824, had feet which were dropped, propelled, and lifted in regular succession.

Gurney's steam-carriage of 1825 employed legs or crutches which were operated in a similar manner to the preceding. In his patent of 1831 he abandoned the legs, and substituted horizontal steam-cylinders below the body of the carriage and act-

Fig. 5647.

Gurney's Steam-Carriage.

ing upon cranks on the hind axle. The boiler and furnace were behind the carriage, with the fireman's seat in the rear. The carriage was steered by a wheel in front, the shaft of which acted by gearing upon the fifth wheel of the fore-carriage.

Mr. Gurney seems to have been more persevering and successful than most of his predecessors, and had the benefit of their experience. He built several carriages on his plan, which ran regularly on the Cheltenham and Gloucester road for some months.

Hancock's steam-carriage, 1827, had 3 wheels, and the power was applied through the medium of 2 oscillating engines, whose piston-rods were connected to the crank-axle of the fore-wheel There were several other details that might be mentioned, did space permit. The third engine built by Hancock seems to have been well constructed, and ran for hire in the neighborhood of London. It was called the "Infant."

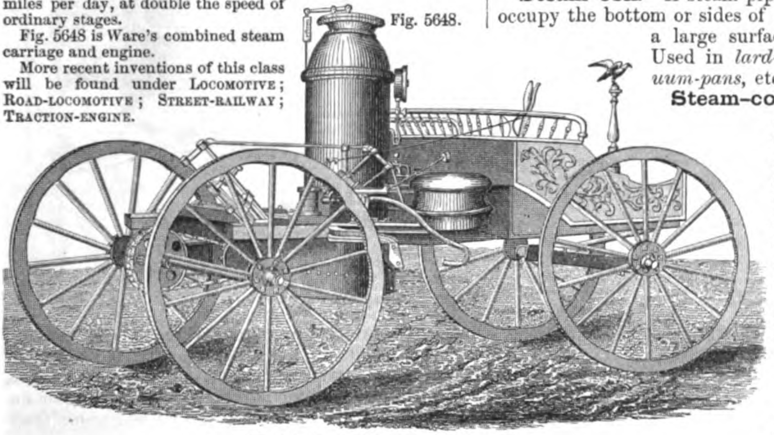
In following the record chronologically, we find the names of Gough, Summers and Ogle, Bosse and Rawe, Heaton, Napier, Palmer, Gibbs and Applegath, Church, Redmund, Squire and Macaroni, and Hills. This brings us down to 1833.

Hills seems to have been the most successful of the whole series of inventors. He traversed many of the roads leading out of London, traveling as much as 128 miles per day, at double the speed of ordinary stages.

Fig. 5648 is Ware's combined steam carriage and engine.

More recent inventions of this class will be found under LOCOMOTIVE; ROAD-LOCOMOTIVE; STREET-RAILWAY; TRACTION-ENGINE.

Fig. 5648.



Ware's Steam Engine and Carriage.

ing-box for the valve-stem being made of one piece, or rigidly connected as usual; the nut, instead of being provided on its outer surface with a screw-thread, is turned off smooth, and fitted in the socket of the shell, where it is held by a cap, the relaxation of which cap permits the nut to revolve, with the stem, to grind the valve to its seat.

Fig. 5649.

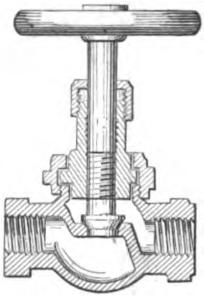
Steam-Valves.

Fig. 5650.



Globe-Valve.

Steam-coil. A steam-pipe bent into a shape to occupy the bottom or sides of a boiler, so as to have a large surface in compact space. Used in *lard-tanks, malt-vats, vacuum-pans*, etc. (which see).

Steam-col'ors. A style of calico-printing in which a mixture of dye extracts and mordants is topically applied to cloth, while the chemical reaction which fixes the colors to the fiber is produced by steam. (URE.)

The different descriptions of apparatus used in the steam process are,—

1. The *column*.
2. The *lantern*.
3. The *cask*.
4. The *steam-chest*.
5. The *chamber* (which see).

Steam-cook'ing Ap'pa-ra'tus. That in which the heat of steam in pipes or jackets is made to cook the food, without the direct action of fire by radiation, conduction, or convection. See STEAMER.

Steam-case. See STEAM-CASING; STEAM-CHEST.

Steam-cas'ing. (*Steam-engine.*) A steam-jacket around a cylinder or other object to keep in the warmth. Invented by Watt, to prevent the radiation of heat from the cylinder.

Steam-cham'ber. 1. The *steam-room* in a boiler; the space for the collection of steam, above the water-line. A *steam-dome.*

2. A chest or chamber in an apparatus in which the object is subjected to the wet heat of steam.

Steam-chest. 1. (*Steam-engine.*) A box or chamber above the boiler to form a reservoir for the steam, and from whence it passes to the engine.

2. The *steam-chest* or *box* is one form of steam-apparatus in which steam is applied to cloths, in order to fix the colors; called *steam-colors* from this mode of treatment.

The cloths are wound upon blanket-covered rollers and laid in rows in the tight chest, to which steam is then applied for about 45 minutes.

3. A steam-chest is also used for softening timber which is to be bent to a curved form, as ships' planking. See STEAM-TANK.

Steam-chim'ney. (*Steam-engine.*) An annular chamber around the chimney of a boiler-furnace for superheating steam.

Steam-cock. A valve or faucet in a steam-pipe.

In Fig. 5649, *A* is a *gland* stop-cock; *B*, a stop-cock with flanges, by which it is attached to tanks, chests, or boilers.

Fig. 5650 is a globe steam-valve, so constructed as to facilitate the grinding of a globe-valve down in its seat, the nut and stuff-

Steam-crane. A crane worked by a steam-engine; frequently carries the engine upon the same frame.

The railway portable crane (Fig 5651) has two cylinders fitted with link motion for reversing; single and double purchase gearing; and the radiating motion can be given in either direction without stopping or reversing the engine. The lifting and radiating motion may both be in action at the same time.

The locomotive steam-crane is designed to do the ordinary heavy lifting at a railway-station, and is also adapted to take itself from station to station along the line of rails.

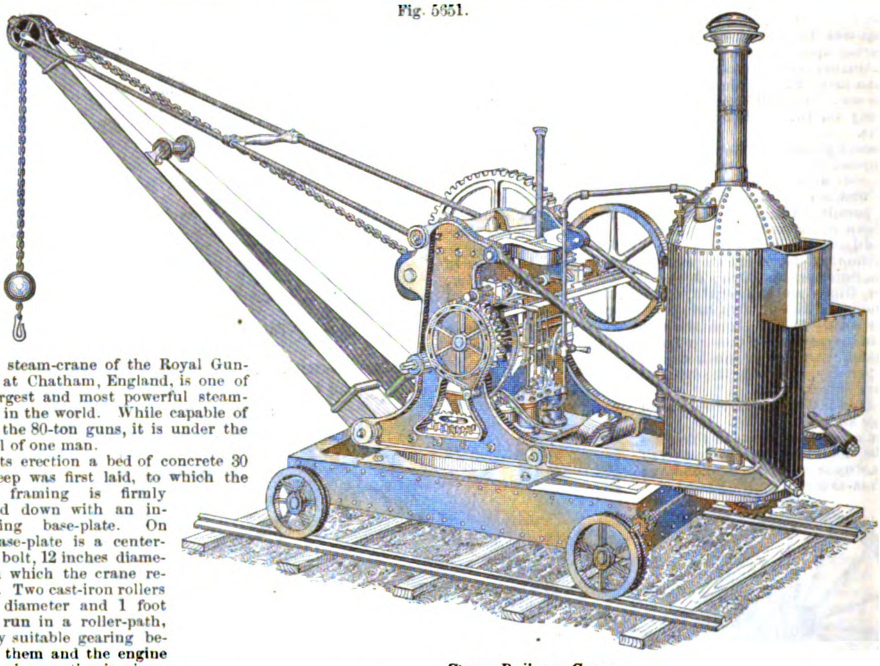
The illustration (Fig 5652) shows the crane at the Middlesborough Docks, England.

The traveling-stage or *gantry* on which it is mounted is composed of timber uprights braced and strengthened by cast-iron brackets, and two wrought-iron plate girders connected to the timber uprights by four plate-iron brackets, strengthened with angle-irons. The girders are planked over, and the traverse-circle on which the crane revolves is bolted to their ends. The stage has a hight of 17 feet 6 inches in the clear, and the rails on which it traverses are 23 feet from center to center, affording ample room for two lines of cars between them.

It is moved by gearing and shafts, which transmit the motion of the engine to the traveling-wheels; warping-drums or capstans are fitted on a countershaft on the inner side of each frame, which may be worked independently of the traveling-wheels for towing the trucks into position beneath the crane for loading and unloading. The arrangement may be modified by making the crane movable on its gantry, to adapt it to the case of a jetty to which vessels are moored on each side, or it may be fixed on an overhead traveling gantry.

The works of the crane (Fig. 5653) are carried on a flat-bottomed boat, which may be towed from place to place and moored by attachment to piles. The pile or other object to which the end of the boat opposite the derrick is fastened serves as a fulcrum to resist the strain of heavy weights, as well as to hold the boat in place.

Fig. 5651.



Steam Railway-Crane.

The steam-crane of the Royal Gun-wharf at Chatham, England, is one of the largest and most powerful steam-cranes in the world. While capable of lifting the 80-ton guns, it is under the control of one man.

In its erection a bed of concrete 30 feet deep was first laid, to which the main framing is firmly screwed down with an intervening base-plate. On this base-plate is a center-pin or bolt, 12 inches diameter, on which the crane revolves. Two cast-iron rollers 3 feet diameter and 1 foot broad run in a roller-path, and by suitable gearing between them and the engine the slewing motion is given to the crane. The top of the jib rises 36 feet above the wharf level, a circle 208 feet in circumference being described by the apparatus when being swung round. The crane is worked by a pair of reversing engines, which are supplied with steam from a vertical multitubular boiler, which, with the engines, is fitted on the main plate. The framing is of cast-iron; the jib is of two rolled girders 40 feet long, well stayed together, and secured by two tension-rods of similar length. Distance-pieces are placed between the jib and the tension-rods, which carry the chain-rollers. See also OVERHEAD-CRANE; TRAVELING-CRANE.

Steam-cyl'in-der. (*Steam-engine.*) The chamber within which the piston reciprocates. The invention of Dr. Papin, of Blois, in France. The first steam-engine with reciprocating motion. The water-raising devices of Worcester and Savary, like the toys of Baptista Porta, Leonardo da Vinci, and De Caus, were steam-pressure apparatus, approximating to pumps, not engines. The pump-cylinder, however, was much earlier, used either for water or for air. See the "Spiritalia Heronis."

Steam-dome. (*Steam-engine.*) A chamber on top of the boiler forming a steam-chest, from which the steam is conducted to the cylinder.

Steam-en'gine. The original steam-engine is the Æolipile of Hero, exhibited in the Serapeum of Alexandria, 150 B. C. It is a true rotary steam-engine, and there are quite a number of late patents in which the same principle is maintained. Originally it was a philosopher's experiment, and late attempts to utilize it have not been successful from some cause. The principle is the same as that of the turbine or reaction water-wheel, which is a very effective mode of applying the power of a head of water. (See Barker's mill, page 231.) In the Æolipile a pressure of steam is maintained internally, and the rotation is due to the recoil of the wheel in a direction opposite to that of the issuing steam. The same description will answer for the turbine, substituting water for steam in the description. The agencies differ in this respect: the steam is elastic, and the water otherwise. Whether that will account sufficiently for the success of the latter and the want of success of the former the writer is not able to state. In each it is a case of positive internal pressure and recoil, and modern inventors are loath to give it up, as the records of the Patent-Office show yearly, not understanding why a given pressure per square inch in a rotary engine on the Æolipile principle should yield a less result than the same pressure in a turbine.

It has been the fashion to call the Æolipile a "mere toy." The directness and positiveness of the invention can hardly be exaggerated. All that followed it for more than eighteen centuries were not *engines*, and had no means for running machinery directly. They were fountains or water-elevators, not even pumps in the ordinary acceptation of the word, having neither cylinder, piston, nor moving parts, except the spigots of the faucets which governed the induction and eduction of steam and water, and most of them had not even these faucets. They were neither engines, pumps, nor pumping-engines. Hero's was a true engine, and capable of work, according to its capacity, by attaching a pulley and band to the rotating shaft. Size is not an attribute but a proportion, and Hero's was a working machine of model size.

In this connection we notice that cylinders and pistons were used by Hero in his air-pumps and water-pumps (see the "Spiritalia Heronis"). They were revived again by the illustrious Papin, 1699.

Leaving steam-*engines* for a while and coming to steam water-fountains and water-elevators, commend us to the "Spiritalia" of Hero. A fine folio copy, published in France about two centuries since, is in the Patent-Office Library, Washington. It is double-column Greek and Latin, well illustrated from the original drafts, and bears the fleur-de-lis of the old French Monarque.

One great object of Hero in his devices is to surprise by accomplishing unexpected results. For this purpose he uses fire, water, and air in several scores of different machines. The air-pump is used to fill the upper part of a vessel which is partly charged with water. An eduction-pipe passes below the surface of the water, and the pressure of the air forces out the water in a fountain when the faucet is turned. In another case fire is applied, and the pressure of steam performs the same office. This is like the Baptista Porta apparatus of A. D. 1660; De Caus, 1620; Marquis of Worcester, 1655. It has been said Hero merely collected these, and probably derived much from the sublime Archimedes, with whom he was nearly contemporary. Be it as

it may, he recorded them, and we know no other author. His paternity of the Æolipile is evident from the manner in which he exhibited it to the wondering Ptolemy Philadelphus and his court, in the Serapeum of Alexandria.

"He [Hero] describes three modes in which steam is used as a mechanical power: to raise water by its elasticity; to elevate a weight by its expansive power; and to produce a rotary motion by its reaction on the atmosphere."—STUART *on the Steam-Engine*, London, 1829.

Now for a long interval, not forgetting on the way Anthemius of Lydia, one of the architects of Justinian employed on the Church of St. Sophia at Constantinople (A. D. 540). This skillful man imprisoned steam in a long pipe which proceeded from a caldron of boiling water, and caused a vibration and a roaring noise which shook the house and scared the inmates. It is not certain what the good man was after, or that anything of note resulted, unless the report be true that he was only annoying the orator Zeno, who lived next door, and there practiced his studied harangues.

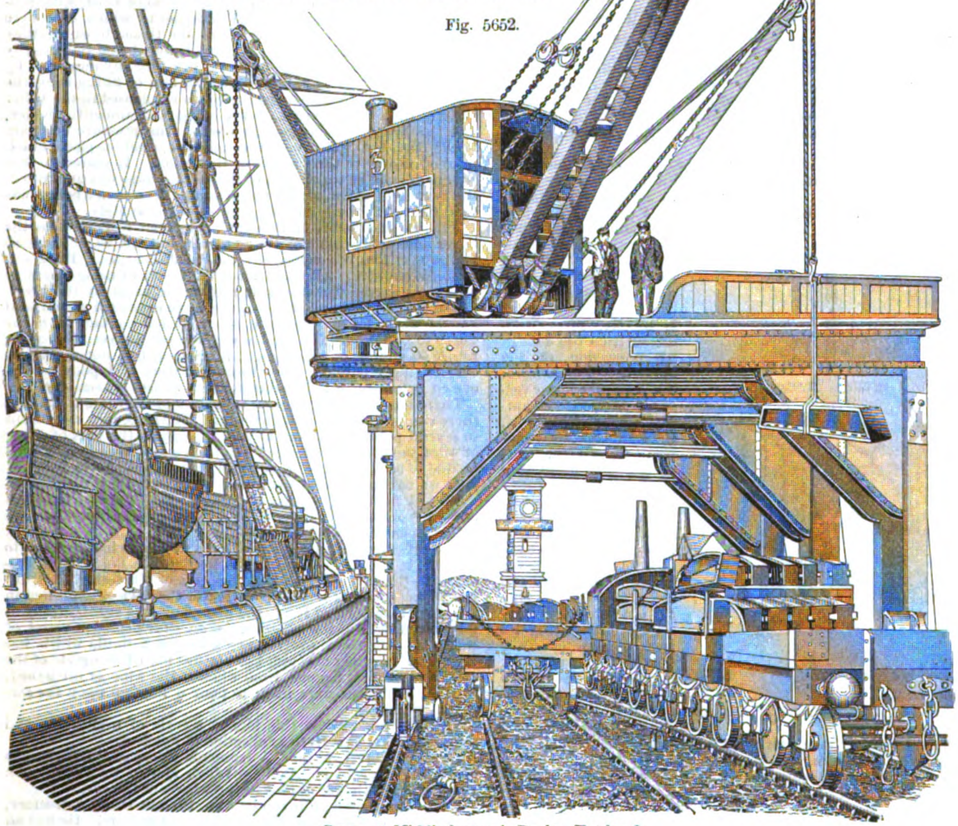
Gerbert of Rheims, A. D. 1000, had an organ played by steam: probably a blast of steam as a substitute for air; not an engine.

As Europe emerged from the transition period, called the Middle Ages, Italy took the lead in arts and sciences, as the names of Leonardo da Vinci, Baptista Porta, Galileo, and others will indicate.

Leonardo da Vinci's steam-gun (A. D 1500) is noticed under that head See STEAM-GUN.

Brancas (A. D. 1629) had a copper boiler and eduction-pipe, the steam issuing from which rotated the vanes of a shaft which worked pestles for grinding-materials, raising water by buckets, sawing timber, etc. This may be considered the first

Fig. 5652.



Crane at Middlesborough Docks, England.

BREAST-WHEEL STEAM-ENGINE (which see).

Baptista Porta (about A. D. 1600) contrived an apparatus for exhibiting the power of steam (*A*, Fig. 5654). Steam generated in a flask below and introduced into a water-chamber raised the

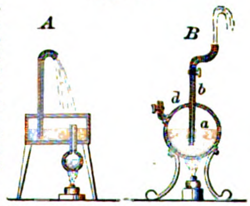
Floating Crane.

water in the discharge-pipe, as in the accompanying figure His description is too long for insertion.

Solomon De Caus, perhaps a mythical personage, about 1620, is said to have written a book, "Les Raisons des Forces Mouvantes," and to have invented an engine somewhat after the style of the annexed cut (*B*). This is like Hero's devices. The spherical vessel *a* has a nozzle and stop-cock at *b*, and another at *d* through which water may be introduced by means of a syringe. The pipe leading from nozzle *b* nearly touched the bottom of the sphere. Water is introduced as required, and the pressure of steam raises a jet of water.

Fig. 5654.



Baptista Porta's Water-Elevator. *De Caus' Water-Elevator.*

The fiction of Solomon De Caus has been used to deprive the inventors of the steam-engine of their just reputation. The romance recites how the Marquis of Worcester, at the asylum of Bicêtre, saw a miserable man in a cage, who

cried, "I am not mad! I am not mad! I have made a discovery," etc., etc. Farther, that the book of the captive, the said Solomon De Caus, was exhibited to the Marquis, who pronounced the madman the greatest genius of the age. The idea took with an imaginative people, and became a subject for painters and dramatists. Finally, grave writers on mechanics and compilers of dictionaries inserted the name of De Caus as the inventor of the steam-engine.

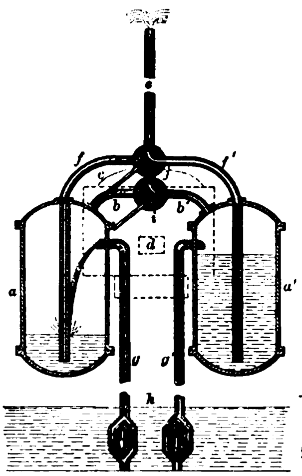
The authority for all was a letter, purporting to have been written in 1641 by Marion de Lorme to her lover, Cinq Mars. Mr Muirhead, in his life of Watt, might exclaim, "See how plain a tale shall put thee down!" There was, says he, no Marquis of Worcester in 1641. The title of Marquis was not conferred till 1642, and then upon Henry Somerset, the *father* of *the* Marquis, the author of "The Century of Inventions," and the person who was *doing* the mad-house. A French historian farther cites that Solomon De Caus could hardly have been seen at Bicêtre in 1641 in a raving condition, as he died in 1630; and farther, that Bicêtre was not a hospital in 1630 or 1641.

At all events, the device of De Caus' fountain is inferior to that of Porta, as the boiler and water-chamber are not distinct in the former.

Next in the line we behold the Marquis of Worcester, who so faithfully adhered to the faithless Charles I. and his fortunes, losing his own. Following the style of his day, he wrote in a mysterious manner, veiling his devices in superlatives, and leaving his "Century of Inventions" as a hundred "nuts to crack" for future generations. Many teeth have been ruined on them, and it is shrewdly suspected that some of them are all shell, — a stony endocarp without a kernel. Powerful jaws are still at them.

The Marquis of Worcester's "water-commanding engine," as he called it, was patented to him in 1633, and was exhibited in action at his works at Vauxhall, London. (See an elaborate but too partial digest of authorities by Dircks in his Memoir of the Marquis, London, 1865.) The accompanying cut is by Mr. Dircks, deduced from the data in his possession, of the Marquis's contrivance. $a\,a'$, two cold-water vessels; $b\ b'$, the steam-pipe; c, the boiler; d, the furnace; e, the eduction water-pipe, connected by branching pipes $f\,f'$ to the vessels; $g\,g'$, water-supply pipes; h, the well. On the steam-pipe $b\,b'$ is i, a four-way steam-cock operated by its lever handle. On the horizontal portion of pipe $f\,f'$ is a four-way water-cock j operated by its lever handle.

Fig. 5655.



Marquis of Worcester's Water-Elevator.

The four-way cock is generally credited to Watt, but this seems to anticipate him. It is the original *valve*, and still has its uses, though its glory has sadly departed.

The Worcester apparatus was in no proper sense an *engine*, but a water-raising apparatus; an expensive kind of pump. It was called by him a "water-commanding engine"; and Watt's engine was denominated by him a "fire-engine." Upon this question of names Tomlinson very justly remarks: —

"If the name 'fire-engine' had been retained, we should not have had to consider the absurd questions about 'superseding steam.' Steam is not the agent, but only the medium or instrument by or through which it acts, as our will acts by means of muscles, which it has the power of contracting. All that is required in this medium is materiality, and the property of filling more or less space by the action of fuel upon it. Steam, or rather water, is selected on account of its abundance," and other good qualities.

Air is the only other costless material: and while it probably will not produce a greater motive effect than water with a given increment of heat, it has the disadvantage of requiring a very much larger body of the medium to carry the said increment, and a corresponding increase in the capacity of the vessels in which the pressure is utilized, say the cylinder of the engine. Air also requires a more perfect packing, and lubrication of the surfaces is more imperative with dry air than with wet steam, as well as being less readily effected. Tomlinson well states that "a liquid expanding into an *air* has immense advantages over a body retaining either state unchanged. The change of state always involves a change of bulk far greater than the same change of temperature would produce on a body retaining even the aëriform or most expansible state. It seems indeed proportional, not to the change of *sensible* but of *total* heat, most of which becomes latent in the aëriform body.

"This absorption of heat is advantageous in several ways: It greatly diminishes the difficulty of retaining the heat where it is wanted, since only the sensible and not the latent heat tends to spread and equalize itself. It keeps the whole machine cooler than it must otherwise be, by the whole amount rendered latent, which in steam is near 1,000°, or enough, if sensible, to produce a *red* heat. Lastly, it leads to a most useful phenomenon which could never happen with a body retaining one constant state, such as air. Air ever so hot, and ever so cold, mixed together, would occupy nearly the same bulk as before the mixture; but steam coming in contact with such a body of water, so much colder than itself that the total heat of both is insufficient to keep both vaporous, is suddenly condensed, and the whole, becoming water, occupies some hundreds of times less space than when the steam and water were separate, although their total heat remains the same; as no time is required for the transfer of heat to surrounding bodies, the change may be made instantaneously."

Worcester's invention was a duplication of that shown as the steam-fountain of De Caus. Two boilers were used, with separate means for filling them, and branches by which they were connected with the common ejection-pipe through which they were alternately discharged. A given boiler, being temporarily shut off from the discharge-pipe, was filled by any means, — by pouring water into it, probably, for the idea of filling it by the pressure of the atmosphere as the steam condensed in the boiler had not then been devised. A fire being made under the boiler, and the branch discharge-pipe opened, the pressure of steam forced the hot water out through the ejection-pipe, which reached nearly to the bottom of the boiler. It ceased to discharge as soon as the mouth of the ejection-pipe was uncovered, the issuing of steam giving notification. The other boiler was then treated in the same way, and so on alternately.

This, as said before of De Caus', is inferior to Porta's, as the boiler and water-chamber are identical, and the water must all be brought to a boil before any can be discharged. Porta's is wasteful enough. All three missed the idea of using steam to produce a partial vacuum, and raising the water by the pressure of the atmosphere. Each of the three expended actual heat on the water by allowing the steam actual contact with the water to be raised. The time of engines was not yet. Worcester raised 40 pounds of water (hight not stated, but not much) by evaporating 1 pound. The theoretical duty of 1 pound evaporated is to elevate 1,700 pounds about 83 feet (at sea-level).

There may be many *original* inventors of the same thing, but there can only be one *first* inventor. The same idea may occur to several persons, without any knowledge on the part of either of what the other has devised. In such a case equal credit may be due to each for an original idea, but in a historic point of view we naturally insist upon the claims of the prior inventor.

Viewed in this light, that of priority, the claims of the Marquis of Worcester are reduced to a mere duplication, alternate action in each of two reservoirs.

The pressure of steam upon water, as we have had occasion to observe, in the manner contrived by Baptista Porta, 1600, Solomon De Caus (?), 1620, and the Marquis of Worcester, 1633, differs in no essential respect from one of the devices exhibited in the "Pneumatics" of Hero, 150 B. C. This was substantially as follows: A light being placed upon an altar heated a vessel of water, and the steam evolved pressed upon a liquid which was conducted by pipes through two statues placed alongside of the altar and holding flagons, from whence the wine or oil issued, so that the figures were made to pour a libation upon the sacrificial victim.

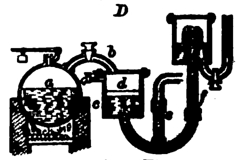
The Marquis worked this idea on a scale of usefulness, and probably never saw Hero's collection of wonders.

Father Verbrest, in his "Astronomia Europæa," 1680, speaks of driving a car by an Æolipile which ejected its steam upon wings whose axis was geared to the wheels of the car.

Next is presented an inventor who, though called a dreamer, added more to the *engine* than all his predecessors. He had an original mind, like Watt, and was fertile in resources. This was Dr. Papin, of Blois, in France (about 1695).

Papin started with one vessel (like De Caus); then separated them (like Porta); then he commenced to add items of efficiency actually new. To obviate to some extent the condensation of steam by its contact with the water to be raised, he interposed a *float*, upon whose upper surface the steam pressed, while its lower surface rested on the water, as seen in the annexed figure. The float being of wood, a good non-conductor, much of the heat would be saved, especially if the float fitted well. It was the precursor of the piston, also invented by Dr. Papin; we have, however, seen that Hero used it in water and air pumps 1,850 years before

Fig. 5656.



Papin's Water-Elevator.

Another feature may also be noticed in the apparatus of Papin. The water in contact with the float was to some extent unchanging, so that whatever warmth it acquired was

not communicated except in part to the water to be raised. *Another feature* visible in the apparatus is the safety-valve, of which Papin was the inventor.

Another feature will be detected by a description of the operation, namely, the charging of the water-chamber by atmospheric pressure incident to the condensation of steam therein. Now we begin to see sunlight in the investigation of the history of the machine.

In Papin's engine (Fig. 5656), the boiler was connected by a pipe *b* with a cylinder *c*, in which is a float *d*, resting on the surface of the water. The supply-pipe *e* has a valve opening downward, and the discharge-pipe *f* has a valve opening upward. Steam from the boiler being admitted to the cylinder *c*, the water is ejected therefrom, and passes by pipe *f* to the tank to be filled. Communication between the boiler and cylinder being closed by the faucet or pipe *b*, the steam in *c* condenses, and the pressure of the atmosphere forces water by pipe *e* to fill up the vacancy; the valve in pipe *f* closing by gravity. A repetition of the process need not be detailed.

Another feature is the air-chamber at the summit of discharge-pipe *f*. The air therein, being condensed during the entrance of the water, assists by its elasticity in discharging the water through a second ascending pipe in a continuous instead of an intermittent stream.

Dr. Papin is also the inventor of the *atmospheric steam-engine*, though his form is somewhat crude as he left it. A smooth cylinder was fitted with a piston, which was raised by the vaporization of a small body of water below it, and depressed by the pressure of the atmosphere when the steam condensed. Fire was applied directly to the lower end of the cylinder, and the downward stroke of the piston was the effective one. This was the *first* true engine since Hero.

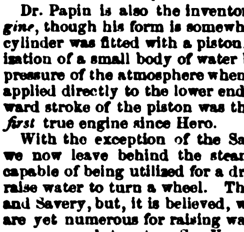
With the exception of the Savery engine, yet to be noticed, we now leave behind the steam-fountains, which were only capable of being utilized for a driving power by setting them to raise water to turn a wheel. This was proposed by both Papin and Savery, but, it is believed, was never put in practice. They are yet numerous for raising water for boiler supply, for ordinary pump duty, etc. See VACUUM STEAM-PUMP.

Papin, we see, has furnished us with a reciprocating piston-rod, and we shall see what Newcomen and Watt will do with it. The latter studied hard to convert the motion thus acquired into a rotary, and applied the crank, — he did not invent it. The crank had been used on foot-lathes for 2,000 years. Hero's engine had the rotary motion all ready to hand.

Dr. Papin has introduced us to so many improvements that it seems like going back, to consider the original Savery engine; but while we were enumerating the Doctor's services, it seemed well to complete the list, and it must be recollected that he and Savery were contemporary. It is even claimed that the idea of lifting water into a chamber by atmospheric pressure against a partial vacuum is Savery's invention. It appears to be otherwise, but was adopted by the latter in his patent of 1698, and in his joint patent with Newcomen, of whom we shall have to speak after Savery's first apparatus is described.

Savery's apparatus (Fig. 5657) is illustrated in the 21st volume of "Philosophical Transactions," A. D. 1700, the patent being granted by the astute William III. in 1698. It is stated to be "for raising water by the help of fire." The illustration shows a double apparatus, the respective portions of which are used alternately. The steam from the boiler *a*, being admitted into chamber *b*, expels the air therefrom. The cock *c* being then turned, so as to isolate the chamber *b* from the boiler, the condensation of the steam makes a partial vacuum, into which the water from the well is driven up, lifting the valve *v*. Steam from the boiler is then admitted into chamber *b*, expelling the water below and causing it to pass valve *v'* and to rise in the stand-pipe, which discharges into a tank above. The water *injection*-pipe *d* is then opened, to condense the steam, the cock *c* being turned for this purpose, simultaneously closing the steam supply and admitting water, which issues in a spray from the rose at the end of the pipe *d*.

Fig. 5657.



Savery's Water-Elevator.

Savery's engine was employed with good results in the drainage of mines in Cornwall and Devonshire, though at an expense for fuel that we should consider terribly wasteful. His was perhaps the first valuable working machine.

Hero, Leonardo da Vinci, and Papin excepted, all the preceding would read just as well as a prelude to the history of "devices for raising water"; and, with the exceptions noted, all down to and including Savery, made the raising of water their object and end. Their intention is indicated plainly in the names they bestowed on their devices: Worcester's "water-commanding engine"; Savery's "engine for raising water and occasioning motion to all sorts of mill-work by the impelling force of fire." The mill-work, as we have stated, was to be driven by water raised by the engine, and not directly by the engine. This was not yet; but Savery joined with others, and together, with what they borrowed from Papin, they made an engine capable of giving motion directly to machinery.

A controversy has arisen in regard to the respective claims of the Marquis of Worcester and Savery, and it has been much embittered by the ungenerous remarks of Dr. Desaguliers, in his "Experimental Philosophy" (1734).

While the respective engines agreed in the feature that the direct pressure of steam on the surface of water in a chamber forced the water thence and up a stand-pipe to an elevated tank, there are yet two special points to be noted in the Savery apparatus which distinguish it from Worcester's.

Savery separates the heating-chamber from the water-chamber. Worcester does not. Savery may have derived the idea from Porta or Papin, but that does not concern the matter as between him and Worcester.

Savery charges his water-chambers from a lower level by atmospheric pressure induced by a partial vacuum produced in the chambers by the condensation of steam therein. Worcester does not. Savery may have derived this from Papin, but that is nothing to Worcester.

Savery stands between Worcester and Newcomen thus: —

Worcester raises water by direct pressure of steam only.

Savery raises water by direct pressure of steam, alternating with atmospheric pressure.

Newcomen raises water by atmospheric pressure alone; steam being only used to make a vacuum.

By way of bringing another disturbing element into the inquisition, Solomon De Caus, already referred to, has been cited, and the erudite Arago had declared him the author of the modern steam-engine; but the same argument that would exalt the Frenchman De Caus over the English Marquis of Worcester would exalt the Italian Baptista Porta over the Frenchman.

Again: —

The same argument that Desaguliers uses to exalt Worcester over Savery would place the Italian Porta over the Englishmen. But Desaguliers misses the point. Papin and Savery had carried the work beyond all previous attainments, and then came Newcomen, who, as Tomlinson remarks, brought the "steam-engine to the general form and properties it has retained to this day, insomuch that there is not a single change introduced by him which has not been permanent, nor a single part or feature of his engine but continues essential in all future engines, merely improved in detail, but identical in name and principle." This is presumed to refer to engines of its class.

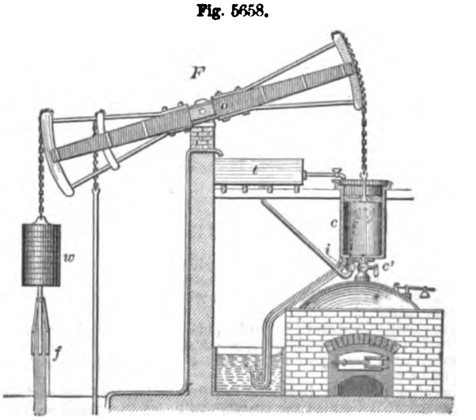
Newcomen's engine (Fig. 5658), which followed Savery's, was introduced in 1705, and perfected the principle which was initiated by Papin. It differed from Savery's in several respects. One difference has been noted. It is this: —

Savery raised water partly by the pressure of the atmosphere, and partly by the pressure of steam, the actions being alternate. Newcomen raised water by the pressure of the atmosphere, steam being employed alternately to create a vacuum. Another: —

Savery allowed the direct pressure of steam on the surface of the water. Newcomen had the pressure of the steam and air alternately on the respective sides of the piston, that of the water on a pump-piston which was attached to the other end of the walking-beam from that to which the steam-piston rod or chain is attached. The walking-beam is Newcomen's.

Newcomen separated the boiler from the cylinder; Papin, we have seen, *generated* and *condensed* his steam in the cylinder beneath the piston, which consumed much time in the alternate heating and cooling. The boiler had already been separated from the cylinder, in Papin's apparatus, and also from the reservoir in Savery's apparatus, so that it is singular that Papin should have missed this point, which gave value to the idea of the atmospheric engine.

Fig. 5658.



Newcomen's Engine.

In Newcomen's engine, the piston depended from one end of the walking-beam *a*, and the pump-rod from the other end. The pump-rod was heavy enough to sink it in the shaft and raise the steam-piston, or else a weight *w* was added. The periphery of the piston was covered with leather, and kept air-tight by water above it from a tank *t*. The cylinder *c* was placed above the boiler *b*, and steam was admitted to it through the cock *c'*, which was tended by hand, the strokes being slow. At starting, the air from the cylinder, displaced by the steam, passed down the pipe which proceeds from the bottom of the cylinder, and issued at the valve *s*, which opened upwardly. This is the *blow-valve* or *snifting-valve* of the engine. The cock *c'*, being then opened, shuts off the steam, and the cock *i*, being opened, allows injection water to enter the cylinder from the tank *t*. The water, being condensed into $^1/_{1700}$ of its bulk, formed a nearly perfect vacuum, and the atmospheric pressure of 14 pounds to the square inch bearing upon the piston depressed the latter, and consequently raised the pump-rod, the weight *w* (if any there be), and the load of water. The downward stroke only of the piston was used effectively. The pump-rod *f* was to lift water to supply the tank *t*. The water of injection and condensation passed by the pipe leading from the bottom of the cylinder to the hot-well, issuing at the valve *s*, and was used to feed the boiler.

It will be observed that the piston and pump-rod are merely suspended by chains; the action of each is to pull, — not push, — and a stiff connection was not necessary.

At first Newcomen adopted Savery's plan of external condensation, but a faulty cylinder having admitted water internally, the condensation was more rapid, with increased effect from the engine. Since that accidental discovery, internal injection has been generally adopted.

The beam, pump, internal condensation, and self-action were important additions to the previous steam-engines, earning for Newcomen and Cawley a well-deserved fame.

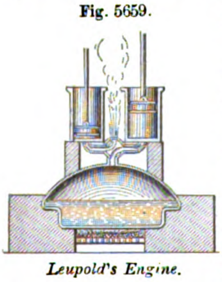
The taps which answered as valves in the Newcomen engine required the most unremitting attention of the person in charge, to introduce steam into the cylinder to lift the piston, or the shower of cold water which was to condense the steam and cause the depression of the piston by the atmospheric pressure above it. A Cornish boy, named Potter, in order to have some time for play, conceived and put in execution the idea of connecting the beam to the handle of the taps, so as to work them automatically. Hence the valve motion. For the first time, the engine worked by itself.

With the exception of Smeaton's improvements in details, the Newcomen engine remained in the state to which its inventor had brought it, from 1710 to 1764, about which time Watt appeared.

Desaguliers' steam-engine, invented about 1716, was substantially similar to Savery's. The steam pressed directly upon the water to drive it up the eduction-pipe. Cutting off the steam caused the steam in the water-chamber to condense, and atmospheric pressure again filled the chamber from the well.

Leupold, 1720 (Fig. 5659), invented an engine in which two vertical cylinders were placed parallel, their pistons being raised by the direct pressure of the steam, necessitating the use of piston-rods. A four-way cock of ingenious construction made the necessary changes of induction and eduction. The steam was used at full power, and then exhausted into the atmosphere. This latter feature was novel. The positive pressure of steam was not. Papin had used it 25 years before. The two coacting, alternate cylinders was a novel feature. The engine never had any practical importance.

Fig. 5659.



Leupold's Engine.

In 1756, Blakey took out a patent for a water-raising apparatus, as an improvement on Savery's, to avoid the condensation of steam incident to its contact with the water. To avoid this he interposed a stratum of oil or air between the water and the steam.

Smeaton devoted himself to the details of the Newcomen engine, laid down some rules for proportions, and determined a mode of measuring the power. It was formed upon the data: —

Rate of the piston.
Area of the piston.
Pressure of the steam.

The number by which he denoted the power was obtained by multiplying together, —

1. The number of feet which the piston traveled in a minute.
2. The square of its diameter in inches
3. The number of feet of water to which the pressure driving it was equivalent.

The calculations and the subject may be pursued in treatises devoted to this subject, but the result may be stated: Smeaton's dynamic unit was a power that lifts ¼ of a pound 1 foot high per minute.

Smeaton probably invented the flue-boiler, and by various improvements doubled the effective value of the steam-engine. (See DUTY.) Smeaton also invented the CATARACT (which see).

James Watt was born in Glasgow, in Scotland, January, 1737.

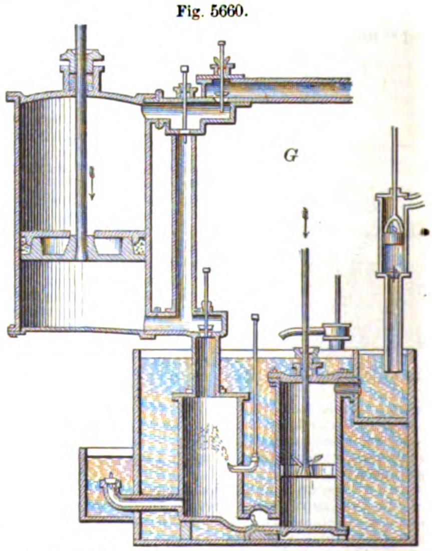
" His attention seems to have been directed to the steam-engine by a model of Newcomen's engine, which was sent him to repair. He set about repairing it as a mere mechanic; and when it was repaired and put in operation, he was surprised to find that the boiler belonging to it could not furnish a sufficient supply of steam, although apparently large enough for this purpose, for the cylinder of the model was only 2 inches in diameter and 6 inches stroke, while the boiler was about 9 inches in diameter. By blowing the fire the machine was made to effect a few strokes, but it required an enormous quantity of injection-water, although it was very lightly loaded with the column of water in the pump. It soon occurred to him that this was caused by the fact that the cylinders of small engines expose a greater surface to the condensation of their steam than the cylinders of large engines, in proportion to their capacity. He seems to have been well aware of the mathematical principles, that solids are to one another as the *cubes* of their dimensions, but that their surfaces are to one another only as the *squares* of their dimensions. He found, by shortening the column of water in the pump, the boiler could be made to supply the cylinder with steam, and that the machine would work regularly with a moderate quantity of injection-water. He also found that the cylinder of the model, being made of brass, conducted heat much faster than the cast-iron cylinders of large engines, and that considerable advantage would be gained by making the cylinders of some substance that would conduct heat slowly. Wood seemed most likely to answer this purpose, provided it were found sufficiently durable. Accordingly he made a small engine, of 6 inches diameter and 12 inches stroke, of wood, soaked in linseed oil and baked to dryness. With this engine he made many experiments; but he soon found that the wooden cylinder would not prove durable enough, and that the steam condensed in filling it still exceeded the proportion of that required for large cylinders, according to the statements concerning them, given by Dr. Desaguliers. He found, also, that all attempts to produce a better state of exhaustion, by throwing in more injection-water, occasioned a disproportionate waste of the steam. Meditating on the cause of this, he attributed it to the fact that water boiled *in vacuo* at low heats (100° Fah.), — a discovery made by Dr. Cullen, the predecessor of Dr. Black in the University of Glasgow, — and he naturally inferred that at greater heats the water in the cylinder would produce a vapor which would partially resist the pressure of the atmosphere. We now know that the vapor of water at 180° is equal to half the pressure of the atmosphere."

Watt made experiments on the power of steam by means of Papin's digester.

See also Muirhead's " Mechanical Inventions of James Watt," London, 1854.

The single-acting steam-engine of Watt is shown at Fig. 5660.

Fig. 5660.



Watt's Single-Acting Steam-Engine.

Watt, after the invention of the separate condenser and *air-pump*, which go together (see CONDENSER), devoted himself to farther improvements.

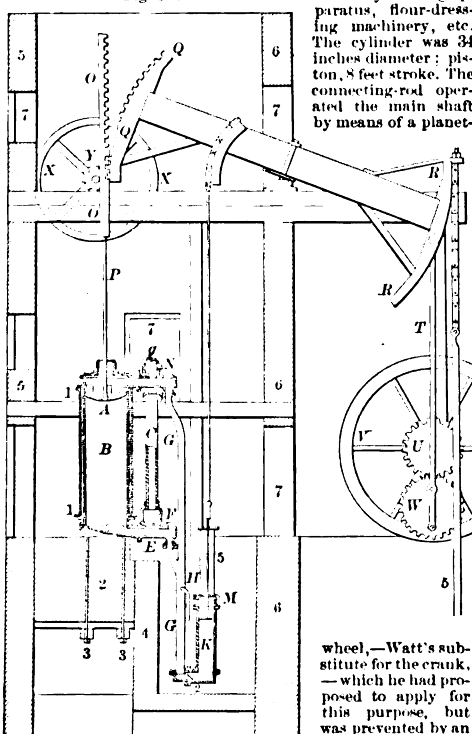
He added a *jacket* to the cylinder, and surrounded the latter with an envelope of steam to prevent its cooling.

He substituted for the open cylinder of the Newcomen engine and the piston covered with water a *cover to the cylinder* and a *greasy packing*.

He next sought for a means of excluding the air from the cylinder above the piston, in order that the heat of the cylinder might be maintained. For this purpose he admitted a body of steam above the piston, merely to occupy the space at first, but afterward he substituted *pressure of steam* for the *pressure of the atmosphere;* and finding that he could obtain a pressure greater than that due to the atmosphere when the space below was nearly a vacuum, he constructed that form of engine, the *double-acting* In doing this he adopted the *stuffing-box*, the invention of Sir Samuel Morland.

Watt made double-acting engines in 1782, and soon after that date put up two of them, of 50 horse-power each, at the Albion Flour Mills, Blackfriar's, London. They jointly drove 20 pair of mill-stones with the necessary hoisting apparatus, flour-dressing machinery, etc. The cylinder was 34 inches diameter; piston, 8 feet stroke. The connecting-rod operated the main shaft by means of a planet-wheel,—Watt's substitute for the crank,—which he had proposed to apply for this purpose, but was prevented by an interloper, who stole his idea and patented it See Fig 1692, page 722, Vol. I.

Fig. 5661.



James Watt's Double-Acting Steam-Engine (from original sources).

The following is from the inscription on the original drawing:—

"Fig. 12th [it is one of a number of figures on a broad sheet] Represents the New Improved Engine the Piston of which is pressed forcibly both Upwards and Downwards by the Powers of Steam.

A. The Piston.
B. The cylinder or Steam Vessel.
C. A Pipe which brings Steam from the Boiler to a lower Regulator box or Nozle.
D. The place of a Regulating Valve, which admits Steam into the upper end of the Steam Vessel.
E The place of the Regulator which admits Steam below the Piston.
F. The place of a Regulator which lets Steam go out from below the Piston into the Condenser.
N. Place of a Regulator which discharges the Steam from above the Piston.
G G. The Eduction or Condenser Pipe.
H. The Injection Pipe.
J. The Hot-water Pipe.
K. The Air Pump
L. A Valve at the Eduction Pipe foot.
M. A passage from the Air Pump to the Hot-water Pump.
O O. A Toothed Rack which connects the Piston Rod and the Working Beam.
P. The Piston Rod.
Q Q. A Toothed Sector or Arch which also serves to assist the Piston in its descent.
Q R. The Working Beam.
S S. The Pump Rod which is made double when the Rotative Machinery is used.
T. The Connecting Rod of the Rotative Machinery.
V. The Wheel fixed upon an Axis.
W. The Wheel fixed to the Connecting Rod.
V V. The Fly.
X X. The Fly of the Reciprocating Rotative Motion.
Y. The Pinion by means of which it acts is acted upon by the Working Beam.
g. The pipe which brings Steam from the Boiler.
1. The steam case which surrounds the cylinders.
2. The platform on which the cylinder stands.
3. Beams which support it.
4. Wall of the Condenser Cistern.
5. Back wall of the Engine house.
6. The Lever wall.
7. Doors and Windows."

It will be perceived that the fly-wheel is connected to the working-beam by a "sun and planet" motion. This was adopted as a substitute for connecting-rod and crank; a motion which was well known to Watt, and which he had designed using, but which was surreptitiously patented by another party, with the result of depriving the Boulton and Watt engines of its use. It was used on the "Charlotte Dundas" steamboat, built by Symington. This, by various modifications, made the Cornish engine substantially as we know it, but the actual improvements in detail of construction and excellence of workmanship have been vast. Watt never saw a good power-lathe or a planing-machine of any kind.

Watt next proposed, in certain cases where cold water was scarce, to abandon the condenser and allow the steam to exhaust into the atmosphere, thus reviving Leupold's idea of 1720. This is one feature of the ordinary high-pressure engine, but Watt was always afraid of high-pressure, and though he included a steam-carriage in one of his patents, it was not a success until Trevethick and Vivian built their steam-carriage, in 1802. See Steam-carriage.

Thirteen years after Watt's first patent, that is, in 1782, he obtained another patent, in which he describes and claims the working of steam expansively; that is, cutting off the supply of steam from the boiler to the cylinder after the latter has been partly filled, and allowing the steam to expand during the remainder of the stroke. See Cut-off.

The conversion of a reciprocating into a rotary motion was long a puzzle to mechanicians.

Papin tried to avoid the problem, suggesting the direct action of the steam on a kind of wheel. A rotary engine. Watt repeated this 70 years afterward, and included it in his first patent, but neither he nor Papin accomplished anything in that line.

Papin suggested another plan, which was adopted a century afterward, but was abandoned more than half a century since. It consisted of a pair of pistons acting alternately on a wheel or axle, each pulling it round, while the other was being drawn back to its starting-place by a weight disconnected with the revolving parts. The alternate reciprocating motion was used upon a number of carriages and boats before the crank was generally adopted.

Hulls, in 1737, used an arrangement of cords and pulleys, involving the use of a ratchet. This was repeated by Symington in 1789.

The Newcomen engine, which was doing the heavy work from 1705 to 1770, or thereabouts, had no rotary motions, but employed a walking-beam, with arcs upon the ends, from which the piston and pump-rod were respectively suspended by flexible connections. No parallel motion as yet, and no rotation.

Watt applied the crank Such men are not impostors; and this meek, earnest man says:—

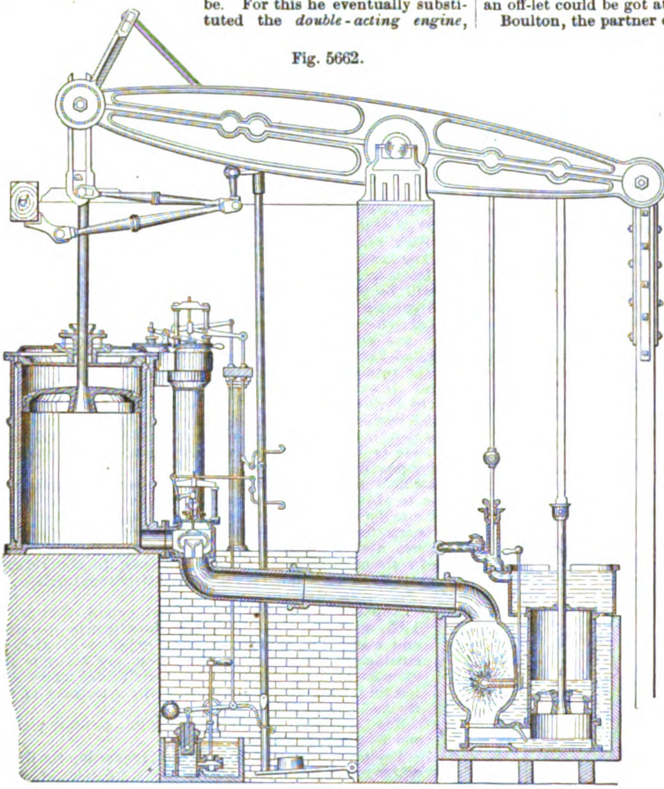
"The true inventor of the crank rotative motion was the man, whose name unfortunately has not been preserved, who first invented the common foot-lathe. The applying to the steam-engine was merely taking a knife to cut cheese which had been used to cut bread." The device designed to be applied by Watt was pirated by a man who overlooked a sketch of the machine, and, rushing to London, patented it. It would be a pity to embalm the name of a scoundrel by recording it.

The use of a crank to change a rotary to a reciprocating motion, the inverse of the Watt proposition, was not new at the date. A 4-throw crank was employed on each end of the wallower or lantern-wheel which was driven by the water-wheel under the north end of London Bridge, as described by Beighton, 1731. The water-wheel was first placed there by Morice in 1582, but the mode of driving the pump-piston from the rotary-shaft is not known to the writer.

To make the rotary motion continuous, passing the dead points was the next problem, and various suggestions seem to have been entertained. The crank, receiving an impulse in one direction, might then be abandoned to the momentum of a counter-weight which was raised the previous stroke. This weight might be placed on a wheel, and constitute a fly-wheel. Better still, a positive motion might be given to the crank in each direction. For this purpose, Watt arranged 2 or 3 engines acting

on as many different cranks on the same shaft, and arranged at 180° or 120° apart, as the case would be. For this he eventually substituted the *double-acting engine*,

Fig. 5662.



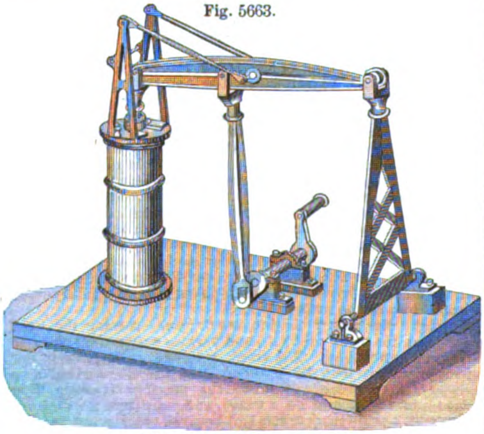
Cornish Steam-Engine.

which served the purpose of two, acting alternately, within the compass of a single cylinder and piston.

For the purpose of communicating a vertical motion to the pump-rods and plug-rod from an engine-beam which oscillated on a horizontal axis and described arcs, Watt contrived the PARALLEL MOTION (which see).

Watt's governor was adopted from an ancient device in windmills. A pair of balls are suspended by jointed rods from a collar on a rotating axis. According to the speed of the latter such is the lateral extension of the balls, that their divergence under the centrifugal effect of the rotation is made to operate through certain devices upon the throttle-valve, by which steam passes from the boiler to the cylinder. See GOVERNOR.

Fig. 5663.



Oliver Evans' Steam-Engine.

He also devised the mode, since adopted, of removing the water, which, he says, might be run off by a descending pipe if an off-let could be got at a depth of 30 or 35 feet.

Boulton, the partner of Watt, who, by business tact and sterling sense, smoothed the asperities of the road for his studious and previously desponding friend, was proud of his vocation, and is described by Boswell as "*an iron chieftain, with 700 work-people, and the father of his tribe.*" The works of Boulton — afterward Boulton and Watt — were established in Birmingham, 1764. Steam-engines were made there in 1774.

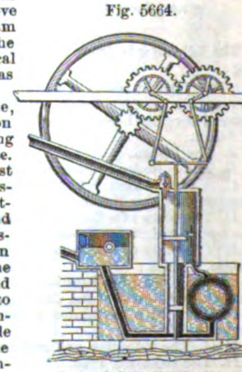
The first trial of the "Watt engine" took place in Cornwall under the inventor's supervision. The sea had broken into a copper-mine in that county, and the owners were unable to cope with the waters. Boulton, with his accustomed enterprise, announced that he had an engine which would retrieve the disaster. To back his own statements, he offered to supply the engine for a royalty of one third of the proved saving of coal as compared with the Newcomen engine. The offer was accepted. Watt toiled and ran the engine, making a register to mark the number of strokes, so that the duty performed might be positively ascertained. The saving of coal, for a given number of hogsheads raised, was found to be 75 per cent over the Chacewater engine on the Newcomen principle, which amounted to £7,200 per annum. The economy and effectiveness of the Watt engine were then fully admitted, and orders for the "fire-engine," as Watt called it, flowed into Soho.

Pirates commenced work immediately, and law expenses gobbled up the money of these men, of whom the world was not worthy. The separate condenser, which gave especial character to the "Watt condensing-engine," was a boon to the Cornish miners, and as such they appropriated it. The studious and conscientious Watt hated a lawsuit, with its lies and vexations, and retired on a moderate competence due to the extension of his patents to the year 1800.

The Spanish cinnabar-mine of Almaden is one of the last places where one would expect to find one of Boulton and Watt's original engines, but it appears that one was erected there in 1799, and has been at work ever since.

Fig. 5663 illustrates the parallel motion invented by Oliver Evans. The working-beam, also known as the *grasshopper-beam*, connected at one end to the piston-rod, was pivoted at the other in a rocking frame; it was connected near its mid-length with two standards secured to the cylinder head by two rods which were pivoted to these standards and to the beam; the effect being that while the rocking-frame, the crank connecting-rod attached to the piston near its center, the two rods above named, and the working-beam itself, vibrated freely as the crank revolved, the vertical movement of the piston-rod was not interfered with.

Fig. 5664.



Cartwright's Engine.

Cartwright's steam-engine, 1797, had a long piston-rod, on which were two pistons working in two cylinders of varying size. It is said to have been the first engine in which a metallic piston was used. Steam is admitted by the pipe to the upper end of the upper cylinder, depressing both pistons; as the piston reaches its lowest position, the valve in the piston is lifted and allows the steam to escape to the condenser, which is an annular cylinder with water inside and outside. The contact of the cross-bar closes the steam-valve. The force of the fly-wheel raises the pistons, and as the upper one rises it closes the valve in the piston and opens the steam-valve in the cylinder-head. Another stroke is then made. The descent of the lower piston forces the water and air into the pipe leading to the reservoir on the left, a foot-valve preventing it from running back toward the condenser. The

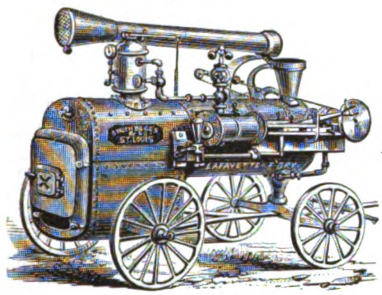
boiler is fed from the reservoir, and superfluous water and air escape therefrom.

Hornblower's steam-engine was an expansive engine, having two cylinders. His patents were 1781, 98, 1805. The steam was worked expansively in a second and larger cylinder, after a previous use in a primary cylinder.

Woolf very much improved this idea about 1804. See DOUBLE ENGINE; COMPOUND ENGINE; DUPLEX ENGINE.

The oscillating-cylinder engine was patented in England in 1813, by Witty.

Fig. 5665.



Portable Engine.

For notices of portable and traveling engines, see PORTABLE ENGINE; LOCOMOTIVE.

In the Corliss engine (Fig. 5666), the steam-valves, which are of peculiar form, their acting portions forming a segment of a cylinder, are oscillated by connection with a wrist-plate journaled on a shaft at the side of the cylinder, and vibrated by a lever and connecting-rods, operated by the movement of the fly-wheel eccentric. They are so arranged as to cut off at any required part of the stroke by rods, which cause the connection between the wrist-plate and the valve-stems to be completed and released when the rods are brought into action by or freed from the action of the governor, which merely performs the function of connecting and disconnecting the levers which work the valves, without being called on to exert any force in opening and closing them. The exhaust-valves have also circular acting faces, and are similarly actuated by connection with the wrist-plate before referred to, this connection, however, being permanent. The area of the exhaust-ports is about four times that of the steam-ports, to obviate any risk of back pressure, and the eduction-pipe is made proportionately large. The induction-valves are at the top and the eduction-valves at the bottom of the cylinder, which is thereby kept free from water of condensation, and are in immediate proximity to the bore of the cylinder, having no long passages to be filled with live steam.

Fig. 5667 illustrates the Eickemeyer steam-engine. *A* is a perspective; *B*, sections in parallel planes through the steam-cylinder *a* and crank-wheel *b*; *C*, transverse section of the cylinder; and *D*, sectional plan, showing the connection of the piston-rod *c* and crank-wheel.

The piston *d* is hollowed at the ends, and its sides have grooved passages *e f* which communicate with the cavities, and, alternately, with the steam induction and eduction passages *g h*.

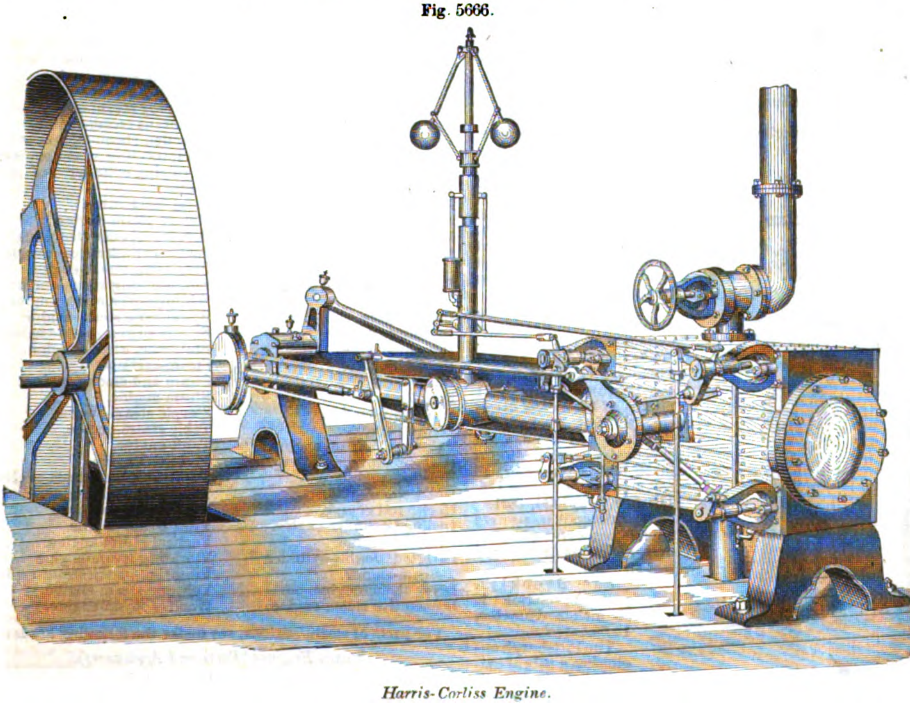
A compound lug *i* on the piston-rod, secured by set-screws, receives a wrist-pin *k* having a ball on the end, which enters the lug and forms the axis of an eccentric roller *m* entering a groove in the side of the crank-wheel and causing it to rotate at each reciprocation of the piston.

Root's double-reciprocating engine has a square piston, which reciprocates in one direction while a piston inside the former reciprocates in a direction at right angles thereto.

The inner piston is connected to the wrist, and communicates both its motions thereto, — its own vertical motion *in* the outer piston, and its horizontal motion *with* the outer piston. The resultant is a rotary motion of the crank without dead-centers. See Fig. 1710, page 728.

A steam-engine driven by the heat of the sun has been made at Tours, France, by Professor Mouchot. A silver-plated concave reflector abou t five feet in diameter collects and throws the heat in the solar rays upon a copper boiler which, in from fifteen to forty minutes, gets so hot that the heat must be moderated to prevent it from bursting by the conversion of all the water into steam. The reflector turns with the sun by clock-

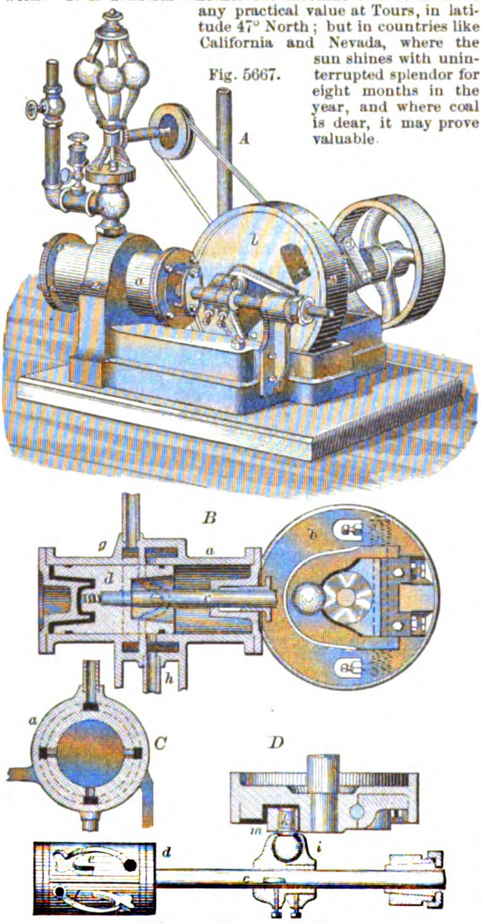
Fig. 5666.



Harris-Corliss Engine.

work. It is doubtful whether the machine can be made of any practical value at Tours, in latitude 47° North; but in countries like California and Nevada, where the sun shines with uninterrupted splendor for eight months in the year, and where coal is dear, it may prove valuable.

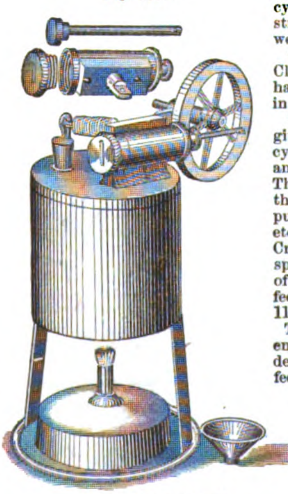
Fig. 5667.



Eickemeyer's Steam-Engine.

The dollar steam-engine is a working toy. It is a reciprocating steam-engine, with cylinder, piston, fly-wheel, boiler, and patent safety-valve, taking steam at both ends of the cylinder, with half-inch stroke. All complete it weighs less than 4 ounces.

Fig. 5668.



Dollar Steam-Engine.

The engines of the "Lord Clyde" British iron-clad have cylinders 116 inches in diameter, 4 feet stroke.

The Haarlem Mere engines have annular outer cylinders of 112 inches diameter, 15 feet stroke. There are three of them: the Leeghwater works 11 pumps of 63 inches diameter, 10 feet stroke; the Cruquius and Lynden respectively work 8 pumps of 73 inches diameter, 10 feet stroke. See pages 115, 116, 739, 740, 1830, 1831.

The Chicago Water-works engine has a pair of cylinders 44 inches diameter, 8 feet stroke.

The Brooklyn pumping-engine is 85 inches diameter, 10 feet stroke.

The Pittsburgh engine has a pair of cylinders 64 inches diameter, 14 feet stroke.

The Lehigh zinc-works, 110½ inches diameter, 10 feet stroke.

The Providence Sound steamers' cylinders, 110 inches diameter, 12 feet stroke.

The Baxter steam-engine, described and pictured on page 1770, has the following sizes and prices: —

Horse-power.	Revolutions to the minute.	Price.
2	300	$ 400
4	266	600
6	240	800
8	200	1,000
10	170	1,200

The Maxim steam-engine is also vertical, the engine being above the boiler, and not sunk within it, as in the Baxter engine.

Small steam-engines are coming much into favor to relieve hand and horse work in establishments where but a moderate amount of power is required. Many of these are attached to their boilers, the bed-plate being common to both. The upright form of boiler and engine has the preference, partly for compactness, and partly on account of the evenness of wear. The rate is usually quite rapid. The Washburn engine, used some years since at the Massachusetts State Fair at Worcester, was not larger than an ordinary ice-cream freezer, and its proportions and work are reported as follows in a Worcester paper: "It has two cylinders, 3 7-10th inches bore by 1 85-100th inches stroke; runs about 370 revolutions per minute, and drove all the machinery in the hall. The machinery is as follows: one loom, one carding-machine, one 20-shuttle tape-loom, one cloth-loom, one spinner, twenty spindles, envelope-machine, six fine wire blocks, three hoop-skirt covering machines, one 8-foot planer, one 16-inch engine-lathe, one 15-inch engine-lathe, one card and two small printing presses."

One or two very small engines are described under MODEL, page 1457.

The several forms of engines are considered under the specific heads. The Cornish, pages 626 and 1828; the Haarlem Mere engines, pages 1830, 1831; Portable, pages 1769, 1770; Worthington Duplex, Plate XV., opposite page 763; etc.

Steam-en'gine In'di-ca'tor. A contrivance to make a record of the pressure of steam at all points of the motion of the piston. See also STEAM-GAGE; PRESSURE-GAGE; INDICATOR, etc.

In the indicator (Fig. 5669), a pencil or tracer is fixed centrally in the middle one of three connected levers forming the parallel motion. The two end members of the series are jointed to two opposite arms *b* near the top of the indicator-cylinder *c*. The cylinder is attached to a convenient part of the boiler, and steam admitted to the piston, whose rod is connected to the lever *d*, causing a vertical upward movement of the tracer, which is opposed by a weight suspended from the hook *e*. As the cylinder *f* is rotated by appropriate mechanism, the pencil traces a continuous line upon a sheet of paper secured thereon, varying in hight according to the steam-pressure. The use of the parallel motion is to prevent the wabbling of the stem of the piston-rod, preserving it directly in line during its vertical excursions.

Steam'er. 1. A steam-vessel. See STEAMBOAT.

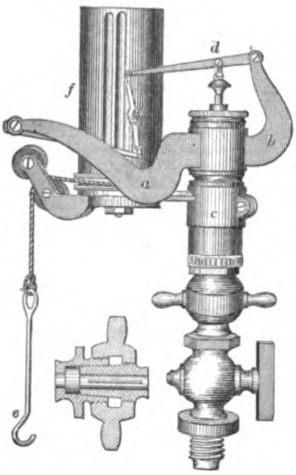
2. A steam fire-engine. See FIRE-ENGINE.

3. (*Domestic.*) A culinary vessel with a perforated bottom, placed upon a cook-pot and having a lid to keep in the steam.

In Fig. 5670, the steam passes up through a central channel

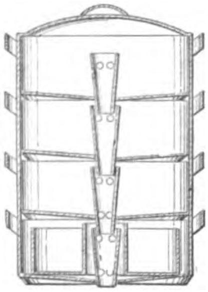
composed of frusto-conical sections of pipe, one of which is attached to each steamer. The lower smaller end of each section enters the top of the one below, and the drip which flows from the close bottoms of the steamers into the pipe is carried off without contaminating any matters in the steamer beneath.

Fig. 5669.



Parallel-Motion Indicator.

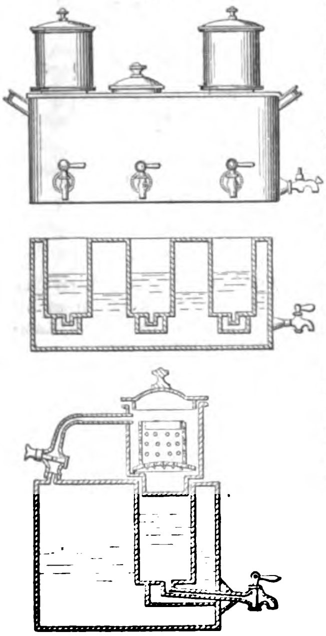
Fig. 5670.



Steamer for Cooking.

A primitive mode of cooking in use among several savage nations is called "stone-boiling," and is as follows: A hole is dug in the earth, dry wood is placed in it, and on that a number of stones. When the stones become red-hot the unconsumed fuel is removed, wet, green leaves placed upon the stones, and upon the leaves the food to be cooked. More leaves are placed on the food, and a mat over all. Then some water is poured on the mat, and finally earth as an outside coating; thus the food is cooked by a combined baking and steaming process. But a simpler method of stone-boiling than this of the New-Zealanders was probably practiced by the pit-dwellers. Stones made red-hot in the fire were thrown one after another into a vessel of water containing the food to be cooked. This is the plan adopted by certain North-American Indians, and traces of it still survive on the Continent of Europe.

Fig. 5671.



Coffee and Tea Steamer.

Fig. 5671 is a tea and coffee steamer for hotel purposes, with double walls extending nearly to the bottom, placed in the boiler so as to allow the water to pass all around them, while upon them set vessels with perforated bottoms and containing each a strainer in which the coffee is placed.

4. *a.* An apparatus in which wood (for instance) is placed within a chamber, in order to expel the natural juices, inject preservative compositions, or merely soften the wood so that it may be readily bent.

b. A vessel in which paper stock or other fiber is treated in order to soften it, to facilitate the removal of siliceous matters.

Fig. 5672 is an apparatus for steaming paper-stock. See also PULP-DIGESTER.

5. (*Milling.*) An apparatus for steaming wheat preparatory to grinding.

Fig. 5673 shows Hunt's apparatus for steaming wheat. The grain flows from the hopper *a* down through the passage *b*, which is larger at the bottom than at the top; in its progress downward steam is admitted to it from the perforated chamber *c*, which receives steam from the pipe *d*, and it is then dried by coming in contact with the walls of the chamber *e*, supplied with steam by the pipe *f*. By means of the cock *g* the steam may be shut off from the upper chamber if the grain does not require steaming; or it can be cut off entirely by the globe-valve *h*. The water of condensation is drawn off by the pipe *i*.

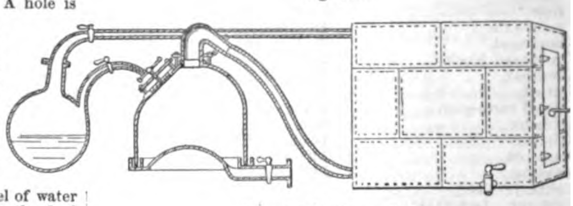
Steam Fire-en'gine. Mr. Braithwaite's fire-engine, used in London, was described in Partington's "British Cyclopedia," published in 1833. It is there described as a portable steam-engine, to move the pump-rod, the steam being prepared during the passage of the fire-engine to its destination. See FIRE-ENGINE.

Steam-foun'tain. A jet or body of water raised by the pressure of steam upon the surface of the water in a reservoir.

This is shown in the "Spiritalia" of Hero, 150 B. C., in several forms. The device was a part of the priestly jugglery of the temple. The fire, being lighted on an altar, heated water in an adjoining chamber; the steam evolved pressed upon the surface of a liquid, oil or wine, and ejected the same by means of pipes hidden within a statue, so as to run out of a flagon in the hand of the figure, and thus pour a libation upon the altar.

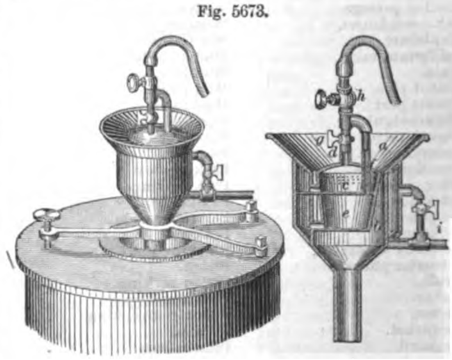
The idea of Hero was revived by Baptista Porta in 1600; De Caus (?), in 1620; the Marquis of Worcester in 1633; Savery, in 1698. See STEAM-ENGINE.

Fig. 5672.



Steamer for Paper Stock.

Fig. 5673.



Steamer.

Steam-gage. (*Steam.*) An attachment to a boiler to indicate the pressure of steam.

a b c d e, in Fig. 5674, are forms of mercurial gages; the pressure of the steam rising in the longer leg of the tube is read against the graduated plate.

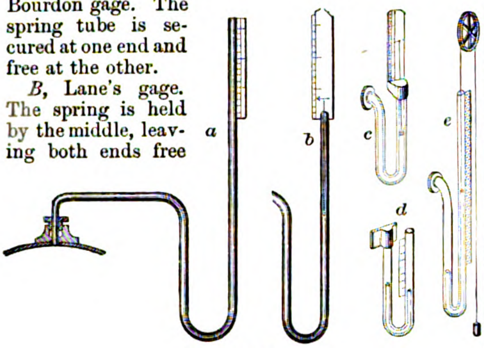
Fig. 5675 represents piston-gages. The cylinder has a solid plug, turned and ground, the pressure of

the steam elevating the plug against the force of the spring.

A (Fig. 5676), Bourdon gage. The spring tube is secured at one end and free at the other.

B, Lane's gage. The spring is held by the middle, leaving both ends free

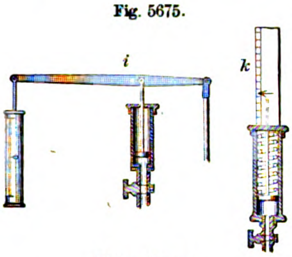
Fig. 5674.



Mercurial Gages.

and pointing upward, so as to prevent water from the siphon which transmits the steam pressure collecting in the tube and freezing in cold weather. Both ends of the tube are connected by a lever to the index, and vibration of the latter is prevented.

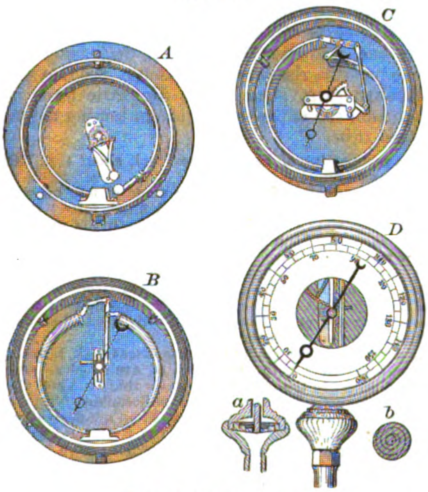
Fig. 5675.



Piston-Gages.

C, Crosby's gage. The spring-tube is arranged in a manner similar to the last; three connected levers are employed for transmitting motion to the index, and it is claimed that a stronger and heavier tube may be used, obviating danger of straining or bursting under high steam-pressures.

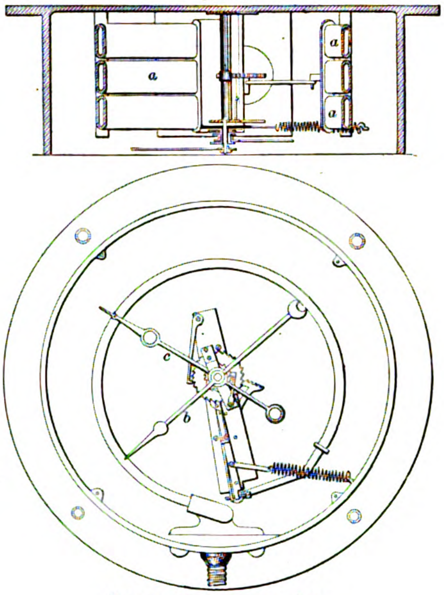
Fig. 5676.



Bourdon Steam-Gages.

D, Allen's gage. This is a box or diaphragm gage, on the principle of the aneroid barometer. *a* is a section through the box, and *b* a plan of the diaphragm. See also PRESSURE-GAGE; INDICATOR, etc.

Fig 5677.



Bourdon Tube Pressure-Gage.

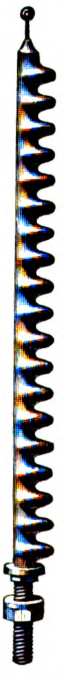
Fig. 5677 represents a steam-pressure gage on the principle of the Bourdon barometer (see page 347). The views are respectively a front elevation and a horizontal section, the upper part of the casing being removed.

A series of spiral tubes *a a a* communicate at one end with a common opening connected with the steam-chamber, and at the other are joined by a T-piece, which, by means of a connecting-rod, is attached to a lever operating a segment-rack that engages a pinion on the shaft of the index-hand *b*, which shows the pressure on a dial

A second index *c* has a projection on its under side, which is struck by the index *b* when the steam pressure exceeds a limit to which it has been previously set, carrying it forward till the extreme amount of pressure has been reached; and a ratchet-wheel and pawl prevent it from receding from this point.

A third and shorter index, also controlled by a ratchet and pawl arrangement, is caused to advance a step, and is prevented from returning each time that the limited amount of pressure has been exceeded, so that the gage is caused to register both the maximum pressure and the number of times that the engineer has allowed the pressure to exceed the proper amount.

Fig. 5678.



Matthews' Pressure-Gage.

Fig. 5678 is a view of Matthews' tube for pressure-gages. It is made without seam, by electro-deposition of metal upon a core of some fusible material, such as stearine or wax. The tube has offsets on one side, in the form of hollow plates. The lower part is fused to the dial-plate, and has a screw coupling for the steam or carbonic-acid gas pipe. The effect of elastic pressure in the tube is to press apart the horizontal portions of the offsets and elongate that side of the tube, which becomes bent thereby; the upper end being attached to a short lever or rack, which moves the pointer on the dial.

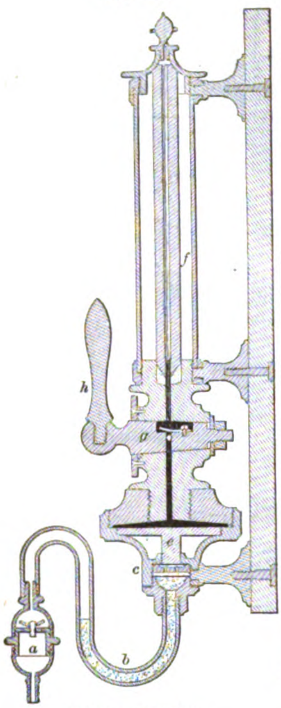
Shaw's (Fig. 5679) is also particularly designed to measure the pressure of elastic gases generated by explosive substances. The pressure from the chamber *a* is transmitted through the curved pipe *b*, which is partially filled with glycerine, and the perforated disk *c* to the foot of the plunger *e*, the top of which forms the bottom of a mercurial reservoir; the plunger rising causes a thin column of the fluid to ascend the tube *f*, where it is retained by a valve *g* until its hight can be conveniently noted. On partially turning the cock *h*, the pressure having been removed, the mercury falls to its normal hight.

In Fig. 5680, steam pressure acting from within upon the curved metallic diaphragm *a*, causes it, through the medium of a series of interposed levers and a segment-rack, to turn the spindle *b*, carrying

an index-hand, by which the pressure is indicated on a dial; the mechanism employed gives a much larger amount of motion to the index than that originally imparted to the first of the series of levers by the expansion of the diaphragm. As the pressure diminishes, the motion of the index is reversed by a spiral spring surrounding its shaft.

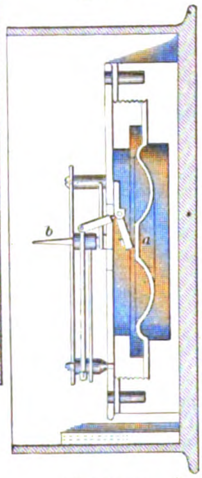
In Fig. 5681, the steam admitted within the box of the gage expands its elastic corrugated top, forcing up a rod, which, through interposed mechanism, moves the dial index. As the pressure falls, the course of the index is reversed by a conical spiral spring, which reverses the movement of the rod.

Fig. 5679.



Differential Piston Pressure-Gage.

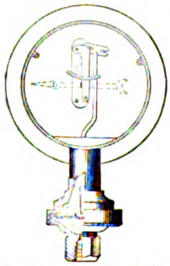
Fig. 5680.



Diaphragm Pressure-Gage.

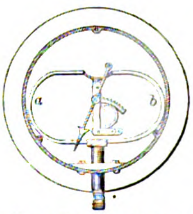
In Fig. 5682, the two tubes *a b* have a common base, to which steam is admitted, and their free ends are connected by a flat, bent spring. A link and rod, centrally connected to the spring, actuate the segment-rack, which gears with a pinion on the index-shaft in the usual manner.

Fig. 5681.



Diaphragm Pressure-Gage.

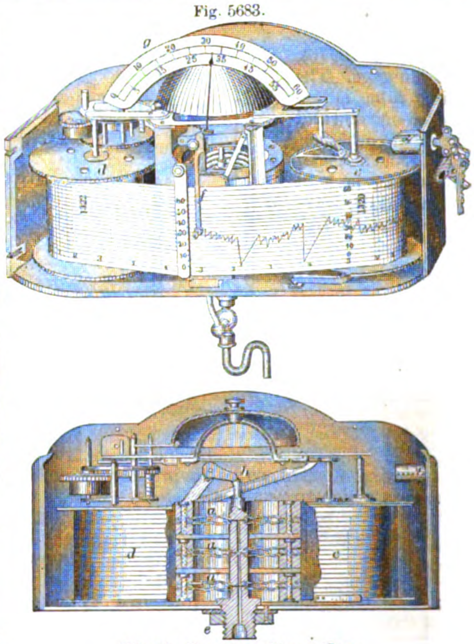
Fig. 5682.



Duplicate Tube Pressure-Gage.

Edson's recording steam-gage (Fig. 5683) consists of a case, secured by a lock and key, and having several connected air and steam tight drums *a a a* of thin flexible metal. A rod *b* on the upper one of these is attached to a segment which directly, or through intermediate gearing, actuates a rack-bar provided with a pawl, which rotates the cylinder *c* to the right, causing it to take up some of the paper from the cylinder *d*, on which a roll is wound, as the gage is expanded by steam from the boiler entering the apparatus through a pipe *e* in the bottom compartment. An opposite pawl prevents the paper-carrying cylinders from turning backward as the boxes *a a a* collapse under a diminished pressure of steam. By means of suitable gearing the arm *f*, carrying a pencil or tracing-point at its lower extremity, is caused to rise and fall, impressing a zigzag line on the paper as the steam pressure varies. By means of clockwork mechanism, actuated by the engine or otherwise, the motion of the cylinders *c d* may be made uniform and continuous, so as to leave a permanent record of the variations of pressure for 12, 24, or a greater number of hours, the paper having been previously ruled with a system of horizontal lines indicating the pressure in pounds and vertical lines for the hours. A scale and pointer *g* enable the pressure at any moment to be more readily ascertained by inspection.

Fig. 5683.



Edson's Recording Steam-Gage.

The handle of the inlet steam-cock enters the gage, and is so secured that it cannot be withdrawn until the gage-door is unlocked, thus preventing tampering with the record.

Steam-gas. Superheated steam.

Steam-gov'ern-or. A regulator which determines the passage of steam, and thus its pressure in a chamber or cylinder beyond.

Usually a device placed between the boiler and the valve-chest of a steam-engine, which operates a valve and graduates the opening, decreasing its area as the pressure rises and conversely. See GOVERNOR.

Steam-gun. One whose projectile force is derived from the expansion of steam issuing through a shotted tube.

In a manuscript of Leonardo da Vinci, about A. D. 1500, occurs the following: —

"The *architonnere* is a machine made of fine brass, which throws iron balls with great noise and much force. One third of this instrument consists of a great quantity of fire and fuel. When the water is properly heated, the screw on the vessel where the water is must be turned; at that moment the water will escape below, will descend into the heated part of the machine, and be immediately converted into steam so abundant and powerful that the effects of its force and its noise will strike one with amazement. This machine will propel a ball weighing rather more than a talent."

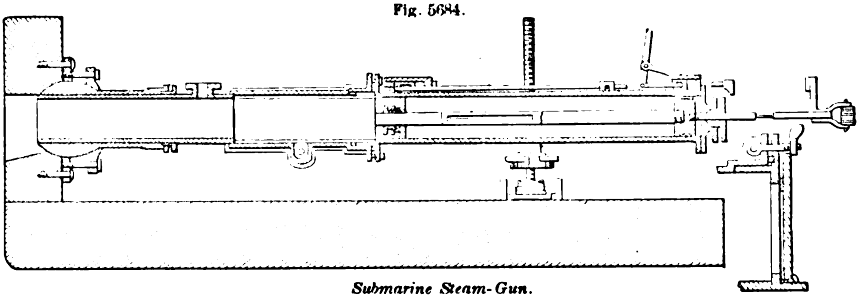
L. da Vinci, in describing this gun, uses Greek terms, and it is surmised that it is the invention of Archimedes. One who has had access to the manuscript states that Da Vinci gives the credit of the invention to the Greek philosopher.

A steam-gun is described in Van Etten's "Recreations Mathematique," 1629, 83d Problem. It is a very clumsy contrivance, but used steam acting on a wooden piston or sabot to expel the ball.

Perkins exhibited a steam-gun in England before the Duke of Wellington, 1824. It was very effective, but the "Iron Duke" considered that a steam-boiler that threw away balls as fast as that did would be out of place in an army, and would waste ammunition. The same objection has been until lately urged against the use of breech-loading fire-arms. "The men shoot too fast."

Mr. Henry Bessemer's idea is to have a steam fire-engine to throw bullets instead of water. He calculates that it will throw

Fig. 5684.



Submarine Steam-Gun.

181¾ pounds, representing 2,540 rifle-bullets per minute, to a distance of 1 mile, with a consumption of 5 pounds of coal and 3 gallons of water. "An increase in the weight of the projectile would increase both its range and force, and 2-ounce bullets might be used for a long range, being propelled at the rate of 1,000 a minute. A machine with three parallel barrels could throw 2-ounce shot at long range from the center barrel, and 1-ounce shot (2,000 a minute) at short range from the side barrels."

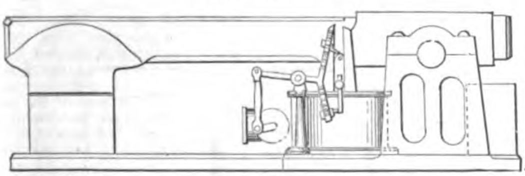
The calculation for steam at 150 pounds pressure is that it would escape at an initial velocity of 1,900 feet per second, and, acting upon a 2-ounce leaden ball, presenting an area of .6 of an inch, would exert a force upon it of 90 pounds. 1,100 to 1,200 feet per second is the initial velocity of the Armstrong gun projectile. Mr. Bessemer suggests a universal joint tube for delivering a sweeping fire; and a mantlet to shield the gunners.

Fig. 5684 shows the Wood and Lay submarine steam-gun. The side of the ship, below the water-line, has an aperture, which is closed by a ball and socket joint. This joint has connected with it a tube, which extends inward, and terminates in a box in which is a trunk with two compartments for containing the shells. This trunk is capable of being moved in the box, so that while one shell is being discharged another can be placed therein. To the rear end of this box a steam cylinder is placed, having a piston therein, which, when the shell is placed in the trunk, has steam admitted in the rear by means of suitable valves, and is pressed forward with such force as to eject the shell and force it to a considerable distance. The piston-rod is hollow, and a cord is passed through it, and is wound around a spool upon its outer end. The opposite end of this cord is secured to the shell, and thus, when the shell has traveled any determined distance, the cord is made to discharge it.

Steam-ham'mer. (*Forging.*) Properly, a steam-operated hammer. The term is usually, however, restricted to one working vertically by the attachment of its rod to a piston in an upright cylinder above.

The first application of steam to the hammer was to the tilt, which was worked by *wipers* or cams on a rotating shaft driven by the usual steam-engine. A more direct application of steam to the tilt-hammer is shown in Fig. 5685, which has a T-shaped lever, having adjustable dogs on its lower and upper

Fig. 5685.



Steam Tilt-Hammer.

arms so arranged with reference to the tappet placed upon the cross-head of the engine that, by moving dogs up or down upon the arms, the stroke of the piston, and consequently the force of the blow of the hammer, may be varied at pleasure.

See also Atmospheric Hammer, pages 178, 179, and list under Hammer.

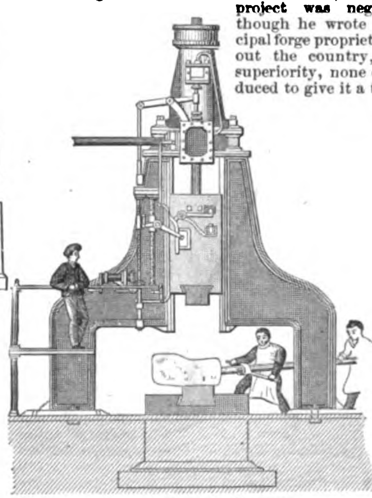
Hague, in 1827 (English patent), raised the hammer by atmospheric pressure below a piston, whose rod is attached to the hammer. The pressure is obtained by a partial vacuum above the piston, obtained by an air-pump or other means. The same idea is applied to cranes. See Fig. 409.

In Watt's proposed steam-hammer, in 1784, the steam-cylinder was at one end of a wooden beam, while the hammer was at the other; the shaft being journaled like the old tilt-hammer, and the hammer moving in the arc of a circle.

William Deverell, of London, June 6, 1806, obtained a patent for "improvements in the mode of giving motion to hammers," etc. The inventor says: "I raise steam in a boiler or steam-vessel as in the common way. I have a steam-cylinder with a piston and rod in it; at the end of the rod that comes out of the steam-cylinder is a hammer, either made fast to the rod by welding, or in any other proper way. The steam from the boiler or steam-vessel is let in underneath the piston by means of opening a cock or valve, or cocks or valves; the air at the top of the piston will be then compressed by the superior pressure of the steam underneath the piston. After the piston has been raised to a given hight, there will be an opening made from the under side of the piston to a vacuum formed as in the common way, or otherwise the steam may be let out into the common air. The compressed air on the top of the piston will then drive down the hammer with a velocity equal to what it may be compressed." It does not appear that any valuable practical result followed.

In November, 1838, Mr. Humphries, who was superintending the construction of the machinery for the "Great Britain," the largest steamship which had, up to that time, ever been built, wrote to Mr. Nasmyth (who was a workman in Maudslay's shop) that there was not a forge-hammer in England or Scotland powerful enough to forge a paddle-shaft for that vessel, and requesting his advice. Mr. Nasmyth immediately went to work and designed an apparatus embracing the essential and distinctive features of the steam-hammer now in use. It consisted of an inverted cylinder, to whose piston the block of iron forming the hammer-head was attached. Steam entering below the piston raised the hammer, and the escape of steam allowed the hammer to fall. The sketch was shown to Brunel and other experts, by whom it was highly approved. About this time the screw-propeller was brought prominently forward, and it was determined to adopt this means of propulsion for the "Great Britain"; the forgings required for this were within the capacity of the appliances then in use, and Nasymth's project was neglected; and though he wrote to the principal forge proprietors throughout the country, urging its superiority, none could be induced to give it a trial.

Fig. 5686.



Nasmyth Hammer.

Some time afterward, M. Schreider, the celebrated French ironmaster, with M. Bourdon, his superintendent, being on a visit to

the Patricroft works, were shown the sketch made by Nasmyth, and Bourdon was so favorably impressed that on his return home he constructed and put in operation the first steam-hammer. In April, 1840, Mr. Nasmyth, then on a visit to France, in passing through the works at Creusat, observed a crank-shaft of unusual dimensions forged in the piece and punched, which he was informed by M. Bourdon had been forged by his (Nasmyth's) steam-hammer. On his return he constructed a 30-cwt. hammer for the Patricroft works, and in December, 1842, obtained a patent for the invention.

The steam pile-driver was soon afterward invented by Nasmyth. See Holtzapffel, ii. 961.

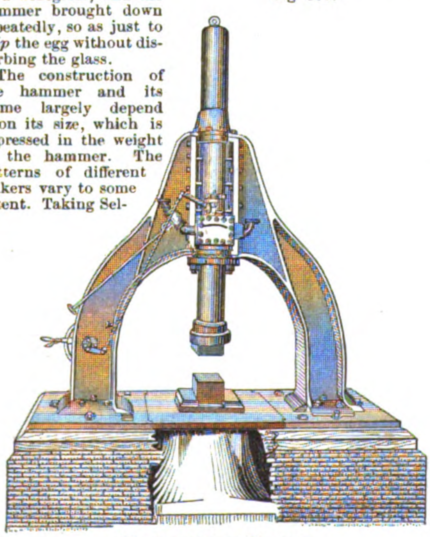
The Nasmyth was the first steam-hammer of the modern type, and the works, as well as name, are noted throughout the world; but the machine-tool has been much modified and enlarged. The first idea was to simply lift the hammer and let it drop; the force of the blow was afterward very much increased by making the engine double-acting, that is, by allowing steam under pressure to pass above the piston and add its force to the weight of the falling hammer. Condie made the piston stationary, the cylinder moving in guides. Morrison made the hammer of one long bar of wrought-iron, the piston being welded thereto, and forming part of it, and he then dispensed with the guides on the frame, and guided the bar by the top and bottom cylinder-heads only. This left the entire space below the cylinder free for the use of the workman in handling his work.

In the automatic hammer the motion to work the valves has been obtained from inclined grooves, diametrically opposite to each other, and made to work a brass yoke, whose line of vibration is through the central axis of the bar. A supplemental valve is used to throttle the exhaust below the piston, without impeding the free exhaust above the piston. This enables the hammer to strike quick, light blows for finishing; in other words, the hammer can go up as quickly, but in coming down its force may be gaged by the steam cushion upon which it descends, which steam, thus condensed in bulk, re-expands in the up-stroke, economizing steam.

As an illustration of the capacity for adjustment and command of the steam-hammer, an experiment may be cited in which an egg was placed in a wineglass, and the hammer brought down repeatedly, so as just to *chip* the egg without disturbing the glass.

The construction of the hammer and its frame largely depend upon its size, which is expressed in the weight of the hammer. The patterns of different makers vary to some extent. Taking Sellers', it may be stated that the piston-rod or hammer-bar is of solid wrought-iron, passing through both heads of cylinder; the piston-head forged solid with piston-rod. The hammer-head is adjustable on the lower end of the bar, which is prevented from turning by the upper cylinder-head. The slide-valve is balanced

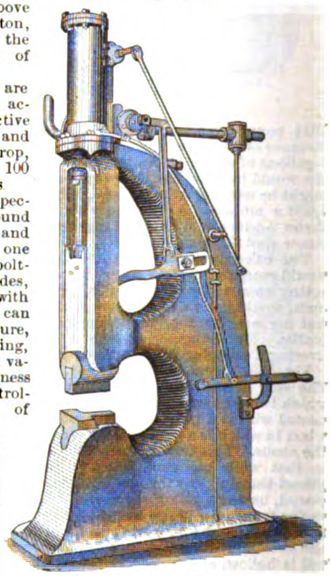
Fig. 5687.



Morrison Steam-Hammer.

Hammers of 2,500 pounds weight, and under, have one upright only, are double-acting, taking steam above and below the piston, with self-acting valve-gear and hand-motion operated by the same lever; these can be changed, at will, while in operation, thus affording complete control over the length, rapidity, and force of blow, also enabling the hammer to be used as a vise or squeezer. Hammers of 1,000 pounds and under have anvil blocks passing through the base of the upright. Double upright hammers are hand-working only, taking steam above and below the piston, thereby increasing the force and rapidity of blows.

Fig. 5688.



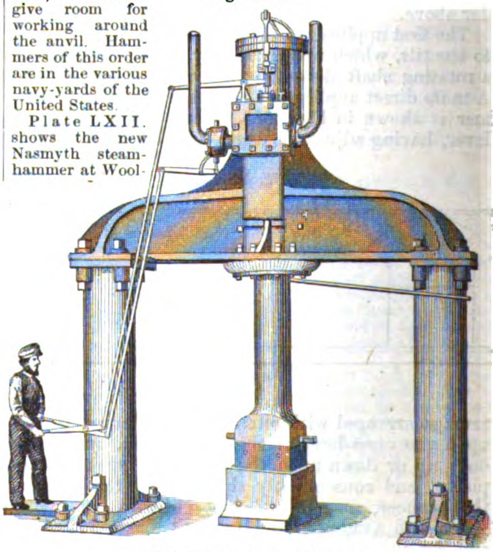
500-Pound Steam-Hammer.

Steam-hammers are rated or classified according to the effective weight of the piston and hammer-head or drop, and range from 100 pounds up to 80 tons

Fig 5688 is a perspective view of a 500-pound hammer, whose anvil and frame are cast in one piece, to which are bolted the cylinder, guides, etc. It is fitted with valve motion, which can be worked at pleasure, single or double acting, adjusting itself to all variations in the thickness of the forging, controlling the admission of steam so as to produce at will a short and quick or a long and slow stroke, and graduating from the light-cushioned blow to the dead blow, in which no steam is admitted beneath the piston until after the blow is struck, thus utilizing the *vis viva* of the falling weight impelled by the top steam. It can also be used as an ordinary hand-working hammer, without altering the setting of the gear.

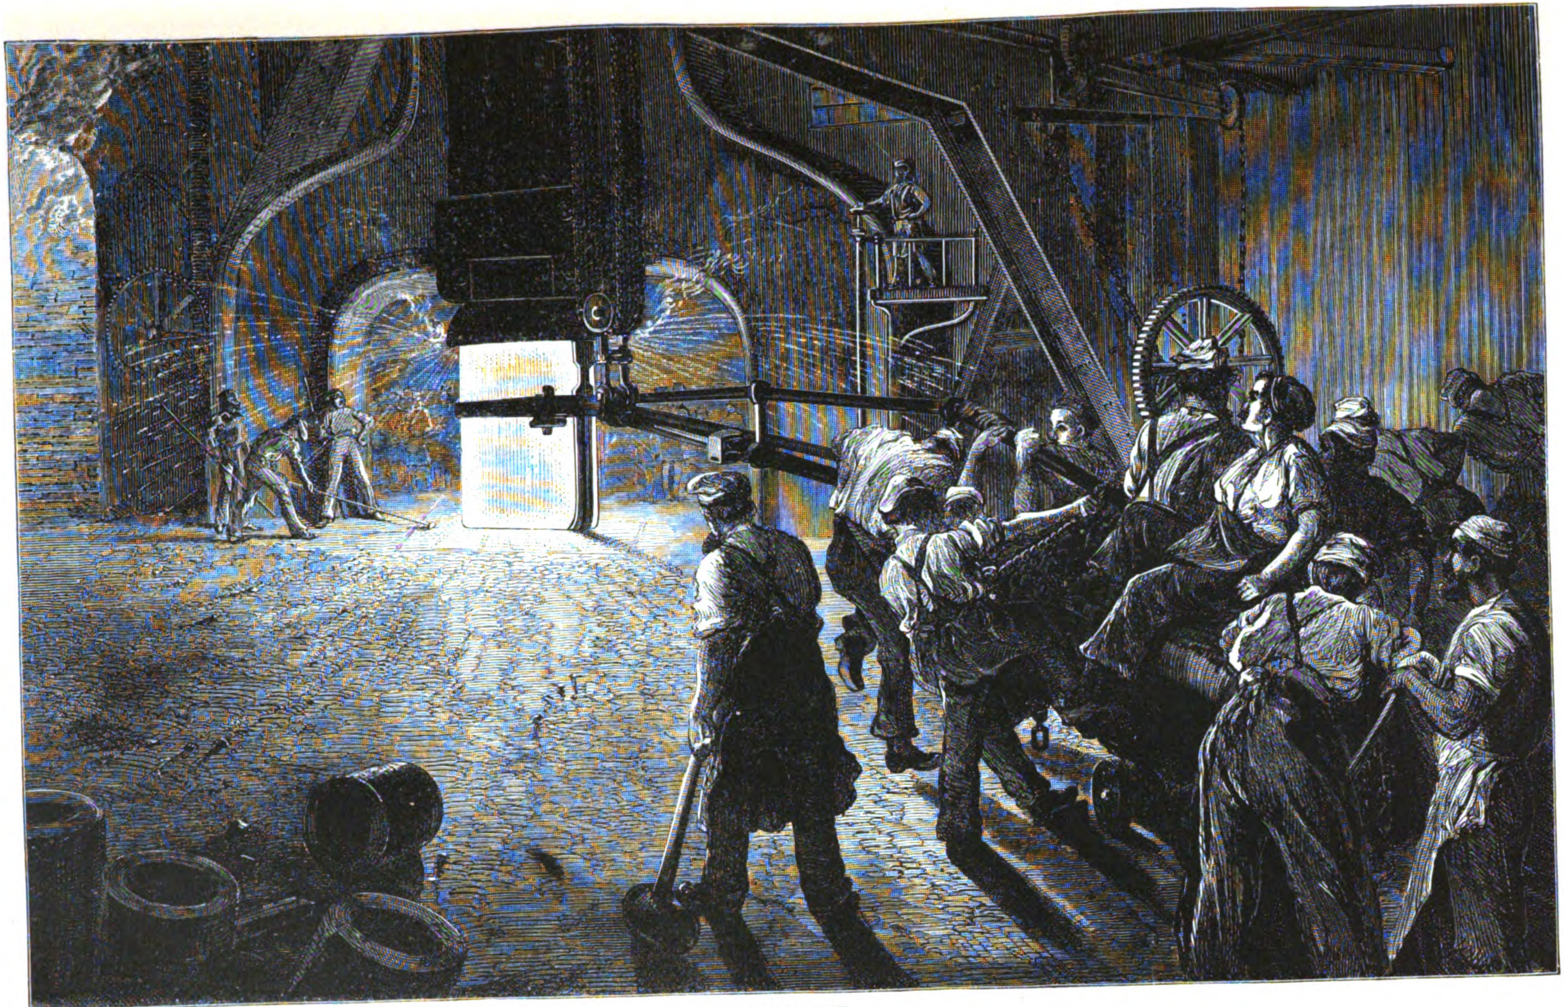
Fig. 5689 is a view of a hammer in which the frame is high and its pillars distant, in order to give room for working around the anvil. Hammers of this order are in the various navy-yards of the United States.

Fig. 5689.



High-Frame Steam-Hammer.

Plate LXII. shows the new Nasmyth steam-hammer at Woolwich, England. It is at present the largest and most powerful in the world, but it is understood that Krupp of Essen is now building one to work a mass of steel of 100 tons (of 2,240 lbs.)



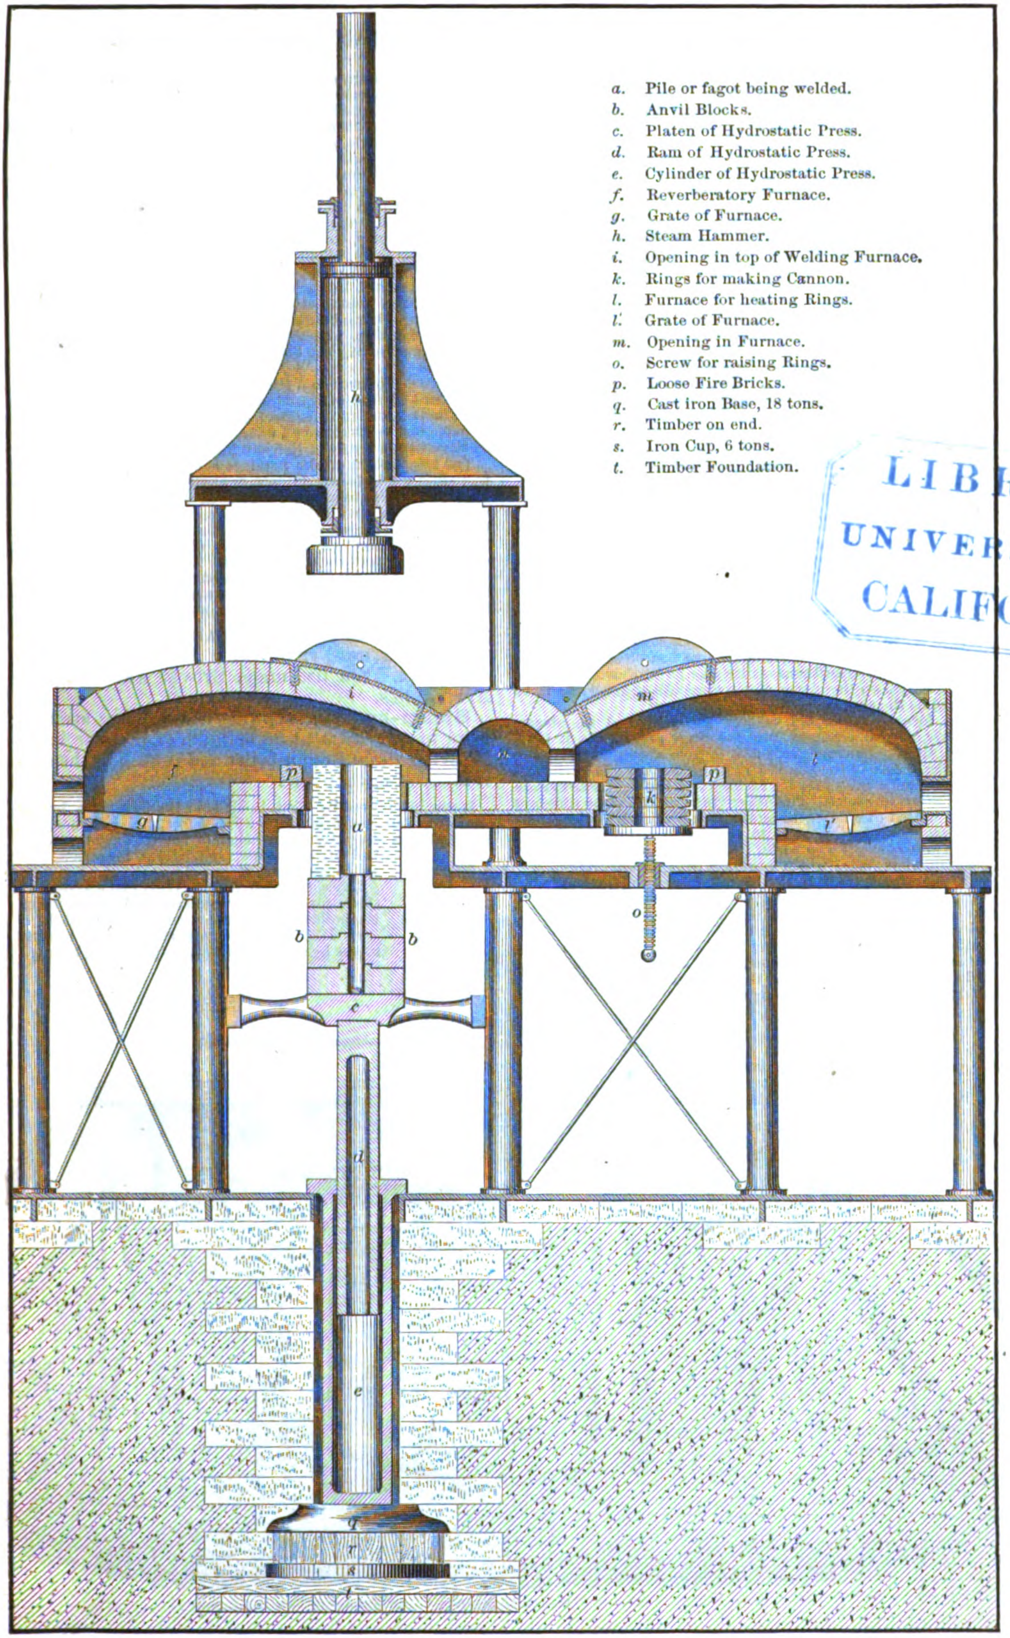
STEAM HAMMER.

WOOLWICH ARSENAL, ENGLAND.

[*For forging the 80-ton guns for the " Inflexible," and sister vessels.*]

See page 2348.

PLATE LXII.



ALONZO HITCHCOCK'S CANNON-FORGING STEAM-HAMMER AND FURNACE.

PLATE LXIII. *(Springfield, U. S. A. Arsenal.)* See page 2350.

weight, and which is expected to cost $ 1,000,000. The weight of the falling portion of the Woolwich hammer is 40 tons, and the force of the falling weight is accelerated many times by the use of steam to drive it down from the top. It is four times as powerful as the present "Krupp" hammer. It is estimated that the use of top steam is equal to allowing the hammer to fall of its own weight 80 feet. It has been allowed a striking fall of 15 feet 3 inches, and the force of the blow is estimated as equal to a weight of 800 tons. The hammer is 45 feet in hight, and covers, with its supports, a base of about 120 feet square. Above the ground it weighs 500 tons, and the iron in the foundations below weighs 655 tons. It cost $ 250,000.

In making the foundations, an excavation was made 45 feet square and 20 feet deep, then 100 piles were driven 20 feet into the solid gravel, and the intèrstices filled up with concrete; on these was placed a block of iron 30 feet broad and 11 inches thick, weighing 160 tons, and on this two layers of oak balks. On this timber was next placed another iron plate, 10 inches thick and 27 feet square, weighing 121 tons, and then followed a number of oak balks as before, standing vertically and bound together with wrought-iron bands. Two more iron plates, weighing together 214 tons, were lowered upon the oak balks, and one heavier than any yet followed upon these. Upon this the anvil block, weighing 102 tons, was placed, and it, in turn, was crowned by the anvil face, which was 12 feet in diameter, and weighed 60 tons.

The new steam-hammer in the Bessemer Steel Works, at Harrisburg, Pa., weighs 35,000 pounds, and cost $ 92,000, and is said to be the largest in the United States.

Plate LXIII. illustrates the system of Mr. Alonzo Hitchcock, of New York, for forging cannon, hollow shafting, hydraulic cylinders, and other large masses of iron, particularly those of tubular form.

The metal is heated in a reverberatory furnace to avoid its contact with sulphur and other impurities of coal. The gun is formed of rings of wrought-iron, or low steel made without welds. The rings are so formed as to be united first in the center, that the superfluous cinder may be squeezed out. The anvil is seated on the piston of a hydrostatic press, so as to be lowered as the successive rings are added.

The furnace is situated between the anvil and the steam-hammer, and so arranged that the rings project into it from below, and the hammer drops into it from above. The ring to form the muzzle of the gun is laid upon the movable anvil, and projected sufficiently into the furnace to allow the flame to raise it to the welding heat. The other rings at the same time are being heated to welding in another part of the furnace; the dampers being so adjusted as to proportion the degree of heat to the masses in the two parts. Without being removed from an atmosphere which contains little, if any, oxygen, one of the rings is transferred to that upon the anvil, and the two welded together by a few strokes of the steam-hammer. The anvil is then lowered by the thickness of another ring, and the same process is repeated. Although the gun may be of any size, the parts actually united at one operation may be made so light by reducing their thickness that the pressure of a hammer of moderate weight will be adequate.

Fig. 5690 illustrates a large steam-hammer at the Alexandrowski Steel Works, St Petersburg, Russia. This was originally a 35-ton hammer, the arched standards springing from the ground line. They were subsequently mounted on vertical stands 12 feet high, giving a clear hight below the cylinder of 28 feet 8 inches, and guides for the hammer added; the hight of the whole apparatus is 46 feet. The guides consist of two cast-iron columns 20 feet high, and 4 feet 6 inches in diameter, weighing each 25 tons, resting upon cast-iron girders 40 feet long, level with the floor line. These are connected by 8 wrought-iron bars, 4 on each side, 20 feet long, 16 inches deep, and 7 inches thick. Four vertical steel bars 14 inches wide and 7 inches thick serve as guides for the hammer. They are not rigidly connected to the cross-bars, but are kept up to their work by oaken beams between them and the cast-iron columns. There are 6 of these beams on each side of the hammer, arranged in pairs, between which are cast-iron shoes with interposed wedges for adjusting the beams. The whole weight of this part is 97 tons.

The guide columns and the anvil have each foundations independent of that of the standards. The hammer weighs 42 tons, its face, of Bessemer steel, 3 tons, the piston, 6 feet 6 inches in diameter, weighs 2 tons 1 cwt., the total falling weight being 51 tons, with a stroke of 12 feet 6 inches.

The total weight of the hammer above the ground line, not including the bed-plate, girders, or anvil-block, is 402 tons. The anvil-block was cast in situ. It is in 3 tiers, each of smaller diameter than that below it, weighing in all 240 tons. It is bedded upon concrete and wooden piles inclosed in a wrought-iron casing 73 feet deep by 25 feet in diameter, the foundation extending down to the solid ground. The hammer and its four 60-ton cranes are supported on a masonry platform resting upon timbers supported by piles. The steam-valve is of the equilibrium kind, and the hammer is easily worked by one man.

Steam-heat'er. See STEAM-HEATING APPARATUS; HEATING-APPARATUS; HYPOCAUST; FURNACE, etc. See list under STOVES AND HEATING APPLIANCES.

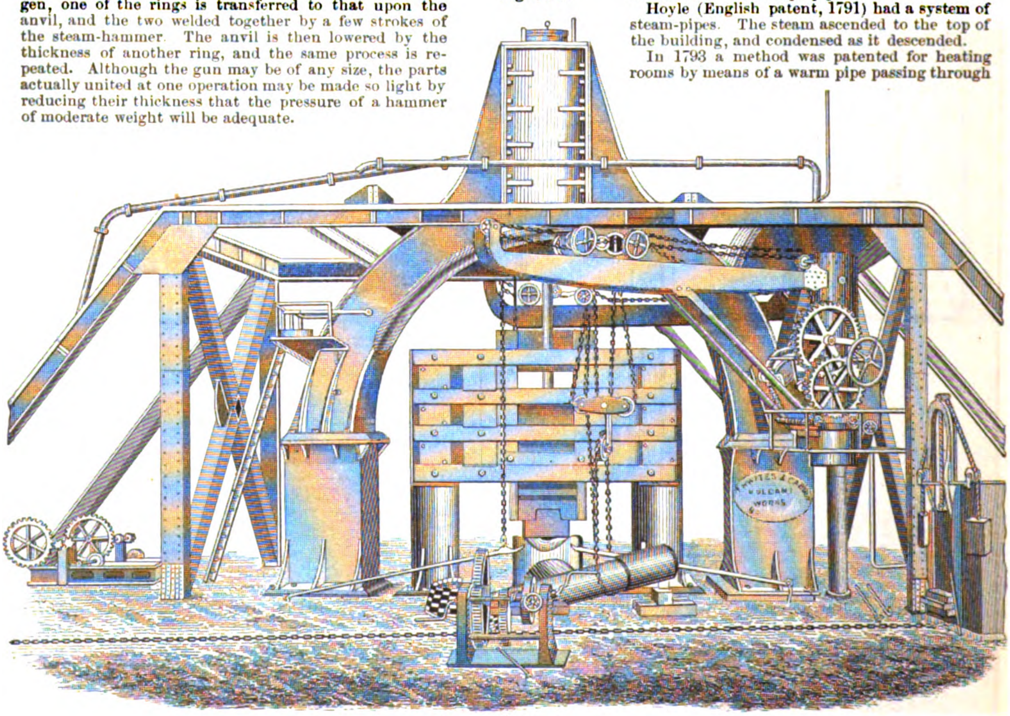
Steam-heat'ing Ap'pa-ra'tus. An arrangement in an apartment or building of pipes or boxes receiving steam from a boiler and returning the condensed steam thereinto.

It was introduced by Watt, in 1784, in the form of a hollow sheet-iron box, made of plates $2\frac{1}{3} \times 3\frac{1}{4}$ feet, and 1 inch apart, supplied with steam from the boiler of the establishment. It had an air-escape cock, steam induction, and condensed-water escape-pipe.

Hoyle (English patent, 1791) had a system of steam-pipes. The steam ascended to the top of the building, and condensed as it descended.

In 1793 a method was patented for heating rooms by means of a warm pipe passing through

Fig. 5690.



Steam-Hammer.

a boiler containing hot water or steam, on its way to the apartment to be warmed.

By another method pipes from a steam-boiler were inclosed in other pipes, and the air heated during its passage between them.

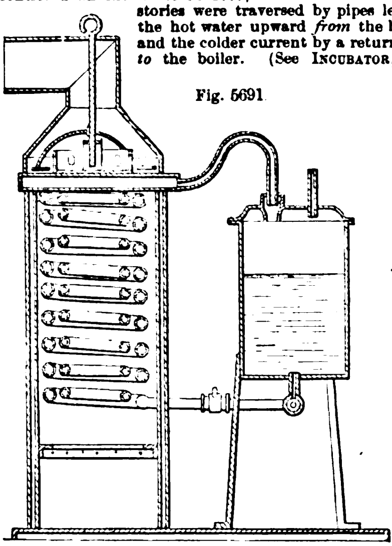
About this time steam was applied to heating hot-houses by being discharged directly into them, thus raising the temperature and affording a greatly increased supply of moisture, which was said to have the effect of causing the plants to vegetate luxuriantly and of destroying insects.

In 1799, Boulton and Watt constructed a heating apparatus, in Lee's factory, Manchester, in which the steam was conducted through cast-iron pipes, which also served as supports to the floor. See also HEATING-APPARATUS, pages 1088-1091.

One of the first buildings heated by steam is said to have been a silk-mill at Waterford, in Hertfordshire. It was 106 × 33 feet, 4 stories high. A furnace was built on the outside, and from the boiler rose a stand-pipe which had branches suspended from the ceiling of each story. The lower story had a pipe 5 inches in diameter; the 2d and 3d stories, pipes of 4 inches; the 4th story, one of 3 inches. The hight of the stories decreased upwardly. The pipes had a slight inclination to allow the water of condensation to run off, and valves at each story governed the admission of steam to the heating-pipe of the said story.

Heating by heated air conveyed in caliducts is much older, being found in the hypocaust of the ancient Romans, and the palaces of the Spanish Saracens. Heating by hot water is older than steam-heating, and probably originated with Bonnemain, who contrived an incubator in 1777, in which the different stories were traversed by pipes leading the hot water upward *from* the boiler, and the colder current by a return pipe *to* the boiler. (See INCUBATOR, Fig. 2666.) He also had an automatic heat-regulator. See Fig. 2476.

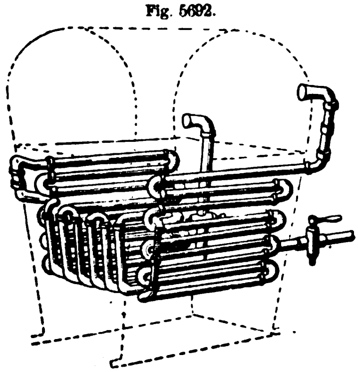
Fig. 5691.



Steam-Generator for Heating Buildings.

Fig. 5691 is a simple form of apparatus, having concentric series of heating coils in the furnace, and a supply reservoir at the side where the condensed water from the various pipes in the building is gathered to resupply the coils. The water passes to the lower ends of the coils, and the upper ends of the latter communicate with the steam space in the reservoir, and form an injector to supply the reservoir with waste water from the heaters. Dampers above the coils regulate the circulation within the furnace.

Fig. 5692.

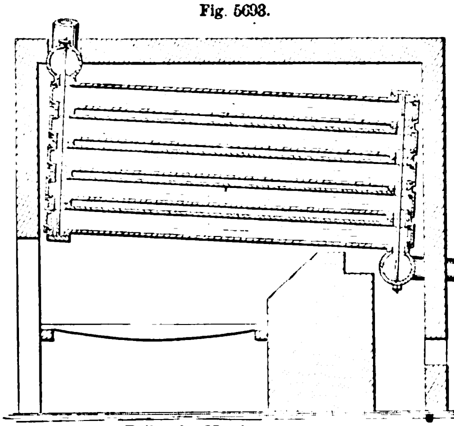


Basket-Grate for Steam-Heater.

Fig. 5692 shows a basket-grate made up of pipes, in which water is converted into steam, which rises in pipes to the rooms of the house.

Fig. 5693 is a sectional boiler for steam-heaters, having several series of inclined pipes which connect in front and rear. Each one in the vertical series of pipes has an upper and lower thimble at each end, communicating with the pipes immediately above and below. The pipes are held together by stay-rods traversing all the thimbles. The pipes from the heaters receive steam from the higher ends of the pipes, while the water of condensation from the heaters above is returned to the boiler at the lower level.

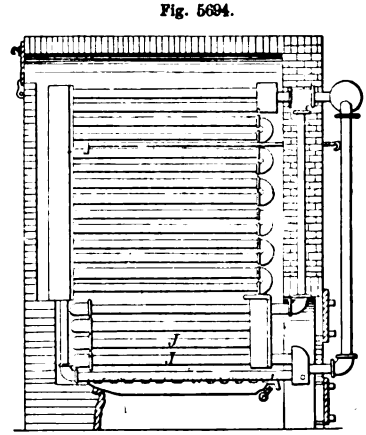
Fig. 5693.



Boiler for Heating-Apparatus.

Fig. 5694 has a series of pipes J J which line the furnace and form the sides of a basket-grate; also an upper series of convolved pipes in which steam is generated. The grate-bars have longitudinal agitation by a ribbed rocking-bar on which their fore ends rest. The furnace is lined and the fire space traversed by horizontal pipes, the current through which is supplied by vertical pipes and headers. From the receiver in front of the furnace the condensed steam is carried to the lower part of the generator.

Fig. 5694.



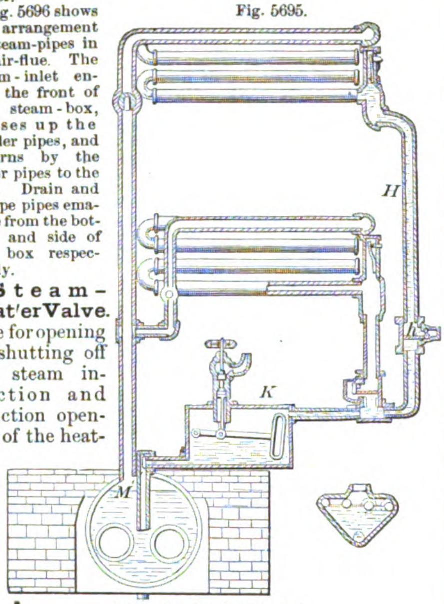
Steam-Generator for Heating-Apparatus.

Fig. 5695 shows the arrangement of circulating pipes on several stories. The steam rises by the pipe M to the heat radiator-pipes, which have automatic air-vents; the water of condensation descends by pipes H, which have valves h which open and close automatically by the alternate action of the back pressure of the steam and the downward pressure of the water of condensation. This as it accumulates passes to a tank K, and thence through another automatic valve to the boiler. In the tank is an elongated float combined with an air-discharge

valve and ventage-pipe, to regulate the flow of water into the boiler.

Fig. 5696 shows an arrangement of steam-pipes in an air-flue. The steam-inlet enters the front of the steam-box, passes up the hinder pipes, and returns by the other pipes to the box. Drain and escape pipes emanate from the bottom and side of the box respectively.

Fig. 5695.

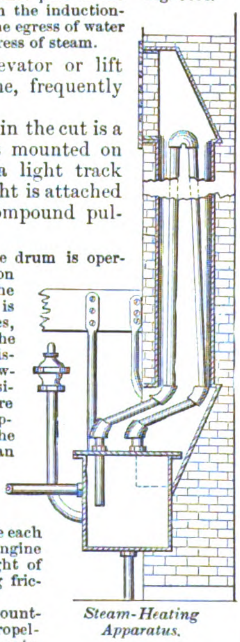


Steam-Heater Circulation.

Steam-heat'er Valve. One for opening or shutting off the steam induction and eduction opening of the heater.

In the example (Fig. 5697), the induction and eduction valves are in one case, both being opened and closed simultaneously by the turning of the same wheel. The screw-threaded pipe connecting the double-valve case and heater is provided with a partition, and that part of the pipe which communicates with the induction-valve is extended to facilitate the egress of water from the heater during the ingress of steam.

Fig. 5696.



Steam-Heating Apparatus.

Steam-hoist. An elevator or lift worked by a steam-engine, frequently portable.

The steam-hoist shown in the cut is a small engine and windlass mounted on a truck which runs on a light track along the wharf. The weight is attached to the lower block of a compound pulley.

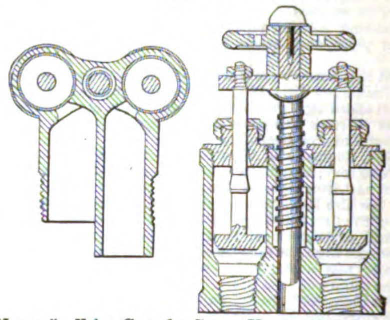
In Otis's hoist (Fig. 5699), the drum is operated by gearing receiving motion directly from the pistons of the double-cylinder engine; it is grooved, and receives two ropes, one of which winds off while the other winds on, so that the raising of one platform and the lowering of another are effected simultaneously. The platforms are stopped automatically at the upper and lower landings, and the apparatus is provided with an automatic brake, which is brought into action at the moment of shutting off steam.

The platforms counterbalance each other, so that the work of the engine is confined to lifting the weight of their contents and overcoming friction.

Montgomery's (Fig. 5700) is mounted on a carriage, and is self-propelling; its arrangements are such as to enable it to be used for hoisting, pumping, etc., and also as a traction-engine. In use, the driving-wheels may be lifted from the ground so as to act as fly-wheels, or they may be unclutched. The rope drum is thrown into gear with the engine, the piston being driven forward or reversed to wind or unwind the rope from the drum, or the rope may be lowered while a friction-brake is applied to the drum.

Fig. 5701 shows a hoisting-machine for a warehouse-elevator. See also ELEVATOR; ROPE-ELEVATOR.

Fig. 5697.



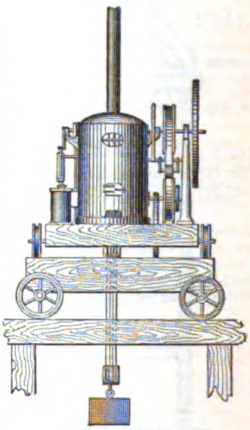
Howard's Valve-Gear for Steam-Heating Apparatus.

Steam-in'di-ca'tor. A device to record the pressure of steam. It was invented by James Watt. See INDICATOR, Fig. 2668; PRESSURE-GAGE, Figs. 3039–3043; STEAM-GAGE.

Steam'ing-ap'pa-ra'tus. An arrangement for exposing material to the softening influence of steam as preliminary to wood-bending; or for cooking food (Fig. 5702); or digesting stock for paper pulp; or as a disinfector or feather-renovator. See STEAMER; STEAM-TANK.

Steaming is used in many trades. Fig. 5703 is an apparatus for steaming on hat-bodies, exposing them to a wet heat, which expands them into shape. The hat-body is placed upon the pyramidal assemblage of levers, to which it is held by clamps with corrugated faces. The size of the frustum being then enlarged, a hat-block is elevated centrally, impinging against the crown of the hat and stretching it into shape. See HAT.

Fig. 5698.



Steam-Hoist.

Steam-jack'et. A steam-tight casing around a cylinder, boiler, or other object, to prevent the cooling of the object so enveloped.

Watt, in 1769, after contriving the separate condenser, in which the injection-water was applied to condense the vaporous contents of the cylinder of the Newcomen atmospheric engine, added to the cylinder a steam-jacket to prevent the radiation of heat from the cylinder and the consequent loss of steam and time in warming up the cylinder after the effective stroke. See also CLEADING; LAGGING.

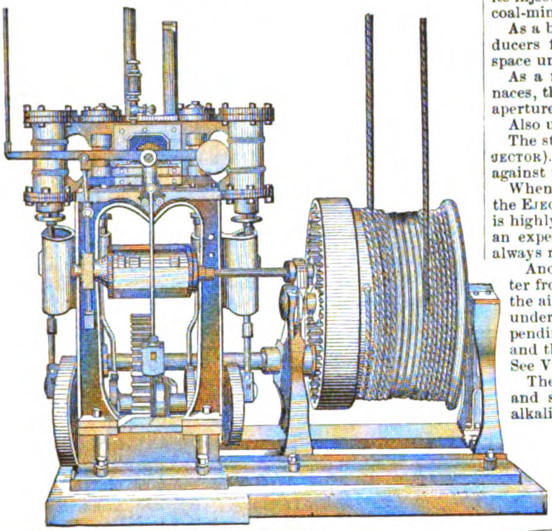
Vacuum-pans, agricultural boilers, evaporating-pans, and many other objects are steam-jacketed.

Steam-jet. A blast of steam emitted from a nozzle.

The steam-jet is used as an air-pump for exhausting one of the pneumatic dispatch-tubes employed at the Central Telegraph Station, in London, for conveying the carriers containing telegraphic dispatches from one station to another. The result of a comparative trial made with the steam-jet and with a good steam-engine and exhausting-pump has been found to be that the expenditure of steam is about the same in the two cases in doing the same work, the advantages of the steam-jet being its very low first cost in comparison with that of the engine and pump, and also its great simplicity, and the small space occupied as compared with an engine and pump.

A very thin annular jet of steam, in the form of a hollow cylindrical column, is discharged from an annular nozzle. The air to be propelled by the steam-jet is admitted through an exterior annular orifice surrounding the jet, and also through the center of the hollow jet, the area of the air-passages being gradually contracted on approaching the jet. The combined jet of steam and air is discharged through an expanding delivery pipe of considerable length, in which its velocity is gradually reduced. See PNEUMATIC TUBE; ATMOSPHERIC RAILWAY.

Fig. 5699.



Otis's Steam-Hoist.

For ventilation, by causing a draft of air in the direction of its injection. It was first used by Mr. Goldsworthy Gurney in coal-mines.

As a blower for accelerating the distillation of fuel in gas producers for heating purposes, the jet being admitted into the space underneath the fire-grate, which is inclosed by doors.

As a means of feeding hydrocarbon liquids and air to furnaces, the steam, air, and petroleum being ejected at concentric apertures in regulated quantities.

Also used as an alarm. See STEAM-WHISTLE; SIREN; etc.

The steam-jet is also used as a water-pump (see GIFFARD INJECTOR). In this case it is used to drive the water into a boiler against the pressure of the steam therein.

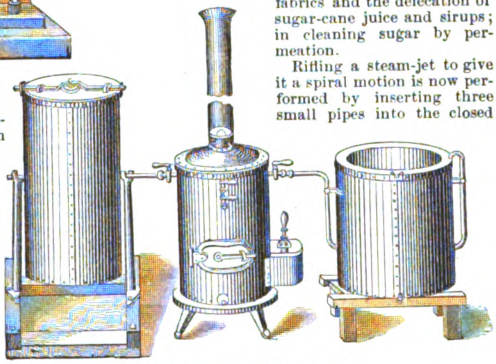
When used as a lift-pump, the device assumes the form of the EJECTOR (which see; see also AIR AS A WATER-ELEVATOR). It is highly recommended as a bilge-water pump, for although it is an expensive form of pump, it involves no machinery, and is always ready in an emergency.

Another application of the steam-jet is to the lifting of water from a moderate depth, by employing the jet to exhaust the air from a closed vessel, into which the water then rises under the pressure of the atmosphere, the hight of lift depending upon the size of the jet and the pressure of steam, and the consequent degree of vacuum obtained in the vessel. See VACUUM STEAM-PUMP.

The steam-jet is also used as a spray in damping sawdust and shavings, to lessen danger from fire; in distributing alkaline liquids upon hemp, flax, or paper stock; as a vehicle in disseminating sulphuric-acid gas in the bleaching of fabrics and the defecation of sugar-cane juice and sirups; in cleaning sugar by permeation.

Rifling a steam-jet to give it a spiral motion is now performed by inserting three small pipes into the closed head of a delivery-pipe. These pipes are then given half a turn each, and the ends brought together. In cleaning flues, this triple nozzle gives three jets, each having a spiral or twisting motion that causes them to strike the walls of the flue, and effectually sweep them clean.

Fig. 5702.

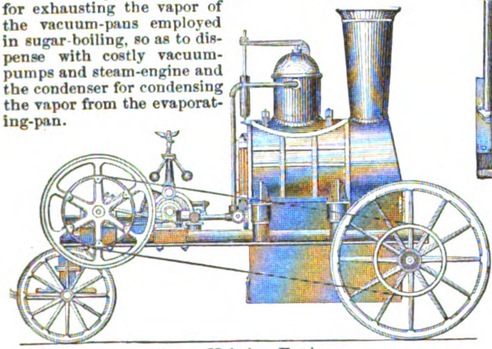


Steaming-Apparatus.

The pneumatic tube is also used for conveying messages between the various apartments of the Western Union Telegraph building, New York.

The steam-jet is also used for exhausting the vapor of the vacuum-pans employed in sugar-boiling, so as to dispense with costly vacuum-pumps and steam-engine and the condenser for condensing the vapor from the evaporating-pan.

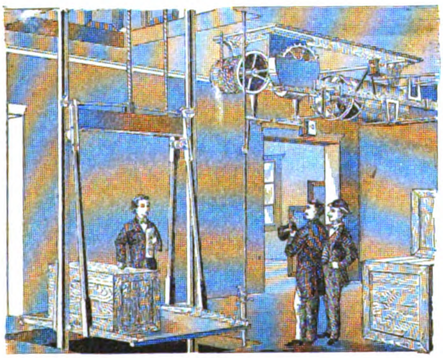
Fig. 5700.



Steam Hoisting-Engine.

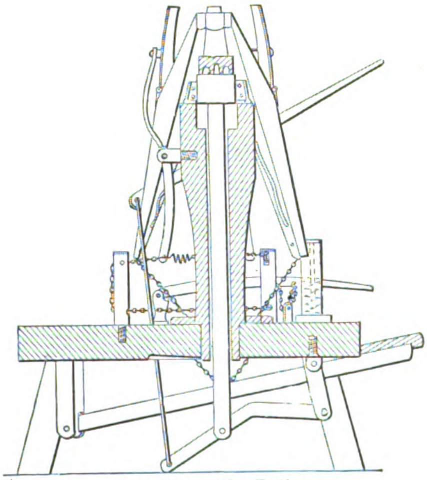
For draining the molasses from the sugar, by exhausting the air from below the perforated bottom of a strainer containing the undrained sugar, superseding the mode of draining by gravitation or by centrifugal strainers.

Fig. 5701.



Hoisting-Machine for Warehouse-Elevator.

Fig. 5703.

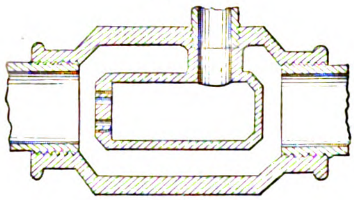


Steaming on Hat-Bodies.

Steam-jet Pump. A form of injector or ejector in which the body of water is put in motion by a steam-jet. See INJECTOR; EJECTOR; AIR AS WATER-ELEVATOR; etc.

In the example, jets of steam are delivered from a nozzle fixed concentrically in the water passage, so as to act within a cylinder of water.

Fig. 5704.

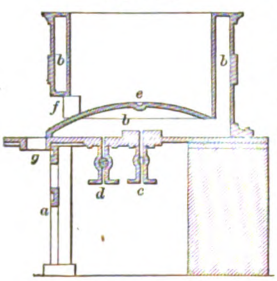


Steam-Jet Pump.

Steam-ket'tle. A pan heated by steam, used for many purposes. See OIL-MILL; LARD-TANK; MALT-VAT; etc. Specifically, —

1. A pan in which bruised flaxseed is heated, previous to pressure. Hallette's (Fig. 5705) is supported on a wall of masonry and pillars *a*; it is surrounded by a jacket, steam being admitted into the space *b b b* at its sides and bottom through the induction-pipe *c*; *d* is the eduction-pipe, serving also to run off the condensed water. The spindle of a rotary stirrer is stepped into the depression *e*; *f* is an opening for discharging the heated seed, and *g* an orifice for the mouth of the bag in which they are received.

Fig. 5705.



Steam-Kettle.

2. An agricultural boiler for cooking food for stock.

Steam-launch. A large man-of-war's boat with a propeller-engine.

The details of one made as a tender to a sailing yacht for use on the fiords of Norway may afford an instance. The boat is 14 feet long by 4 feet 3 inches beam, and is to be carried at the ordinary davits; the total weight, including the machinery, being only 800 lbs. The hull is built entirely of mahogany, and it contains a vertical boiler with engine attached, the arrangement being such that the machinery can be detached from the hull in a few minutes, and hoisted out complete, and the launch then used as an ordinary boat, it being provided with oars and rowlocks. The boiler, which is worked at a pressure of 75 lbs. to 80 lbs. per square inch, is welded up throughout, there being no riveted seams. The boat will carry four persons and a good supply of coal. See also YACHT.

Steam-pack'et. A steamer carrying mails. See STEAMBOAT.

Steam-pan. A vessel with a double bottom, forming a steam-chamber. Used as a hot table, and otherwise. See VACUUM-PAN; LARD-TANK; etc.

Steam Pile-driv'er. Invented by Nasmyth, the inventor of the steam-hammer. See PILE-DRIVER. See also Holtzapffel, ii. 961.

Steam-pipe. Any pipe conveying steam. Notably, —

1. The pipe leading from a boiler to an engine, pan, tank, and what not; or from the same to a condenser or to the open air, as the case may be. Known as *induction* and *exhaust* respectively.

The loss of steam from condensation in a well-protected steam-pipe may be taken approximately as 1 lb. of steam per indicated horse-power per hour for each 100 feet of steam-pipe. In such a case, a stuffing-box expansion-joint should be provided in the steam-pipe allowing an expansion of 2¼ inches for each 100 feet in length.

2. One of the supply-pipes in a system of steam heating or drying.

Steam-plow. A plow, or gang of plows, drawn by portable steam-engines. By the same means, cultivators, harrows, and other agricultural implements are drawn.

The varieties of systems of steam-plowing may be said to be five.

1. *Engines upon a track and plows moving at right angles thereto; the engine advancing between each course of the plows.*

The first steam-plow patented in England was the invention of Clarke, Freeman, & Varley, 1846. This system used a track for a locomotive on each side of the piece to be cultivated, and the plows were drawn back and forth by ropes from the engines.

Osborn, the same year, patented a somewhat similar contrivance of tracks, engines, and plows.

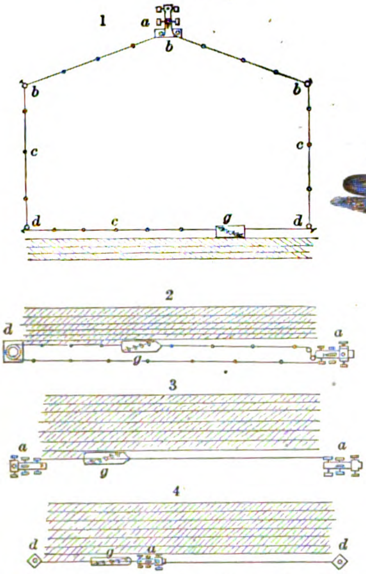
In 1850, Lord Willoughby de Eresby introduced his system of steam-plowing. The machinery consisted of the "California" locomotive-engine, designed by Sir Daniel Gooch, which weighed 3½ tons, and was 26 horse-power. The engine was fitted with a double capstan, which could readily be removed when the engine was required for other purposes. It was intended by the inventor of this system that the engine should be moved "across the center of the field on a light portable railway. The plows advance and recede on either side of the railway at right angles to it." The plows or other implements of culture are intended to be worked by "an endless chain 150 yards in length, which will be put in motion by the capstan of the engine. Provision is made at the moving anchor for taking up the slack or letting out fresh chain"; and by this arrangement the chains could be varied a length of 40 feet to suit the varying length of irregular-shaped fields. The plows that were intended to be

Fig. 5706.

Fowler's Steam-Plow.

used consisted of "four ordinary plows and the like number of subsoil plows fixed in a frame," which were to be guided "by a person standing on a small platform" attached to the frame. Two such sets of plows were intended to be worked, "one on either side of the railway."

Fig. 5707.



Diagrams showing Manner of Using various Steam-Plows.

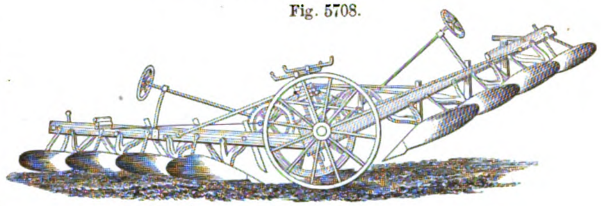
Fowler's engines and plows are used in the manner shown in diagrams 2, 3. In Fig. 5707, 2, if only one engine is used, a snatch-block at the other side of the field turns the rope, and is moved along after each furrow, as is also the engine where two engines are employed, as in Fig. 5707, 3, where one rope draws the plows, and is reeled back and forth from one engine to the other as the gang-plow crosses the field. Only one engine and one gang of plows operate at a time. The engines are of 12 to 20 horse-power each. The gang or *balance* plow (Fig. 5708) is capable of turning four or six furrows, and a double-engine steam-plow will break up 20 to 25 acres per day, requiring six men to attend the plows and engines. 400 sets of these machines have been made and sent to the Pasha of Egypt, yet there are but few in this country, — one in New Jersey, and some in Louisiana and in the West. They are in use in Cuba and South America.

The Magnolia sugar plantation, in Louisiana, has one set of the Fowler steam-plow of 14 horse-power, and one of 20 horse-power. When breaking up, the mold-board is set to plow to a depth of from 15 to 20 inches, and when using the subsoiler cultivating between the cane rows to the depth of from 20 to 24 inches.

2. The "roundabout" system of Howard may use a portable engine of any approved construction, in connection with a windlass for holding the rope. A *snatch-block* is anchored at each point where the rope makes a turn. The rope is kept from sagging by *rope-porters* having anti-friction rollers, over which it passes.

Fig. 5709 shows the operation of this mode of cultivation, which is the same in effect as the diagram 1 (Fig 5707). *a* is the engine; *b* the windlass, to which both ends of the wire rope

Fig. 5708.



Gang-Plow.

are secured, and which winds one way long enough to draw the gang-plow *g* across the field, when it is reversed, and draws it back again. Snatch-blocks *d d* are moved after each furrow, while those *b b* are stationary until the plowing is complete; *c c* are rope-porters. The snatch-block with its anchors and the rope-porters are shown on a larger scale in the perspective view, Fig. 5709.

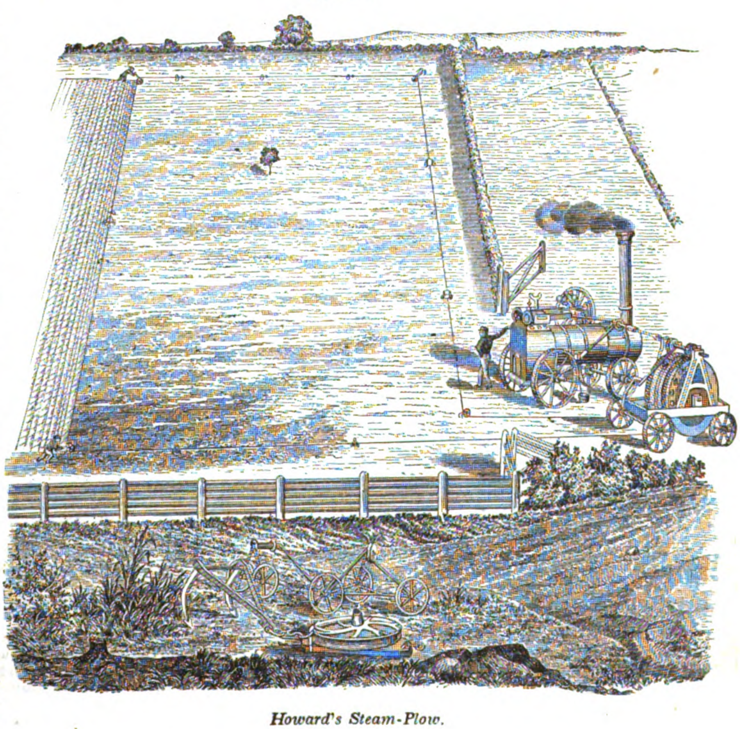
3. *The engine drawing itself and the gang of plows across the field by winding on a rope which reaches between anchors on opposite sides of the field.*

Hall's stationary rope steam-plow, operating in the manner shown at 4, Fig. 5707, is a combination of the rope and traction-engine system. The wire rope is anchored at each side of the field, and the engine travels along it, holding by a clutch or by passing the rope around a drum. The anchors at the sides of the field are moved as the work progresses. It is claimed that four men and one engine can plow 20 acres per day with this apparatus.

4. *Traction-engine drawing gang of plows.*

This has been found difficult, owing to the occasional softness and the inequalities of soils. The

Fig. 5709.

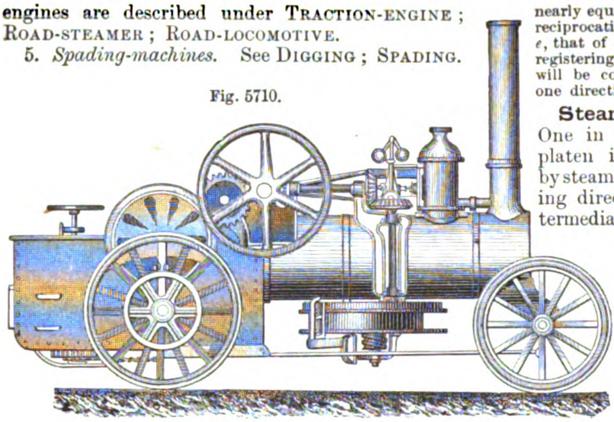


Howard's Steam-Plow.

engines are described under TRACTION-ENGINE; ROAD-STEAMER; ROAD-LOCOMOTIVE.

5. *Spading-machines.* See DIGGING; SPADING.

Fig. 5710.



Traction-Engine for Gang-Plow.

Steam-port. (*Steam.*) An opening through the valve-seat to the inside of the cylinder. Known as the *induction* (inlet) port, or the *eduction* (outlet) port, respectively, according to the course of the steam.

Steam-pow′er Me′ter. A device for ascertaining the amount of work done by a steam-engine. Fig. 5711 is that of Messrs. Ashton & Storey, of Manchester, England.

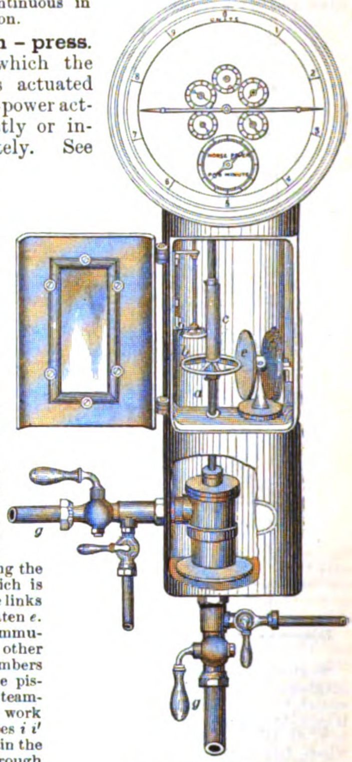
It consists of a double-acting indicator cylinder, having its ends connected with those of the engine-cylinder by pipes *g g*. The indicator piston-rod *a* carries a wheel *b* with a plain rim and a long pinion *c* gearing with the spur-wheel *d*. At the upper end of this rod is a helical spring, which resists either the upward or downward movement of the indicator piston. The wheel *d* is fixed on the lower end of a spindle having a worm at its upper end, which communicates motion to the train actuating the dial.

The wheels *e f* are of the same diameter, and on the same horizontal shaft; the first has a smooth face, which is, by means of a spring, pressed against the rim of the wheel *b*; the other *f* is grooved and connected by a band with the cross-head or other convenient reciprocating part of the engine, causing its partial rotation in one direction; its motion is reversed by a spring, thus causing an alternating reciprocating movement of the two wheels *e f* when the engine is in operation. The tension of the spring at the head of the rod *a* is so adjusted that when the pressures on each side of the piston are equal, the wheel *b* is at the center of the wheel *e*; an excess of pressure on either side causes it to rise or fall by an amount proportionate to this excess.

The principle of operation is as follows: If the wheel *f* be connected with the cross-head of the engine, so that its periphery and that of *e* move an equal distance and at an equal velocity with the cross-head, and a steam pressure of 50 pounds per inch suffices to move the wheel *b* to a point midway between the center and the circumference of the wheel *e*, the periphery of the wheel *b* will move with half the velocity of the engine-piston, and so on in proportion to its greater or less distance from the center of *e*, dependent on the effective pressure. The relation between this motion and that communicated to the gearing of the indicator is such that the dials register the amount of work done in units of 1,000 foot-pounds for each circular inch in area of the piston. The absolute work of the engine in a given time is then ascertained by multiplying the square of the diameter of the piston by the number of units indicated by the dial.

As at each up-stroke of the piston the wheel *b* will be above the center of the wheel *e*, and at each down-stroke an equal, or nearly equal, distance below it, it is evident, owing to the reciprocating motion of *e*, that of *b* and of the registering mechanism will be continuous in one direction.

Fig. 5711.



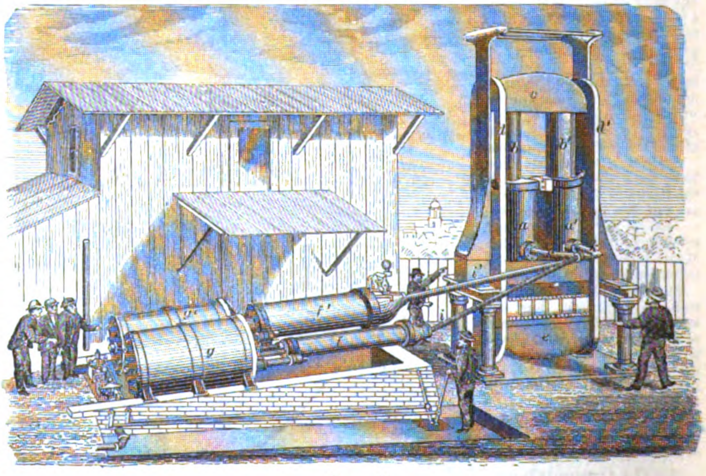
Steam-Power Meter.

Steam-press. One in which the platen is actuated by steam-power acting directly or intermediately. See list under PRESS, page 1784.

Fig. 5712 illustrates a steam and hydraulic baling-press. The cylinders *a a′* inclose the rams *b b′*, carrying the cross-head *c*, which is connected by the links *d d′* with the platen *e*. The cylinders communicate with each other and with the chambers *f f′*, in which the piston-rods of the steam-cylinders *g g′* work through the pipes *i i′ k k′*. These contain the water or oil through which the pressure is communicated.

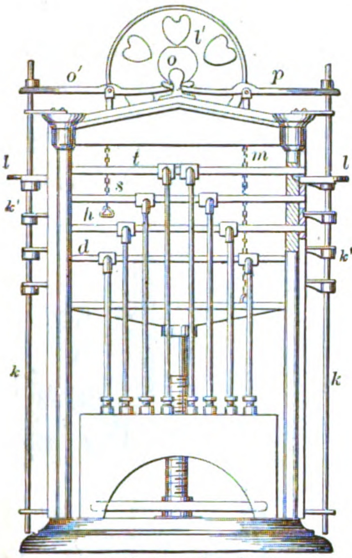
Previous to commencing operations, live steam is admitted to the cylinder *g*, forcing its piston out in opposition to the fluid pressure of the cylinders *a a′*, which, on steam being cut off, forces the piston back again, and the connecting pipe between *g* and *g′* being closed, the steam is readmitted to the other end of the cylinder *g*; by this means it is thoroughly warmed, so as to prevent condensation during the subsequent operation.

Fig. 5712.



Steam-Press.

Fig. 5713.



Press for Steaming Goods.

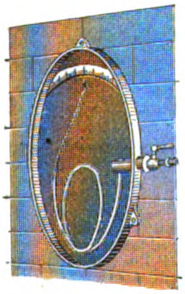
The bales are next placed on the platen, the communication valve between the cylinders g g' is opened, permitting steam to flow from one to the other, forcing the piston f' forward, and the fluid into the cylinders a a', causing the rams b b' to ascend and raising the platen. When the pressure on the two pistons is equalized, the forward motion of this piston stops, an automatically acting valve closes, a valve is opened, admitting live steam to the cylinder g, again forcing its piston forward; this is of smaller area than the piston f', and, receiving the full force of the live steam, exerts a much greater and more rapid pressure, completing the operation. The bale is then tied, and the stroke of the pistons reversed, enabling the bales to be removed and the operation repeated.

The several valves governing the admission and exhaust of steam are controlled by hand-levers.

Fig. 5713 is an apparatus for steaming goods while under pressure. The hollow pressing-plates d h s t communicate, through steam induction and eduction pipes, with a steam-chest beneath, divided into two chambers by a vertical partition. These plates have a limited vertical motion by reason of their outer edges resting upon ledges l l k' k', connected with the rods k k, which are operated by levers o' p by means of a cam o on the wheel l'. The folded goods, with layers of cardboard interposed, are placed upon the follower of the press, and then between the successive steam-plates, in ascending order, until all are filled. The follower is then raised by its screw and hand-wheel, and steam is admitted to the chest, passing through the induction-pipes into the plates, and thence out through the eduction-pipes to the eduction compartment of the chest. The steam-pipes slide in stuffing-boxes, and the plates are lowered to receive the goods by turning the wheel l' through the medium of the chain m which passes over it.

Steam-press′ure Gage. (*Steam-engine.*) An instrument for indicating the pressure of steam in a boiler, cylinder, pipe, tank, or other object to which it is attached.

Fig. 5714.



Steam-Pressure Gage.

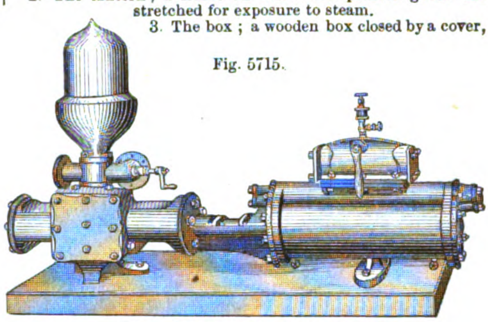
Bourdon's (Fig. 5714) consists of an elliptical copper tube bent into an arc of $1\frac{1}{2}$ circumferences, 540°. One of the extremities communicates with the boiler or reservoir of condensed gas whose pressure is to be measured, and the other carries an index which moves backward or forward on a graduated arc as the curvature of the tube is varied by changes of pressure. See PRESSURE-GAGE; STEAM-GAGE.

Steam-print′ing Ap′pa-ra′tus. An apparatus for fixing colors upon cloth by means of steam. See STEAM-PRESS.

It embraces: —

1. The column; a hollow cylinder having numerous perforations, around which the cloth is lapped, in order to steam it.
2. The lantern; a frame on which the printed goods are stretched for exposure to steam.
3. The box; a wooden box closed by a cover, which is made steam-tight at the edges by a list of felt, and has a perforated steam-pipe at the bottom.
4. A chamber into which steam is introduced through two perforated pipes.

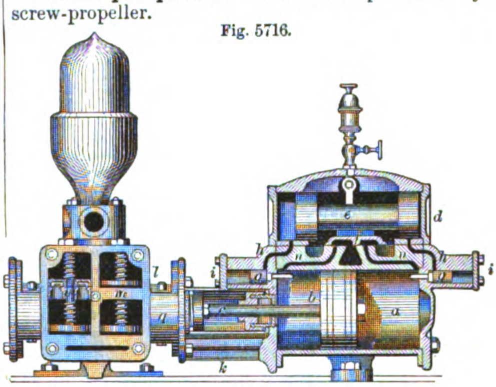
Fig. 5715.



Cameron's Steam-Pump (Elevation).

Steam-pro-pel′ler. A steam-ship driven by screw-propeller.

Fig. 5716.



Cameron's Steam-Pump (Section).

Steam-pump. An application of the steam-engine to pumping purposes.

The steam-pump known as Cameron's special, extensively used in collieries, is shown in Figs. 5715, 5716. a is the steam-cylinder; b c, piston and rod; d, steam-chest; e, plunger, operating the slide-valve f; g g, reversing-valves, covered by bonnets i i; k, body-piece, connecting steam-cylinders and water-cylin-

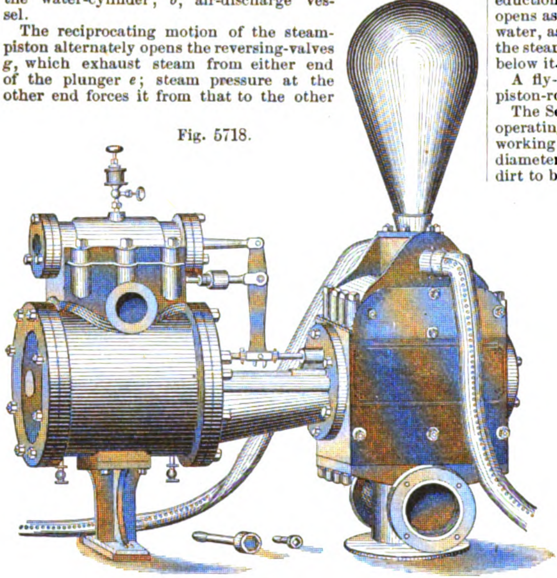
Blake's Steam-Pump.

ders q; l, valve-chest, and $m\ m$, valves of the water-cylinder; o, air-discharge vessel.

The reciprocating motion of the steam-piston alternately opens the reversing-valves g, which exhaust steam from either end of the plunger e; steam pressure at the other end forces it from that to the other

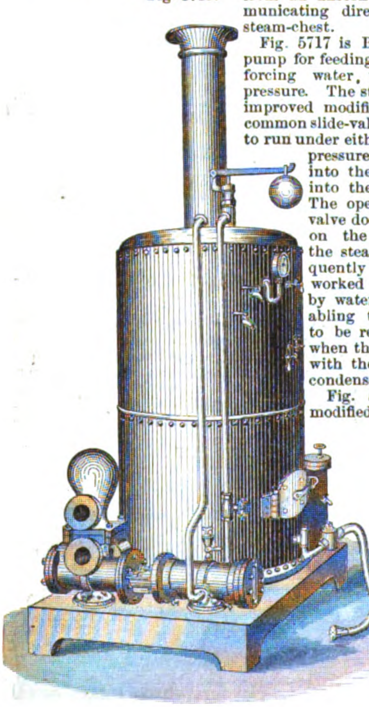
Fig. 5718.



Blake's Steam Fire-Pump.

end of its stroke, and opens or closes the steam-ports $n\ n$ controlled by the slide-valve f, which admits steam to the piston. The exhaust takes place through the ports $p\ p$, and the valves $g\ g$ are reversed by steam from an unseen passage communicating directly with the steam-chest.

Fig. 5719.



Portable Steam-Pump.

Fig. 5717 is Blake's steam-pump for feeding boilers or for forcing water, under heavy pressure. The steam-valve, an improved modification of the common slide-valve, is arranged to run under either high or low pressure, exhausting into the condenser or into the atmosphere. The operation of the valve does not depend on the elasticity of the steam, and consequently it may be worked with certainty by water-pressure, enabling the apparatus to be readily started, when the valve is filled with the cold water of condensation.

Fig. 5718 shows a modified form of this pump, specially adapted for fire-extinguishing purposes.

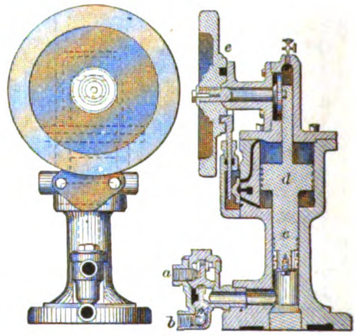
The portable pump (Fig. 5719) has an upright boiler, the pump being horizontal. The water-eduction port is connected with an air-chamber, to render the discharge continuous.

The Paragon steam-pump (Fig. 5720) has its induction and eduction orifices $a\ b$ controlled by valves, so connected that one opens as the other closes, and *vice versa*, by the action of the water, as the ram c, which is in one piece with the piston d of the steam-cylinder, rises and falls as steam is admitted above or below it.

A fly-wheel e rotated by an eccentric connected with the piston-rod regulates the velocity of the strokes.

The Selden steam-pump (Fig. 5721) has two pump-cylinders, operating by a plunger directly connected with the piston-rod, working in a cylinder between them. The cylinder is of greater diameter than the piston, enabling water containing grit and dirt to be pumped without injuring the parts by grinding.

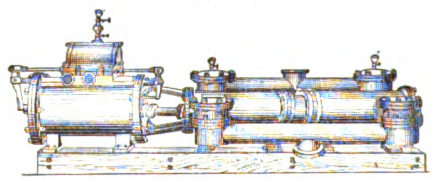
Fig. 5720.



Paragon Steam-Pump.

The steam-cylinder valve-rod projects beyond each end of the steam-chest and has a lever at each end, which is struck by a rod on the piston passing through the two cylinder heads, thus operating the valve.

Fig. 5721.

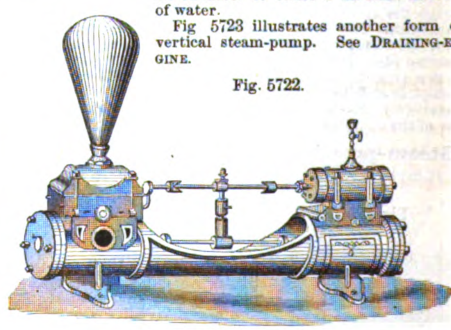


Selden Steam-Pump.

In Knowles's steam-pump (Fig. 5722), the steam and pump cylinders are both horizontal, and the latter is provided with an air-chamber to cause a uniform delivery of water.

Fig 5723 illustrates another form of vertical steam-pump. See DRAINING-ENGINE.

Fig. 5722.

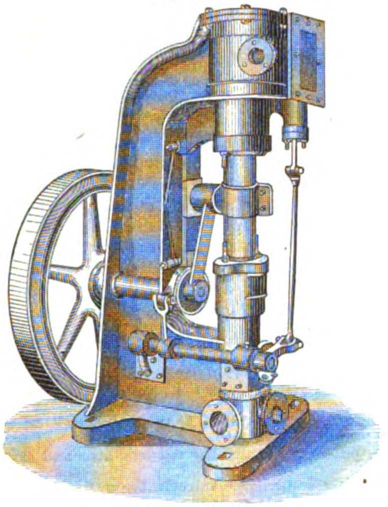


Knowles's Steam-Pump.

The pump (Fig. 5724) is particularly designed for mining purposes, and where gritty or sandy water is to be raised. It is a double-cylinder plunger-pump. The two plungers $a\ a'$ are directly connected to the piston-rod of the steam-cylinder, which does not enter the water-cylinders, but passes through guide-flanges at their sides, and is consequently not subject to the abrasive action of gritty matters contained in the water.

Fig. 5725 is what is known as an "oil line-pump," used in the petroleum regions, where an inclination is to be overcome in conveying oil from the well to a depot or other situation above ground. It has two pumping-cylinders $a\ b$, one at each

Fig. 5723



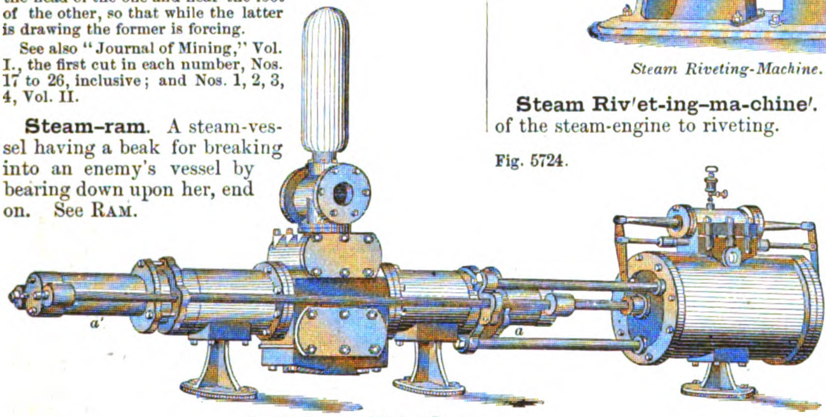
Vertical Steam-Pump.

end of the steam-cylinder *c*; one acts as a suction and the other as a forcing pump; the pipe *d* connecting the two enters near the head of the one and near the foot of the other, so that while the latter is drawing the former is forcing.

See also "Journal of Mining," Vol. I., the first cut in each number, Nos. 17 to 26, inclusive; and Nos. 1, 2, 3, 4, Vol. II.

Steam-ram. A steam-vessel having a beak for breaking into an enemy's vessel by bearing down upon her, end on. See RAM.

Fig. 5724.



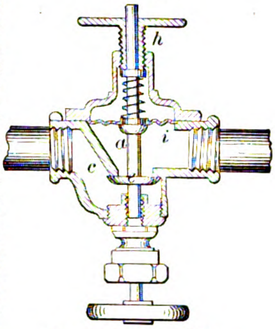
Double-Plunger Mining-Pump.

Steam-reg'u-la'tor Valve. A valve for automatically regulating the passage of steam through a pipe or opening.

In the example, the upper part of the valve-stem *a* passes through and is connected with the diaphragm *i*, the degree of compression of which is regulated by a spring whose tension may be varied by the screw *h*. The lower end of the stem is inserted in a screw operated by a hand-wheel below, by turning which the valve *e* may be forced up against its seat, to entirely close the steam opening. In ordinary operation it is allowed an indefinite amount of downward play, and the tension of the diaphragm is so adjusted that if the normal steam-supply is exceeded, the diaphragm rises and the valve cuts off the supply; but if the pressure is too small the opposite effect is produced, the tendency being in either case to cause a uniformity of steam pressure in the eduction-chamber *c*.

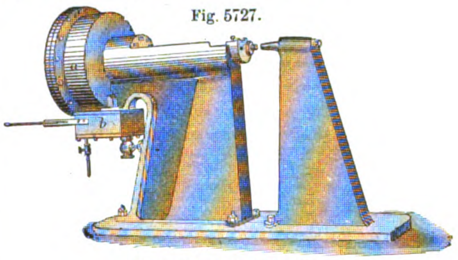
The invention is particularly designed for application to steam-blowers.

Fig. 5726.



Steam-Regulator Valve.

Fig. 5727.



Steam Riveting-Machine.

Steam Riv'et-ing-ma-chine'. An application of the steam-engine to riveting.

In Fig. 5727, the ram and piston of the cylinder *a* are made very heavy and in one piece, so as to act by momentum, and are operated by direct action of steam from the steam-chest *b*. The piston is retracted by the expansion of the steam used in riveting. See also RIVETING-MACHINE.

Steam-room. The capacity for steam over the surface of the water in the boiler.

Steam-shear. (*Metal-working.*) A machine for slitting metal plates. The plates, 20 to 30 feet long and 6 or 7 feet wide, are placed on a table provided with rollers and guides, which is advanced toward the knives until a strip of the desired width and of the whole length of the plate is severed.

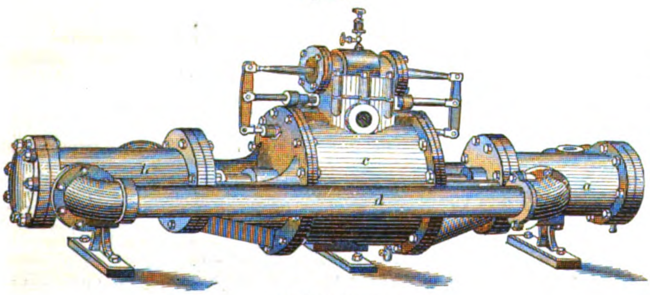
One used by the Otis Iron and Steel Company of Cleveland, O., weighs about 80,000 lbs., has knives 87 inches long, and shears $1\frac{1}{4}$-inch steel plates at a single stroke. See SHEARING-MACHINE.

Steam-ship. See STEAM-BOAT.

Steam-sled. An ice-locomotive.

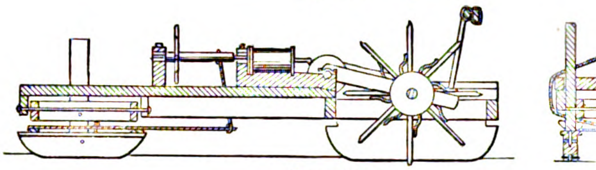
The sled is moved by point-ended radial arms on a rotating wheel, and has two pairs of runners with guide-

Fig. 5725.



Oil Line-Pump.

Fig. 5728.



Steam-Sled.

knives beneath. The forward runner-frame admits of oscillation to guide the sled. See also Fig. 2644, page 1163.

Steam-sli′cer. A steam-operated machine for slicing dried meat and fresh vegetables. See ROOT-SLICER; VEGETABLE-SLICER.

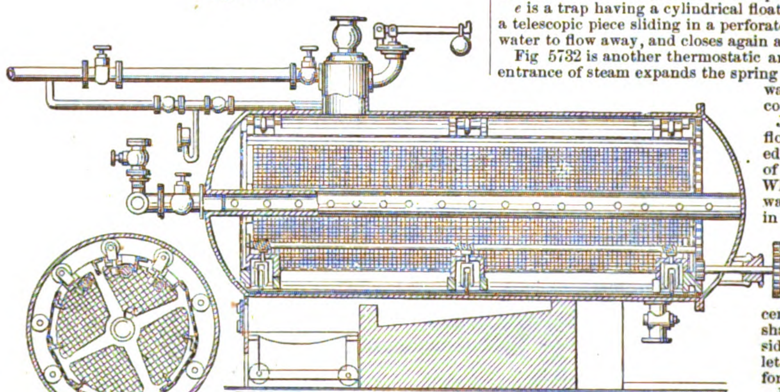
Steam Steer′ing-ap′pa-ra′tus. See STEERING-APPARATUS.

Steam-ta′ble. A hollow table heated by steam, to keep joints and other viands warm in the dining or carving rooms of hotels.

Steam-tank. A chamber heated by steam, used for various purposes in the arts, such as steaming wood, paper-stock, rendering fats, etc. See under the various heads.

Fig. 5729 shows an apparatus for treating vegetable, mineral, and animal matters with steam. The matter to be treated is

Fig. 5729.

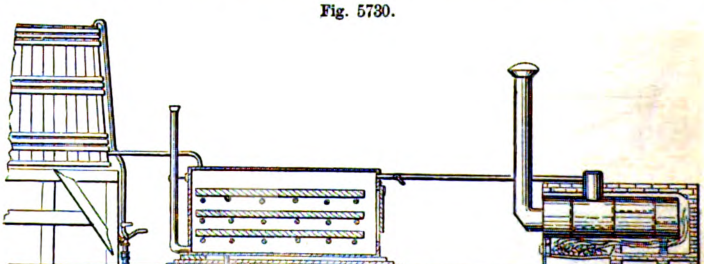


Tank for Treating Matters with Steam.

placed in the retainer, which is run into the boiler, one end of the latter being removable The retainer is a wire-work cylinder supported by a metallic frame, whose circumferential ribs carry rollers to support the retainer when rotated. Some of these rollers are fixed in casters, which are turned by a rod and worm gear to serve as supports when the retainer is run out on to the truck. A perforated pipe, axially attached to and removable with the retainer, communicates with pipes outside the boiler to allow introduction of chemicals. The grate is removable with its supporting truck.

Fig. 5730 represents a steam-chamber in which wood is treated, to preserve it. The timber-chamber is charged with superheated vapor, which is subsequently condensed, and the pores of the wood filled with an oleaginous preservative material admitted from a reservoir. See WOOD, PRESERVATION OF. See also LARD-TANK; etc.

Fig. 5730.



Apparatus for Preserving Wood.

Steam-toe. (*Steam-engine.*) An arm fastened to a lifting-rod to raise it by the contact of the cam or tappet. The toes on the lifting-rods of the inlet and exhaust are *steam* and *exhaust* toes respectively.

Steam-trap. A self-acting device for the discharge of condensed water from steam-engines or steam-pipes. Cocks are frequently applied for the purpose, as we see in the cylinders of locomotive-engines, etc., but they require strict attention.

The preferable forms of steam-traps are automatic. Some are thermostatic arrangements, in which the difference between the heat of steam and the heat of the water actuates a valve to discharge collected water; others act by the rising of a float in the water-chamber; others by the weight of the collected water.

Fig. 5731 shows several forms of steam-traps. *a* is Tredgold's. A square box is placed in such position as to collect water of condensation. When this rises to a certain hight, the float raises the valve and allows the water to flow away. As the float falls the valve closes.

In *b* is a thermostatic valve. As the chamber fills with water the rod contracts in length and opens the valve; as steam takes the place of the water the rod lengthens and closes the valve.

In *c* the water-discharge valve is below the float and the water-line. The air-valve is operated by the expansion of a copper rod.

d has a perforated sliding-tube sliding in a seat, and has a valve on each end. Steam entering at one end blows the valve forward on to its seat and opens the holes at the other end, so that the water of condensation escapes by the central pipe.

e is a trap having a cylindrical float above a valve formed of a telescopic piece sliding in a perforated tube, which allows the water to flow away, and closes again as the float descends.

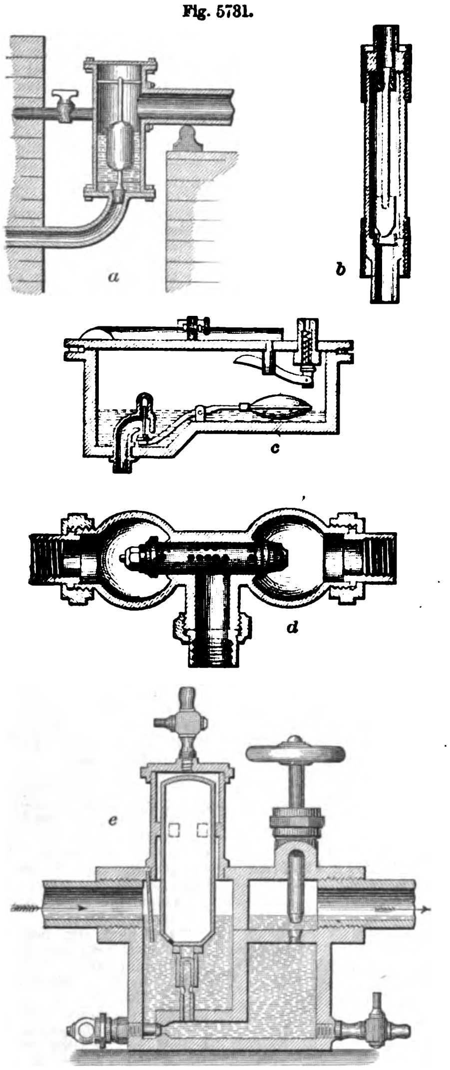
Fig 5732 is another thermostatic arrangement, in which the entrance of steam expands the spring and closes the valve. As water collects, the spring cools and the valve rises.

Jones's steam-trap has a float *a* at the end of a pivoted rod *b*, to which the stem of the valve *c* is connected. When a certain amount of water has been condensed in the trap the ball rises and lifts the valve, allowing the excess to escape into the waste-pipe *d*. The valve may also be lifted by the eccentric *e*, which turns on a shaft passing through the side of the trap. *f* is the inlet and *g* the outlet passage for steam.

Barr's elliptic steam-trap consists of two tubes *a b* united at one end by the casting *c*. *d e* are two castings attached to the free ends of the tubes, one *d* having an aperture for the admission of steam, and the other *e* an aperture for the escape of the water condensed. *f* is a globe-valve; *g*, a yoke secured to the tube *a* and to the valve-stem; *h*, a rod secured to the castings *d e*, and having a nut *i* which regulates the movement of the valve.

Steam entering the opening in *d* expands the tubes, which being prevented from extending longitudinally by the rod *h*, are caused to spread apart the tube *a*, carrying the yoke *g* and

Fig. 5731.

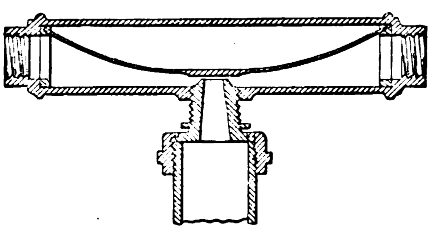


Steam-Traps.

valve-stem in one direction, and the tube *b* moving the valve *f* in the other direction, closing the valve and preventing escape of steam.

As soon as condensation takes place the tubes *a b* cool and contract, opening the valve and permitting the steam to escape.

Fig. 5732.

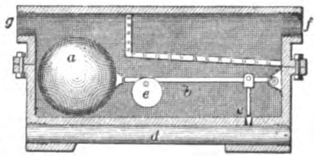


Steam-Trap.

The trap may be set to allow escape of steam at any given pressure by means of the nut *i*.

In Wilson's steam-trap, *c* is the spring, the upper leaf brass and the lower steel; the two are closely riveted together. *b*, the valve, is a plate of common solder, raised on the under side of the steel leaf of the spring.

Fig. 5733.



Jones's Steam-Trap.

Steam-tug. A small but powerful steam-vessel for towing ships in or out of harbor.

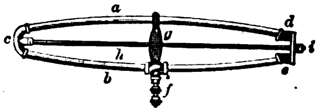
Steam Vac'u-um-pump. One for raising water by the condensation of steam in a vessel situated at such elevation above the water-supply that the atmospheric pressure will raise the water to the chamber and operate the valves. See VACUUM STEAM-PUMP.

Steam-valve. A device for opening or closing a steam pipe or port. See list under VALVE.

Steam-ves'sel. See STEAMBOAT.

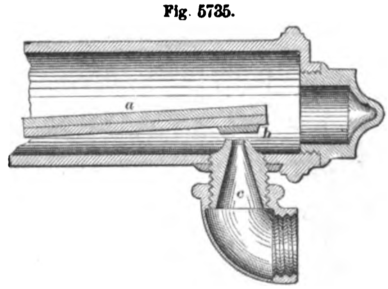
Steam Wa'ter-el'e-va'tor. A water-raising apparatus in which the pressure of steam on the water is the means of elevating it. The old idea of Savery, Worcester, and others. (See STEAM-ENGINE.) The engraving shows a locomotive whose steam-pipe *b* is temporarily connected with the chamber *a* to inject steam, by whose condensation the chamber is filled, and by whose subsequent pressure the water

Fig. 5734.



Barr's Elliptic Steam-Trap.

Fig. 5735.

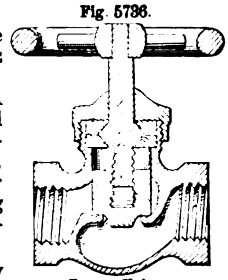


Wilson's Steam-Trap.

is driven by pipe *e'* to the tender; *e* is a valve-box; *c*, an air-chamber. See also VACUUM STEAM-PUMP.

Steam-way. A passage leading from the steam-port of a valve to the cylinder.

Fig. 5736.



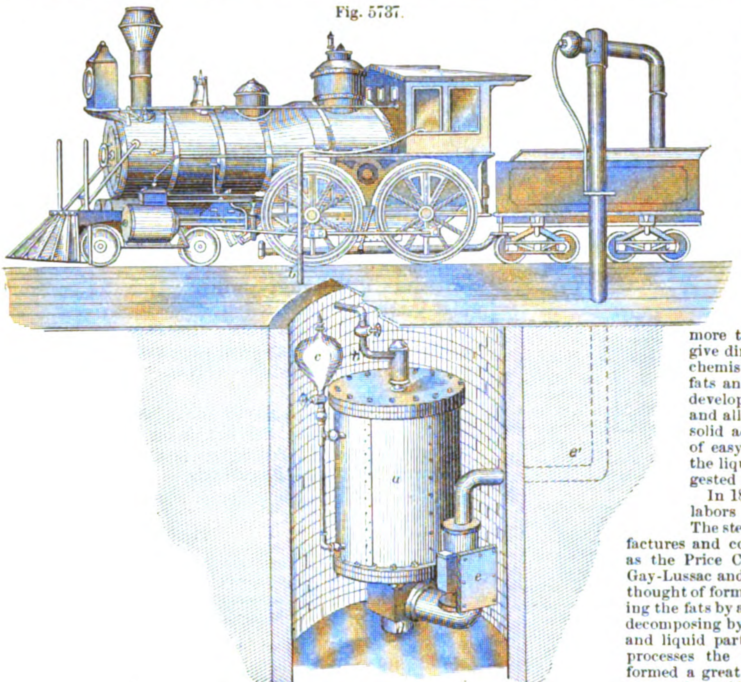
Steam-Valve.

Steam-wheel. The ROTARY STEAM-ENGINE (which see).

Steam-whis'tle. A sounding device connected with the boiler of a steam-engine, either stationary, locomotive, or marine, for the purpose of announcing the hours of work, signaling, etc.

It was invented about 1826 by Adrian Stephens, chief mechanic at Plymouth Works, England, and afterward of Merthyr Tydvil, Wales, and was designed to render clearly audible the escape of steam from the safety-valve.

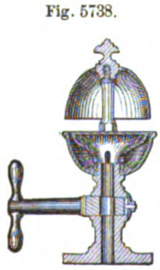
Fig. 5737.



Steam-Pressure Water-Elevator.

Fig. 5738 illustrates the whistle of a locomotive-engine. The foot is bolted on to the fire-box, has an opening for the admission of steam, and is provided with a cock, by turning which steam is permitted to rush into the hollow piece, which is provided with holes around its lower and narrower portion, through which the steam rushes into the cavity of the cup, and, passing out through the narrow annular opening, impinges against the rim of the bell, causing a shrill, piercing sound. Holes in the top of the bell permit the escape of the steam upwardly and increase the volume of sound. The quality of the tone depends on the width of the annular opening, the depth of the bell, and the distance between it and the cup.

Fig. 5738.



Steam-Whistle.

The Calliope (which see) is a series of such whistles tuned to a scale and operated by keys. See Patent 13,668 of 1855.

Steam-whistles are also made to give varying tones by graduating the length of the pipe or cup.

Patent 131,176 of 1872 has in the bell a removable piston which graduates the sound so as to play a tune.

Patent 142,166 of 1873 has a bell which consists of a fixed open cylinder and a slightly larger cylinder closed at one end and sliding over the first. This makes a telescopic sounding-tube, the length of which may be varied to produce musical notes.

Patent 141,280 of 1873 has a series of gates in the body of the pipe, which form *tompons* to vary its length, and so form musical notes.

No. 29,915 of 1860 has a series of reeds in a chamber, and movable shutters for closing all but the one required to sound a given note.

Steam-winch. A form of hoisting-apparatus in which rotary motion is imparted to the winding axle from the piston-rod of a steam-engine, directly, as at *A*, or intermediately, through bevel-gearing, as in *B*. The former is more rapid; the latter affords greater power.

It is specially used for getting freight in and out of vessels. See Crane; Steam-crane; Traversing-crane; and list under Hoisting-apparatus.

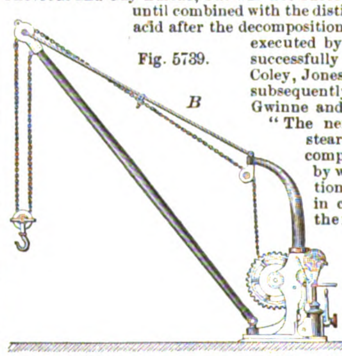
Ste'a-rine. The more solid portion of fats and oils after the fluid portion, *oleine*, has been removed.

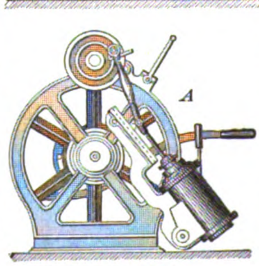
The growth of the stearine industry dates from the labors of Braconnot in 1817, in separating oleine and stearine, followed by the researches of M. Chevreul. Prof. J. Lawrence Smith observed, in his address at the Priestly Centennial of Chemistry: "M. Chevreul did not give to the world the results of his labors as a mass of isolated facts, but he systematized and classified new acids, new bases, and left to us the chemical history of facts almost as fully made out as they are at the present time; and these have contributed as much as, if not more than, any class of researches to give direction and growth to organic chemistry. The decomposition of the fats and formation of the fatty acids developed the fact that, when melted and allowed to cool slowly, the more solid acids crystallized, so as to allow of easy separation of the solid from the liquid part, which fact soon suggested a practical application."

In 1823 a complete account of the labors of M. Chevreul was published. The steps which led to the great manufactures and commercial undertakings, such as the Price Candle Factory, were made by Gay-Lussac and Chevreul in 1825. They first thought of forming the fatty acids by saponifying the fats by alkalies and the alkaline earths, decomposing by acid, and separating the solid and liquid parts by pressure. In the earlier processes the expense of potash and soda formed a great difficulty, but this was subsequently avoided by the use of lime. De Milly and Motard in 1829 in the process, and Cambaceres in the process and also in the invention of the plaited wick, put the industry upon a firm footing. To quote farther from Professor J. Lawrence Smith: —

"A second advance in this industry was the use of sulphuric acid to decompose the fats; this plan originated also with Chevreul and Gay-Lussac, but was not successfully carried out until combined with the distillation of the fatty acid after the decomposition, — a method first executed by Dubrunfaut, and successfully carried out by Coley, Jones, and Wilson, and subsequently perfected by Gwinne and Jones.

Fig. 5739.





Steam-Winch.

"The next step made in stearinery was the decomposition of the fats by water. The conception of this method, in common with all the methods of saponification of fatty bodies, is to be referred back to the author of the discovery of the true nature of fats, M. Chevreul; for in his original researches he pointed out the perfect analogy between the fats and the compound ethers, the latter class of bodies being decomposed into their two constituents, in the presence of water heated in close vessels under pressure; a reasonable deduction from which was that fats would undergo an analogous decomposition. This, however, was not undertaken at the time, but by an accident, about the time of Chevreul's researches, it was observed to take place by Faraday, when his attention was drawn to some changes in oils used by Perkins in his curious steam-engine that employed very hot water.

"No attempt was then made to draw any practical results from these observations, and we find no farther notice taken of the subject until early in the year 1854, by R. A. Tilghmann,

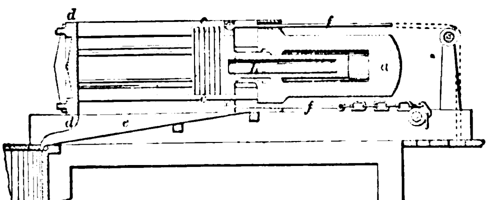
of Philadelphia, when patents were taken out by him for decomposing fats mixed with water, and superheated in vessels of a certain description. The method of Tilghmann, as originally patented, was never introduced into practice; since then, with change in the manner of operating and in the nature of the boiler, it has been successfully conducted in many factories.

"In the latter part of the same year that Tilghmann's process was patented, M. Melsens, of Belgium, took out a patent very analogous, using fats mixed with water in the proportion of 20 to 100 per cent of the latter; the water might be acidulated with from 1 to 10 per cent of sulphuric acid, or the addition of salt would suffice; the whole was heated from 180° to 200° C. for several hours. The success of Melsens's process was immediate, and it was put into operation on a large scale in Antwerp in vessels holding one ton of tallow, to which was added 50 per cent of water, and in six hours the decomposition was complete at a temperature of 180° C. (ten atmospheres). The fatty acids thus made were of a very satisfactory quality, quite as much so as those obtained by other methods of saponification.

"But this method, by superheated water, is now supplanted by a mixed method of using one or two per cent of lime with the superheated water, which addition facilitates and hastens the reaction in a manner not yet understood by chemists."

Ste'a-rine-press. A hydraulic press used for depriving stearine (stearic acid) or spermaceti of fluid oily impurities.

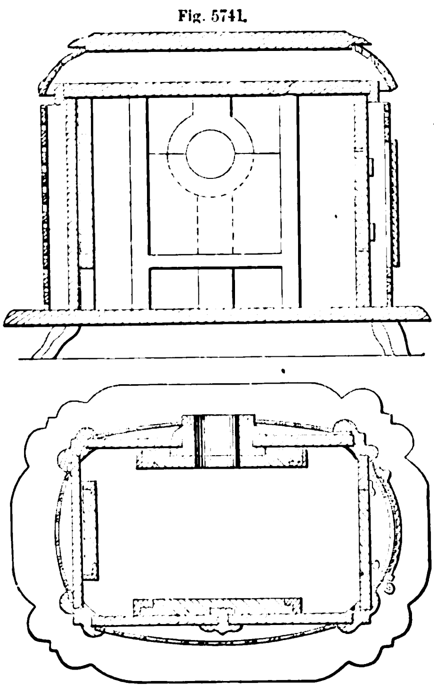
Fig. 5740.



Stearine-Press.

a is the cylinder; *b*, the ram; *c c*, iron plates previously heated, placed between every two cakes of the material, inclosed in hair or cloth bags; *d d*, a head strongly bolted to the cylinder to receive the pressure. The oil flows through a spout *e* to a reservoir. The ram is brought back to place after pressing by weights and chains connected to the rods *f f*.

Fig. 5741.



Soapstone-Stove.

Ste'a-tite-stove. A form of stove in which the sides and top are of soapstone, with iron frames and fittings.

Steel. A most valuable alloy of iron, which possesses certain peculiar characteristics.

This alloy of iron is generally understood to depend for its quality upon the possession of a certain proportion of carbon, which causes it to harden when heated and plunged into water. An expert, Mr. A. L. Holley, defines it as an alloy of iron which is cast while in a fluid state into a malleable ingot. Blister and shear steels, however, made by the usual cementation, are not cast, neither is the native steel cast by the African and Asiatic tribes. The difference between steel and iron is always structural, usually chemical also.

Another definition is, a compound or alloy of iron that will forge, harden, and temper (CROOKER). This includes iron in combination with various other elements besides carbon, as silver, tungsten, chromium, titanium, cyanogen, silicon.

Ordinary steel contains from 0.5 to 1.5 per cent of carbon. Its hardness and fusibility increase with the amount of carbon, and when this element is in excess it becomes cast-iron. When the proportion of carbon is small, the metal is termed *mild* or *low* steel; high steels are those containing a large proportion of carbon.

Steel has been produced, as an experiment, by heating the iron to be converted in contact with diamond.

The earliest discovery or invention of steel is in the remote past, but the nature of the change in the iron was not understood. It was prepared by fusion, and not by cementation.

It would seem that the distinction between qualities was known and utilized B. C. 335, as the Persian and Damascene sword-blades were then in high repute, and were formed of slips or thin rods of iron and steel, bound together with iron wire and united by welding.

The terms used in the original Scriptures are translated "iron" and "steel" according to the context. The "iron" of that day was in fact a "steel," being procured by a single or repetitive process from the ore. See IRON; MALLEABLE IRON.

"He shall flee from the iron weapon, and the bow of steel shall strike him through." — Job xx. 24.

"Shall iron break the northern iron and the steel?" — Jer. xv. 12.

Ezekiel, about 600 B. C., speaks of the "bright iron" of Javan; and Hesiod, 850 B. C., of "bright iron" and "black iron," the former probably meaning steel: it may have been a different quality, and have taken a finer polish, as steel does.

Steel was imported from the country of the Chalybes into Greece about 500 B. C., and the name *chalybs* signified steel. The description of steel-making by Aristotle shows that the process was repetitive, and that dross was eliminated. Heating several times in contact with charcoal was held to purify it. It was not understood till comparatively lately that steel is a carburet of iron.

Polybius, the friend of Scipio Africanus, states that the helmet and armor of the Roman soldier were of bronze, but that the sword was a cut and thrust blade of Spanish steel. The forgers of the latter were in Celtiberia, now New Castile and Arragon. The town of Bilbilis and the little river Salo, a tributary of the Ebro, are celebrated as the center of the iron district.

Diodorus, a Greek, who wrote about 50 B. C., describes the Celtiberians as armed with weapons of excellent temper. He states that they buried the iron till part was consumed by rust, and that the remainder made swords strong enough to cleave a shield or helmet, or cut through a bone. Some wrought bands that were recovered with the piles driven to support the abutments of old London Bridge were bought by a cutler, who became celebrated for the surpassing excellence of the blades forged from the "old scrap-pile."

Pliny gives a long description of iron and the modes of its manufacture.

The varieties of steel in modern practice are very numerous, many of them having peculiar adaptation to a certain specific purpose in the arts; among them are: —

a. Natural steel. A crude steel obtained by the finery process, i. e. by removing the impurities of cast-iron by jets of air blown into the bath of molten metal, which is covered by a layer of charcoal. It is very similar in its properties to puddled steel, and is used as a raw material for crucible cast-steel.

The *natural* steel of Germany is made directly from the ore, and sometimes from pig-iron in the Catalan forge. It is stated by Bergmann to be: —

Iron	96.84
Manganese	2.16
Carbon	1.00
	100.00

The ore is smelted, as for iron, in blast furnaces; but the blast is weaker, and is directed, not upon the metal, but in a horizontal direction above it. The metal is kept covered with slag, and is not disturbed by stirring. When the iron is judged to be sufficiently refined, it is taken out of the furnace and forged.

b. India steel, or wootz. A steel made in India by melting the crude native iron (containing a small percentage of carbon) in crucibles, in which pieces of wood or leaves are introduced. The name has been appropriated by English manufacturers to their own products, which are probably ordinary cast-steel of good quality.

The mode adopted by the native East-Indian for obtaining steel is somewhat primitive, but by the exercise of skill in manipulation an excellent article is produced. It is understood to be made from the magnetic oxide of iron. The ore is stamped to fragments, and the adhering quartz separated by washing and sifting. The smelting is effected in the most primitive way; the furnace is built of clay, and not more than four or five feet high; the bellows is formed of two goat-skins, with a bamboo nozzle, tipped with a clay tube at the end which is to be nearest the fire; the fuel is charcoal. (See SMELTING-FURNACE.) By this process the Hindoo manages to obtain a most excellent steel.

The iron is heated to a low red heat, and is beaten for a long time with stone hammers on a stone anvil; the Hindoos having an opinion that iron implements are injurious. To convert the hammered iron into steel, it is broken into small pieces, and put into small crucibles with a little dry wood; the crucibles are stopped up with clay, and are put into a furnace, where they are entirely covered with charcoal. A blast is then applied for two or three hours; the crucibles are removed, allowed to cool, broken, and the metal removed; it has changed its character from iron to steel. The lumps of steel, called *oollies*, are sorted into different sizes for knives or small tools, daggers, spear-heads, or sword-blades, and find a ready sale in most of the markets in India, at prices varying from six to eight annas, or 24 cents a pound. There is a considerable export-trade of Indian woortz steel from Hyderabad, Masulipatam, the Deccan, and Berar to Upper India, Persia, and Damascus, the *oollies* being carried on donkeys and ponies by Byraghies and wandering tribes, who live by this trade.

c. Puddled steel, or semi-steel. A steel obtained in the reverberatory furnace by conducting the puddling process in such a manner that the iron "comes to nature" and aggregates into the solid form before the carbon is entirely removed. The product is similar in structure to wrought-iron, while the residual carbon gives it hardness and the tempering property.

d. Cement steel, or blister steel. This is obtained by piling bars of wrought-iron interstratified with charcoal in a brick compartment, which is cemented tightly to prevent access of air, and subjected inside the walls of the compartment to a high temperature for several days. Carbon is absorbed in considerable quantity.

In England, the Swedish iron is used for making the best steel. It is received in bars 3 inches wide, 5/8 of an inch thick, and about 12 feet long. These are laid up evenly, in a converting furnace, which consists of two rectangular vessels, technically called *a pair of pots*, made of a refractory silicious freestone, and supported upon solid masonry, with a firebrick top, upon which the pots rest, the brick divisions forming flues underneath. The pots are $3\frac{1}{2} \times 3\frac{1}{2}$ feet, and 12 feet long, and are placed parallel to each other, but 18 inches apart, forming flues, extending up the sides and ends of the pots into the fire-brick vault which covers the whole. This vault has an arched opening at each end, for charging the pots with iron, or taking out the charge when converted into steel. During conversion, they are bricked up and plastered with clay. There is also a small opening over each pot, through which bars can be put. Out of the vault rise three chimneys on each side, opening into a large cupola. The fire-grate is under the middle flues and the whole length of the pots, with a door at each end, kept closely shut, except when being charged. Each pot has a stratum of charcoal evenly laid on the bottom, above which a layer of bars is placed, and covered half an inch deep with charcoal; bars and charcoal are thus laid alternately until the pot is nearly full, and finished off with a thicker covering of charcoal over the top. The pots when filled are covered over with five inches of *wheel swarf*, which contains iron and steel in minute particles, and, becoming partially fused when hot, perfectly protects the steel underneath from the action of the air. Each furnace has a five-inch opening through the walls and into the center of one end of the pots, through which two or three of the top bars project, the opening being filled up with fine ashes, well rammed to exclude the air. The fire, gradually raised to great intensity, is kept up for six or eight days. A furnace holds about 16 tons of iron, and is considered to be well worked if 14 to 16 heats are got out in a year. See Fig. 1197.

When the conversion is supposed to be nearly complete, a top bar is drawn, and, when cold, is broken; its condition shows the state of the whole, and the fire is regulated accordingly. A second or third bar is subsequently drawn, and when the conversion is considered to be complete, the fire is allowed to go out. In four days the man-holes are opened to hasten the cooling, and in four more the steel, still hot, can be taken out. A full furnace charge is called a *heat of steel*, and, according to the degree of carbonization required, is called a *spring* heat, a *cutler's* heat, a *shear* heat, a *file* heat, or a *melting* heat. The surfaces of the bars are now covered with thin blisters, hence the name *blister steel*. These terms do not apply to the *temper* of the steel, but to the length of time in the furnace. This steel is useful for some purposes, but is not adapted for making tools for working wood or metal. See also Fig. 1198.

Shear and spring steel. The bars are now broken and sorted by experienced workmen into the various tempers; the hardest are laid aside for melting, and the softer hammered into shear or spring steel. Those required for shear-steel are broken into lengths of about one foot; are next laid upon each other, three or four together; then heated in a furnace to *welding* heat, and drawn under the hammer or "tilted" to the size intended. It is then *single-shear* steel. If again broken, heated, and hammered, it becomes *double-shear* steel, an extra quality used for best table cutlery and other first-class purposes. Spring-steel is made from bars passed at a red heat between grooved rollers until reduced to the particular size required. Shear and spring steel are the chief, if not the only qualities manufactured direct from the converting furnace.

Mushet's process for making steel, patented in England in 1801, consists in placing malleable iron in scraps or bars in a crucible with a due proportion of powdered charcoal, pitcoal, graphite, or other carbonaceous substance, and subjecting it to intense heat.

Rich and pure iron ore may be inclosed with carbonaceous matter, and treated with heat in a similar manner.

By varying the quantity of the carbonaceous matter, steels of different quality are obtained. In employing wood charcoal from 1/70 to 1/90 of the weight of the iron is usually sufficient. From 1/60 to 1/40 produces a very fusible metal suitable for steel castings.

e. Cast-steel.

Cast-steel was invented in 1740 by Benjamin Huntsman, near Sheffield. His process was to place small fragments of blistered steel in a crucible of fine clay, place some broken green glass above, lute the cover, and then place the crucible in a furnace. When melted, the crucible was withdrawn and the contents poured into an iron mold. Huntsman was a German; born in 1704; began life for himself as a clock-maker.

This is essentially the process yet followed in producing fine cast-steel, suitable for cutlery and tools for working in metal and wood.

Previous to the successful efforts of Bessemer, various efforts had been made to produce cheap steel on a large scale.

f. Bessemer and kindred steels.

For many years it had been believed in England that Swedish iron derived its valuable steel-producing qualities from the presence of manganese.

Heath, of Sheffield, England, in 1839, devised a mode of combining carbon with manganese to produce a carburet, which converted English iron into very good steel. He obtained a patent for it. Unfortunately, he did not patent his improvement, which consisted in putting into the furnace the elements of his carburet (carbon and manganese). The Sheffield manufacturers defied him, and, after years of litigation, he died, broken-hearted, in 1850.

Macintosh, Scotland, patented a process for converting malleable iron into steel by subjecting it to a stream of carbureted hydrogen gas, evolved from coal under distillation. The iron is inclosed in a crucible in the furnace, and when it has arrived at a proper heat a stream of gas is directed upon it by a pipe.

A new method of steel-making, which has recently been patented in France, is as follows: (1) Employing ammoniac and carbonated hydrogen gases in certain proportions for the cementation of iron on a large scale, the gases acting simultaneously, and at the moment of their production, by the decomposition at a high temperature of a mixture of sal ammoniac and a substance supplying proto or carbonated hydrogen; (2) for the making of cast-steel from scraps of iron, cemented by the process above described, and melted by the same operation; and (3) the fabrication of steel by the fusion of cemented iron sponge

produced by the reduction of ores, forge scoriæ, etc., by means of gas derived from peat or hydrogenous matters.

Newton, 1848, Marcy, 1849, directed a stream of air, or of air mingled with carbonic oxide, upon the surface of the molten metal in a reverberatory furnace. This failed for lack of penetration.

Nasmyth employed blowing-tubes to inject steam below the surface of the metal, to agitate the iron mechanically, and by the decomposition of the steam furnish oxygen for the removal of the carbon, and hydrogen for separating the sulphur and phosphorus. The process failed by too great a reduction of temperature.

Martien added air to the steam.

Bessemer used air alone, introduced through tubes.

Berard added hydrogen gas, generated in a separate vessel, to the air of Bessemer, the intention being, as with Nasmyth, to remove the sulphur, phosphorus, and arsenic.

Krupp's steel is prepared from the spiegel ore of Siegen by puddling and then melting in crucibles. The success of the process is due to the quality of the ore, and the remarkable size of the blocks resulting is due to the skill of the workmen, the extent of the furnace, and the power and manageability of the machinery.

The establishment of F. Krupp, at Essen, Prussia, manufactured, in 1873, 150,000,000 lbs. of cast-steel, against 130,000,000 in 1870; 8,810 workmen, and engines amounting to 9,595 horse-power, are employed. 528 furnaces for smelting, heating, and converting; 169 forges, 260 welding and puddling furnaces, 245 coke-furnaces, 130 various other furnaces, 342 turning-lathes, 130 planing-machines, 73 cutting-machines, 172 boring-machines, 94 grinding-benches, 209 various other machines, 174 steam-boilers, 265 steam-engines (from 1,000 horse-power downward), and 58 steam-hammers (from 30 tons downward), were in use. The various articles manufactured consist of axles, wheels, tires for railways, rails, springs for railway and tramway cars for mines, axles for steam-ships, boiler-plates, rollers, tool-steel, cannon, gun-carriages, etc.

By Knowles's method a retort is used instead of a crucible, and the crude iron is mixed with hot gases rich in carbon.

Bessemer's process was introduced to the notice of the British Association at Cheltenham in 1856. It consists in converting pig-iron into malleable by driving air through the molten metal to burn out the impurities, and then converting it into steel by the addition of the requisite ingredient. The effect of the blast is to burn out the silicon, carbon, sulphur, and phosphorus. See BESSEMER-PROCESS; CONVERTOR; PLANT.

Mr. A. L. Holley's improved Bessemer apparatus is designed to enable a greater number of charges to be converted into steel in a given time.

For this purpose the convertors have each two or more movable bottoms, which are run to or from the body of the convertor on cars, and raised and lowered by a hydraulic lift. The tuyeres are packed with dry material, so that no time is lost in waiting for it to set. The two convertors are both placed on the same side of the ingot-pit, and the chimneys are in the walls of the building, so as not to interfere with the cranes.

In Atwood's process, iodide of potassium is used to take up the phosphorus existing in the iron.

While the usual English method of making steel has been by the *cementation* process, *raising* the amount of carbon in *bar*-iron, on the Continent of Europe the *raw* method has been a favorite, pig-iron being *puddled* in a charcoal furnace, *lowering* the amount of carbon in the *cast*-iron.

Riepe's process, used by the Lowmoor Iron Company, consists in adding to the pig-iron in a puddling-furnace a little iron-slag, salt, clay, and oxide of manganese. The molten metal is worked beneath the scum and rolled into balls.

Captain Uchatius, of the Imperial Arsenal, Vienna, granulates cast-iron by running it from the furnace into agitated cold water. The grains are put into a crucible with an oxygen-yielding material such as spathose iron ore, and the pig-iron gives up some of its impurities to the oxygen.

Chenot's method is to incorporate with a peculiar iron carbonaceous matters, such as fat, resins, tar, etc.

Mushet fuses malleable iron with carbonaceous matters in crucibles.

Vickers combines iron scrap, ground charcoal, and black oxide of manganese.

Heaton's process consists in the use of nitrate of soda, producing what he terms crude steel, which may be afterward converted into pure iron or steel. He uses a cylindrical convertor, in the bottom of which is placed a charge of Chili saltpeter (an impure nitrate of soda), mixed with quartz sand, and often with lime, binoxide of manganese, fluor spar, or other material, covered with a perforated iron plate, for the purpose of dividing the generated gas into a number of small streams and preventing its too rapid formation at the beginning of the process. The molten iron is run into the convertor from the blast furnace or a cupola, and the operation commences, slowly at first, but afterward, owing, as is supposed, to the breaking up of the iron plate, very energetically, and is generally completed in from 2½ to 5 minutes. The metal is allowed to cool in the convertor, and when still red-hot is broken up, preparatory to being made into steel, either in the reverberatory furnace or in crucibles.

In Ellerhausen's process, iron ore, generally the magnetic oxide, is mixed with melted pig-iron, in order to take up the carbon, so as to reduce the metal to steel or wrought-iron, as may be desired.

g. Siemens-Martin steel is obtained by melting a certain quantity of cast-iron in a Siemens furnace and adding wrought-iron until the bath attains the desired degree of carbonization. Ferro-manganese is then added to remove the oxides and free oxygen, and the bath is run into ingot-molds.

"In the Martin-Siemens reverberatory furnace the decarbonization of the pig-iron is effected by the reactions, upon the molten bath, of wrought-iron or ore and of the furnace-flame. The operation is slower and more completely under control than that of the Bessemer method; and the ease and regularity with which any desired grade of steel can be produced has led to the employment of this method for some purposes to which the Bessemer is less adapted, — for instance, the manufacture of boiler-plates, machine and tool steel, etc. But the gradual perfection of the arrangements and manipulations of the Martin system, in such works as those of Siemens in Great Britain, Martin in France, and also the establishment at Terre Noire in the South of France, has brought about a competition between Bessemer and Martin steel on the chosen ground of the former, namely, the manufacture of rails.

"One of the advantages of the Martin process in this competition seems to be its capacity of employing old iron rails (usually containing phosphorus) in making new steel rails. It does not appear that the treatment eliminates the phosphorus, but, on the contrary, that a steel is produced containing more phosphorus than was hitherto supposed consistent with tenacity. The secret is asserted to lie in the reduction of the quantity of carbon in proportion as that of phosphorus is increased, or, as it has been expressed, in the substitution of phosphorus for carbon as a 'steelifying agent.' Phosphorus has been universally regarded as the great foe of the steel manufacturer; and if by this means it can be utilized as an ally, a very large amount of material will be rendered available for making steel, and the transformation of thousands of miles of iron tracks on the railroads of the world into tracks of steel will be greatly facilitated. It must be added that engineers and metallurgists are still doubtful about 'phosphorus-steel rails,' though the reports concerning their use in France for a year or two past have been generally favorable.

"The decisive effect produced by minute proportions of a substance like phosphorus in combination with iron may be seen in the fact that one tenth of one per cent of it is considered all that ordinary 'carbon-steels' will bear, while even the 'phosphorus-steel,' of which so much is said, never contains so much as half of one per cent; and usually, we are informed, the proportion of phosphorus in it is about 0.35 per cent, — that of carbon being perhaps 0.12 per cent." — RAYMOND.

Siemens's apparatus for producing steel or iron direct from the ore consists of a set of four regenerators with reversing-valves and gas-producers; the converting chamber is of iron, rests upon anti-friction rollers, and is rotated by gearing. Bauxite, a mineral containing a large proportion of alumina and peroxide of iron, is mixed with small proportions of clay and graphite to form the lining.

The ore is broken into fragments not larger than peas, and, mixed with lime or other *flux*, is charged into the chamber, which is slowly rotated until the mass becomes red-hot; about 25 or 30 per cent of small coal of uniform size is added, and the velocity of rotation increased. A rapid reaction ensues; the peroxide of iron, being reduced to magnetic oxide, commences to fuse, metallic iron is precipitated by the carbon, while the fluxing materials form a slag with the silicious portion of the ore. The rotative velocity is now reduced, the mass as it turns over continually presenting a fresh surface to the heated lining of the chamber and to the flame; carbonic-oxide gas is evolved from the mixture of ore and carbon, and heated air only is introduced from the regenerator to effect its combustion within the chamber, the gas from the producers being nearly or entirely shut off. When the reduction is nearly complete the rotation is stopped, the fluid slag drawn off; the chamber is again set in motion to form the iron into balls, which are shingled in the usual way.

The process may be so conducted as to produce a steel which is afterward transformed into cast-steel by transferring the balls while hot directly to the steel-melting furnace, without being hammered or shingled. This method is preferred, but the metal may be thus converted entirely within the rotating chamber. In this case the amount of carbonaceous matter is somewhat increased; and after the cinder is tapped off, from 10 to 15 per cent of ferro-manganese or spiegeleisen is thrown in, and the heat rapidly increased by urging the influx of heated air and gas from the regenerator. This reduces the metal to a fluid state, when it may be drawn off into molds and afterward hammered or rolled into bars.

h. Granulated steel is made by running melted pig-iron into a cistern of water over a wheel. The fragments are exposed to heat, imbedded in powdered hematite or sparry iron ore. These extract the car-

bon from the surface of the fragments, which are then remelted to form steel.

i. Chromium steel, — a steel containing chromium. It is made in crucibles by adding to the charge either ferro-chromium (an alloy of iron and chromium) or chromic iron ore with charcoal dust. The chromium is reduced by the charcoal and alloys with the steel, giving it great tenacity and hardness, without destroying its malleability or its tempering property.

It is described and claimed in the patent of Baur, No. 49,495, August 22, 1865. See also his subsequent patents, No. 99,624 of 1870, No. 123,445 of 1872.

The chrome is mined near Baltimore, contains 60 per cent oxide of chromium, also protoxide of iron, magnesia, and alumina, but no silica.

On account of its tensile strength it was adopted for the spans of the Mississippi Bridge at St. Louis. Dynamic tests were made in London, also at the West Point Foundry, the average strength of 12 specimens at the latter place being 179,980 lbs. to the square inch, the lowest 163,760 lbs., and the highest 198,910 lbs. The highest strength of steel given in Percy's "Metallurgy of Iron and Steel" is 132,909 lbs. per square inch. The following occurs in the report of Captain J. B. Eads, the engineer of the bridge: —

"Chromium unites with iron and forms an alloy similar in its properties to steel. Chromium is quite different from carbon in some important particulars. It is a metal, while carbon is not. It has little or no affinity for oxygen, and is not affected by excessive heating, while carbon has a great affinity for it, and by the application of heat it is liable to be burnt out of the steel. . . . This steel comes from the rolls much more smoothly than carbon steel, and works quite as easily; being capable of sustaining a greater degree of heat than the carbon steel, it takes the form of the rolls more readily. The tests made of its ultimate tensile strength are considerably in excess of the specifications. In compression almost any degree of resistance can be obtained by the addition of chrome."

It has also been used with great success in planer-saw teeth, stave-machines, rock-drills, machine-tools, etc.

j. Phosphorus steel is the invention of M. Tessie du Motay.

"He," as Holley says, "did not stumble upon a good steel, high in phosphorus, and then avoid mixtures which would give high phosphorus, but set out to make steel containing (for rail grade) .12 carbon, .25 phosphorus, and .75 manganese, as a new article of manufacture, and using cheaper materials."

In the Du Motay process, manganese plays an important part, it acting as an antidote to the large amount of phosphorus, and also in structural steels, toughening, then increasing their soundness, and, of course, as it neutralizes phosphorus, preventing red-shortness.

k. Tungsten steel, a steel containing tungsten. Its production is similar to that of chromium steel, tungsten or Wolframite being substituted for the chromium compounds. Its properties are also similar, and it is an excellent tool-steel, though great difficulty is experienced in obtaining uniformity in the product. It is also remarkable for its great magnetic capacity.

In Barron's process, tools, such as axes, hatchets, and hoes, are cast from pig-iron. They are then placed in rotating drums to remove the roughness, and afterward heated in iron boxes, with oxide of iron and other materials to remove the carbon. They are next placed in a large retort, and subjected to the action of gasoline, and also of charcoal gas, generated in two retorts, by the action of which they are in a few minutes converted into steel, and are afterward ground, polished, and tempered.

Mr. J. L. Davies, of Swansea, Wales, states that resin oil intimately mixed with about one fourth its weight of the residue of paraffine stills will restore steel which has been injured by burning.

Levallois, of Paris, has patented in France three alloys which are very hard, and are made by fusing soft iron, tungsten, and nickel, in a crucible with suitable flux.

The first quality contains 93 parts soft iron, 6½ parts tungsten, and ½ part nickel.

The second is composed of 95 parts soft iron, 4½ tungsten, and ½ part nickel.

In the third, there are 97 parts soft iron, 2½ tungsten, and ½ nickel.

The flux consists of 36 parts boracic acid, 32 parts calcined quartz, and 32 parts of washed carbonate of lime.

l. The *Damascus steel* is made from the ore by the same process which produces the *wootz*.

This is smelted from a magnetic oxide, yielding, by the crude process employed, only about 15 per cent. The ore is placed in a clay crucible with bits of dry wood, covered by green leaves of particular plants. The crucibles are luted with clay and submitted to a blast charcoal furnace. The fire is kept at the highest possible temperature for nearly three hours, and on removing from the fire and cooling, the crucibles are broken, and the steel found as a lump at the bottom. Selections from these lumps are exposed again to a red heat for several hours, and then drawn out under the hammer.

It has been long supposed that fagoting short bars, remelting, and working them over and over, was the true secret of the superiority of the Damascus blades. General Anossoff, a Russian, made many experiments with great minuteness of detail at Zlatoosk in the Ural, where were mines yielding ore. His most successful process was melting the ore with graphite in crucibles in the proportion of eleven pounds of ore with five of graphite, and $^1/_{32}$ part of iron scales with $^1/_{24}$ of dolomite as a flux. The crucible is placed in a blast furnace and kept from four to six hours.

The following are General Anossoff's requisites for the best steel: Charcoal of the clearest sort, as that from pine; a furnace of the most refractory materials; the best quality of crucibles; iron very malleable and ductile; pure native graphite, or that obtained by pulverizing the best crucibles; flux of dolomite or calcined quartz; a high temperature, and fusion continued as long as possible. The working after the crucible is cold is simply repeated heatings and forgings. The sword-blades are tempered in hot oil. The razors made from this steel are of very superior quality, but the cost is excessive; the steel being valued at $1.10 per pound. The blades produced by General Anossoff seem to be of equal value with the original Damascus blades, one of them cutting through a gauze handkerchief floating in the air, cleaving bones and even nails without injury to the edge. General Anossoff died in 1851, and it is said the cutlery made at his establishment is not of so good a quality as when he personally superintended its manufacture.

See also TEMPERING; ANNEALING.

Antoine Galy-Cayalat's process for casting steel under pressure to avoid the formation of air-bubbles, consists in providing the head of the flask with a metallic cap, which is fitted and secured so as to be perfectly tight, and, when the pouring is completed, introducing through a pipe provided with a stop-cock a small charge of an explosive compound composed of niter 80, charcoal 20; this ignites on coming in contact with the fused metal in the flask, causing a pressure equivalent to that of a high head of metal; compressing the fluid metal in the mold and expelling the bubbles of gas therefrom. See STEEL-CASTING; STEEL-PRESS.

2. A round rod of steel, having longitudinal striations, used for sharpening knives.

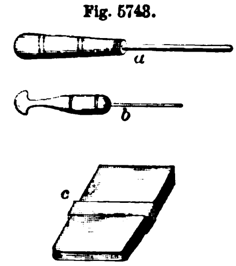
Fig. 5742.

Sharpening the Butcher-Knife (from Thebes).

In the sculptures at Thebes, butchers are represented sharpening their knives on a round bar of metal which is suspended from their girdles or from the hem of the apron, as shown in the figure. This was evidently a steel. It was for a long time supposed that steel or iron was unknown to the Egyptians, but this is disproved by the paintings and by later discoveries. Some of the sickles are represented blue and others red, indicating *steel* and *bronze*.

3. A steel is used by curriers in giving the fine, recurved edge to the knife wherewith to shave the flesh side of the hide upon the beam. The edge is brought up by the whetstone and *turning-steel*, and afterward preserved by the *finger-steel*, which the beam-man holds between his fingers while using the knife.

Fig. 5743.



Currier's Steels.

4. An angular piece of steel, which is struck with a flint to produce sparks in order to ignite tinder.

The striking of fire by flint and steel is mentioned by Virgil and Pliny. The Anglo-Saxon *fyr-stan*.

Steel-bronze. The name given to a very hard and tenacious alloy used as a substitute for steel. Its composition varies but little from that of the usual gun-metal, — 90 copper, 10 tin, — which, in making a gun, is cast upon a copper core of less diameter than the bore. The piece is then reamed out until it is ¼ inch less

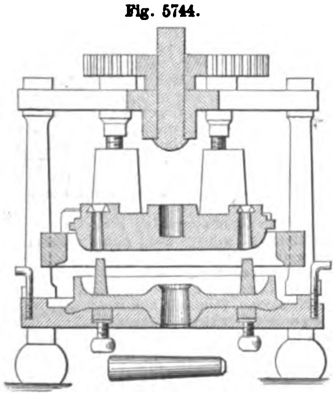
than the bore intended. Conical plugs of hard steel are then driven through it by hydraulic pressure, which confers upon the metal the peculiar qualities.

It was patented by S. B. Dean, Boston, Mass., May 18, 1869, and an order was given in 1870 by the U. S. Ordnance Office for some guns made by his process. His claim reads: "As a new manufacture, a bronze gun, in which the metal immediately surrounding the bore is put in the condition that is produced by the process of condensation set forth."

Colonel Uchatius, director of the Arsenal at Vienna, uses an alloy of 90 to 92 per cent of copper and 10 to 8 per cent of tin, and casts under a pressure of 80 tons, producing a very hard, tenacious metal, but one with little more elasticity than ordinary bronze. On cold-rolling this bronze, cast under pressure, into an ingot, its power of resistance, its elasticity, and its hardness were increased. In casting guns, a double mold with a solid forged copper core 0.05 metre in diameter was used. The cylinders obtained were 0.62 metre in diameter and 0.30 metre long; they were turned down to 0 18 metre outside, and the interior bored out to 0.08 metre. The cylinder was then opened out by means of conical steel drifts and an hydraulic press, so that it was enlarged 2 per cent. The bronze produced in this manner is declared to have all the hardness, homogeneousness, and power of resistance of steel tubes. Its wearing qualities are as great, and the cost of bronze guns made in this way is much less than steel, if the value of the old bronze be taken into account.

The plan has been adopted for the Austrian ordnance. The first cost of the steel-bronze cannon is placed at less than half that of a Krupp steel piece, and very much below that of a Whitworth compressed-steel gun, which, at a rough estimate, is about 20 per cent more expensive than Krupp's.

Fig. 5744.



Apparatus for making Cast-Steel Castings.

Steel-cast'ing. Fig. 5744 is an apparatus for making compressed cast-steel castings. The metallic molds are so arranged that the top part serves as the follower of a press, and is operated upon by screws. The top fits closely into the matrix, and is provided with ingates for the metal, which are closed by slides when the mold is full. The pressure is applied to the metal while in a melted state, by means of the screws, with sufficient force to expel the air and gas from and solidify the metal. See also STEEL-PRESS.

Steel'er. (*Shipwrighting.*) The foremost or aftermost plank in a strake, which is dropped short of the stern or stern-post of a vessel.

Steel-fur'nace. A metallurgic furnace in which ore or iron is treated for the production or refining of steel.

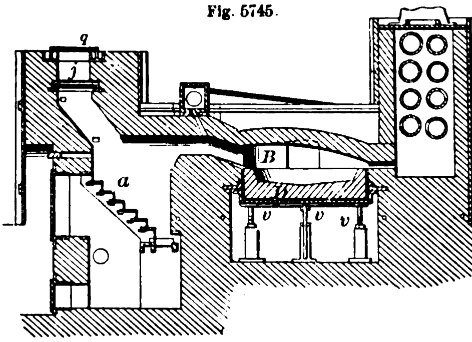
Steel is produced from bar-iron in furnaces in which the bars are built up with charcoal and heated. See CEMENTATION-FURNACE.

Other furnaces operate upon ore of certain kinds to produce steel directly.

Again, other furnaces operate upon steel of a certain quality which is broken up and heated in crucibles. See CAST-STEEL.

Fig. 5745 is a furnace for melting and refining steel. An open hearth *D* of refractory material is inclosed in a metallic pan, which is supported and made adjustable vertically by means of

Fig. 5745.

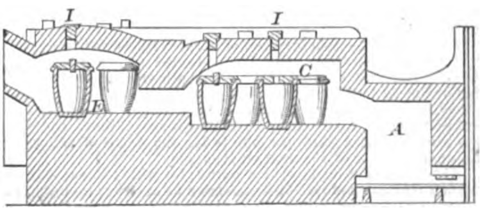


Steel-Refining Furnace.

screws *v v*. The upper part of the fuel-chamber *j* is provided with a slide, on which the fuel is deposited, and has a cover *q*, made gas-tight by an annular space containing water or sand. *a* is the fire-grate The furnace *B* is reverberatory.

In Fig 5746, *A* is the fire-chamber; *C* a crucible-chamber, from which the products of combustion pass to a second crucible-chamber *E*. Each chamber is provided with apertures at top, closed by plugs *I I*. The crucible-covers are also provided with plugs, the construction being such that the metal can be

Fig. 5746.



Steel-Furnace.

readily inspected during the process, and the crucibles removed from or placed in the furnace at any stage of the process without interrupting the operation.

Steel-head'ed Rail. A railway-rail having an upper surface or tread of *steel* welded on to a body of iron. The steel is usually so disposed in the fagot as to form the head when the rail is rolled. See RAIL.

Steel-mill. 1. A mill with metallic grinding-surfaces, usually of steel, but sometimes of cast-iron, as being cheaper and sufficient for the purpose.

Coffee and spice mills are instances.

2. (*Mining.*) A steel wheel revolving in contact with a flint, to make a light in a mine. A device used before the invention of the *safety-lamp*. See Fig. 2952, page 1314.

Steel-pen. Metallic pens, or at least graving instruments, would appear to be coëval with the introduction of metal. The first implement of the pen kind was probably a sort of flint stylus, with which the primitive race whose remains are found in the bone caverns of France traced the rude outlines of the mammoth and the reindeer upon the bones of animals. Metallic pens or gravers appear very early in history, those of iron being referred to by Job and by Jeremiah. These may have been either gravers or chisels. See PEN.

The ordinary pen of the Egyptians and of the ancients in general was a reed, cut and split as in the modern practice. This is still employed among the Orientals. See PEN.

The quill-pen was first introduced in the sixth century A. D., but did not entirely supplant the reed until long afterward.

Job refers to three modes of writing: —

Printed (traced) *in a book.* Probably on a sheet of linen, bark, or a palm-leaf; for this was before the invention of parchment by Eumenes II. of Pergamos (197 B. C.). The use of the *papyrus* was local, though very ancient, and Pliny ("History

of Nature," Lib. XIII. ch. 11) was much mistaken in stating that it was not used before the conquest of Egypt by Alexander the Great, 332 B. C. Rolls of papyrus inscribed by a reed pen and a pigment are found in the mummy envelopes, and were common in ancient times. Bark is referred to by Pliny as common. Palm-leaves are yet used in Southern Asia for this purpose, the writing being done with an *iron pen* or pointed instrument, which etches through one of the layers of cellular matter on the leaf; coloring matter is then rubbed into the channels made by the stylus.

Graven with an iron pen and lead. If this be the correct mode of analyzing the sentence, it refers to the mode of writing by a pointed instrument on a leaden tablet. Pausanius (Lib. XII. ch. 31), giving an account of the Bœotians, who lived near fount Helicon, states that "they showed me a leaden table near to the fountain, on which Hesiod's works were written; but a great part had perished by the injuries of time."

In the rock forever. Chiseled or engraved inscriptions on tablets of stone or on the vertical faces of rocks and cliffs. It seems hardly necessary to multiply instances of the carving of inscriptions on rocks. The Egyptian hieroglyphics are as old as Osymandyas (2100 B. C.). The sarcophagi of Egypt and Phœnicia are elaborately carved with inscriptions in their respective characters.

Thompson ("The Land and the Book"), in speaking of the Pass of Dog River, says: —

"In this grand, wild gorge is an assemblage of ancient mementos to be found nowhere else in a single group, so far as I know.

"That old road, climbing the rocky pass, along which the Phœnician, Egyptian, Assyrian, Persian, Greek, Roman, Arab, Frank, and Turk have marched their countless hosts for 4,000 years, has much to tell the student of man's past history, could we but break the seal and read the long roll of revelations. Those faintly cut emblems of Sesostris; those stern, cold soldiers of Chaldea; those inscriptions in Persian, Greek, Latin, and Arabic, — embody a chain of history which we long to solve." See PEN.

The original flexible iron-pen of modern times was an experimental affair probably, and is mentioned by Chamberlaque, 1685. The first steel-pen in regular use was made by Wise, in London, in 1803, and for several years thereafter. Under great discouragement he persistently carried round his wares, and gradually broke the ground for the Hawkinses, Gillotts, and Perrys who succeeded him. To him is due the credit of being the original inventor of the modern steel-pen.

Wise's pen was made with a barrel, by which it was slipped upon a straight handle. In its portable form it was mounted in a bone case for the pocket.

Perry's first pens were of steel, rolled from wire, the material costing 7 shillings a pound. 5 shillings each was paid the workman for making them; this was afterward reduced to 36 shillings per gross, which price was continued for several years.

Joseph Gillott, originally a Sheffield cutler, and afterward a workman in light steel articles, as buckles, chains, and other articles of that class, gave a great impulse to the steel-pen manufacture, 1822. Previous to his entering the business the pens were cut out with shears and finished with the file. Gillott adapted the stamping-press to the requirements of the manufacture, as cutting out the blanks, forming the slits, bending the metal, and impressing the makers' name on the pens. He also devised improved modes of preparing the metal for the action of the press, tempering, cleansing, and polishing, and, in short, many little details of manufacture necessary to give them the required flexibility to enable them to compete with the quill-pen. One great difficulty to be overcome was their extreme hardness and stiffness; this was effected by making slits at the side in addition to the central one, which had previously been solely used. A farther improvement, that of cross-grinding the points, was subsequently adopted. The first gross of pens with three slits was sold for £7. In 1830 the price was $ 2.00; in 1832, $ 1.50; in 1861, 12 cents, and a common variety for 4 cents, a gross. About 1,300 tons of steel are annually consumed, the number of pens produced in England alone being about 1,000,000,000.

The steel used is a very fine quality of spring-steel, supplied to the pen-makers in sheets 5 feet long by 18 inches wide. These are cut into strips of certain widths according to the size of pen required, packed in cast iron air-tight boxes placed in a furnace and kept at a red heat for about 12 hours; they are then removed to a cooling muffle, and very gradually cooled. The strips are then pickled to remove the scale, and afterward cleansed by rolling in revolving tubs with emery. They are next passed through a series of rolls to reduce them to the proper thickness, which varies greatly in different styles of pen. After rolling, each strip, for first-class work, is gaged with a gage which indicates differences so small as the 1,000th of an inch, and those varying from the true thickness are thrown out. The strips are fed by hand to presses having dies, which cut out the blanks. Another operator takes the flat blanks and feeds them to a fly-press, which cuts the perforation or perforations and the side slits. After piercing they are placed in sealed iron boxes, heated and annealed for 18 hours. Each blank is then stamped in another pass with the maker's name and the device, if any. The metal, now very soft, is shaped to the proper curve by means of fly-presses of heavier construction; barrel-pens are passed through two presses successively. They are then hardened. For this purpose they are placed in small iron pans and heated to a regulated degree of heat; this operation is conducted with great nicety. When the exact heat has been attained, the pans are taken out of the furnace and emptied into a tank containing oil; by this means they are suddenly cooled and rendered extremely brittle. Having been cleansed they are next put in a revolving iron barrel and heated over a fire, letting down the temper and rendering them elastic. In order to whiten them, if this is desired, they are placed in revolving barrels with emery, otherwise they remain of a brown or blue color.

To this succeeds grinding, which is effected by passing the pen lightly backward and forward several times over a small revolving emery-wheel, an operation requiring great delicacy of manipulation.

The central slit is then made by a fly-press, provided with nicely adjusted gages for holding the pen, and two cutters with sharp, smooth, strong edges, one of which cuts into the nib on each side. The points in the better class of pens are now rounded, and the pens polished. They are next colored by heating, as in tempering, and then lacquered or varnished. Some are coated with copper, aluminium, silver, or gold. Finally, in some establishments, each pen is examined with a magnifier to find out defects which may have previously escaped observation. The defective ones are thrown out, and the remainder are then ready for being placed on cards or boxed.

Steel-plate En-grav'ing. This art does not necessarily differ essentially from copperplate engraving; the change, however, in the material operated upon has led to various modifications in the process which could not have occurred with copper; to wit, the inherent capacity of the metal for hardening and softening.

Like copperplate, steel may be engraved by various modes, in *line*, *stipple*, *mezzotint*, *aquatint*. (See ENGRAVING, page 804, where a list occurs of the various modes, each described in its alphabetical place.) The prime art of engraving, and the one to which artists refer when speaking of engraving as an art, is known technically as *line-engraving*, in which the work consists of lines of various forms, the characters of skin, hair, fabric, wood, metal, ground, foliage, water in motion or calm, cloud, or sky, are given by various kinds of lines; the force and prominence being due to the depth, width, and nearness of the lines, enabling them to hold a greater body of ink in the places where depth of color is required, according to the effects required in the picture.

The origin of the art of engraving is very ancient, and is referred to in ENGRAVING, page 804; and COPPERPLATE ENGRAVING, page 618; that of *steel*-plate engraving can hardly be said to have existed previous to Jacob Perkins, of Massachusetts, the inventor of the *transfer-process*. This is described under BANK-NOTE ENGRAVING, page 228, and the *transfer-press* is shown and described under that caption. (See also TRANSFER-PRESS.) It was invented by Perkins, and brought into operation by him in England about 1837, the firm name of "Perkins, Fairbairn, and Heath" soon becoming famous in this branch of the art. The system, however, has never flourished to any notable extent in England, the Bank of England authorities, it was thought, taking a dislike to it as a foreign innovation, and preferring a system which does not produce artistic results, but those of a certain clear and clean precision and unvarying character. They have also, as mentioned in page 229, adopted *surface-printing*, as distinguished from the ordinary copperplate printing (see pages 618, 619). The Bank of Ireland adopted the Perkins method.

Nowhere has the transfer system been carried to so great an extent or perfection as in the United States, and especially in the Bureau of Engraving and Printing, United States Treasury Department. This bureau was organized by S. M. Clark, under the act of June 11, 1862, and has been in charge of G. B. McCartee since August, 1868. The engraving division is superintended by G. W. Casilear.

To these officers the writer is indebted for much of the folowing information, and for specimen of work on Plate LXIV. to illustrate the subject.

The process in the U. S. Treasury is as follows: —

A piece of decarbonized steel, one eighth of an inch in thickness, and somewhat larger than a bank-note, is softened by artificial means, to make it ready for the engraver, who is necessarily an artist of great skill and experience. The engraving of a single die often occupies many months, but, of course, this is a variable element, depending upon the difficulty and size of the work. The principal engraved work of the bureau consists of vignette portraits and the ornamental work upon bank-notes, with which all are familiar. The *denomination counters*, consisting of a variety of oval and circular forms interlacing each other in a series of lines and elongated dots, thus forming curious and complex figures, are executed by a geometrical lathe, a complicated and ingenious mechanism having almost kaleidoscopic powers in the production of geometric figures and designs. This is described under ROSE-ENGINE, pages 1983, 1984. See also GEOMETRIC LATHE, page 963.) When the engraver's work is completed, being in *intaglio*, the steel block, now called

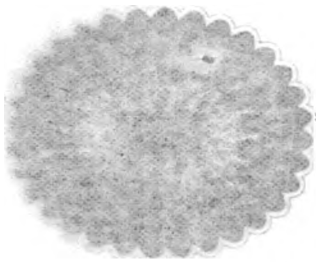
MANUFACTORY



a *bed-piece* or *die*, is subjected to the hardening process. It is inclosed in an iron box filled with charcoal of bone or ivory, and heated to a white heat, after which it is withdrawn and plunged into a bath of oil, a process familiar in the arts. Having thus been hardened, it is placed upon the bed of a TRANSFER-PRESS (which see), a decarbonized cylinder roll adjusted over it, and then submitted to pressure, the roll being moved backward and forward until it has received an impression of the original plate in *relievo*. (See ROLLER-DIE, Fig. 4403.) The roll itself is then hardened, and is capable, by means of the transfer-press, of repeating the original engraving upon the softened steel-plate from which the notes are to be eventually printed.

As the different portions of a note are upon separate rollers, great care is required in assembling the various impressions, each being in turn adjusted above the portion of the plate where its design is to occur. This is originally a matter of extreme delicacy, requiring taste and care of no ordinary degree, but as necessity occurs for making other exact copies of the same engraving, a register is kept of the exact position of the roller relatively to the surface of the plate for subsequent guidance. The notes are printed in sheets of four, so that the necessity for this accuracy occurs even in the first plate, as it afterward recurs in the preparation of succeeding plates of the same denomination.

Plate LXIV. illustrates several features in bank-note engraving: the vignettes executed in line-work by etching, graver, and ruling-machine originally, although the plate from which the impression is taken is the result of the transfer process described. At the bottom is a specimen of the work of the *rose-engine*, and is known technically as a *counter*, forming a shield, label, or escutcheon, according to shape, on which a number, as "500" or "1,000," is worked, as familiar, especially in smaller denominations, to all of us.

The securities of the government are printed on *distinctive* paper, made by J. M. Wilcox, of Glen Mills, Delaware County, Pennsylvania. The essential feature of this paper is a localized fiber imbedded in the body of the paper at the time of its manufacture on the Fourdrinier machine (1, Plate XXXVII.). By the localization of different fibers upon particular sections of the printed notes of various denominations, the raising of notes to a higher denomination is prevented. This mode of making paper belongs exclusively to the government, and as it necessitates large and expensive machinery, it furnishes an additional safeguard.

The mode of trimming and separating the currency is the invention of Mr. Larmon, the engineer of the bureau.

The most important feature introduced into steel-plate engraving since the invention of the transfer-process by Perkins is an adaptation of the process by G. W. Casilear, the superintendent of engraving, to the reproduction of engraved letters and script by rolling in the separate letters of a word from a roller-die which has all the letters of the alphabet on its periphery. It was formerly the practice to engrave each line of lettering, which was then taken up on a roller and transferred to the plate, as described with artistic designs; but, by Mr. Casilear's method, a complete alphabet of any required style, plain, ornamental, or script, is engraved on a plate and taken up on a roller, which is then used, one letter at a time, to produce any word or line required upon the plate which is to furnish the impressions. A force of two men is now sufficient to do the work formerly done by twelve, and in a more accurately uniform manner.

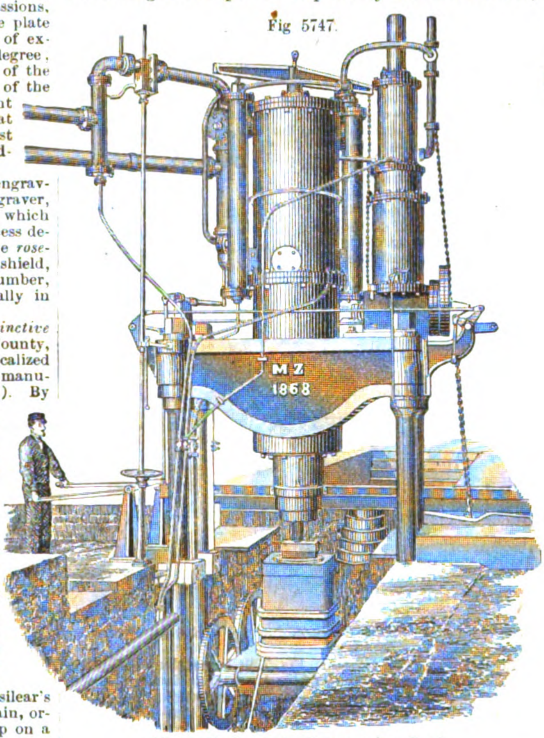
Other improvements have originated in the bureau, among which may be cited devices to prevent the alteration of numbers; an automatic register adjusted to every press and to the paper machinery, to keep an accurate account of every sheet worked; a process for water-proofing notes and fractional currency; the adaptation of power to the numbering-machine; an improved medallion-machine which rules with greater precision and celerity than by previous methods; a peculiar process by which the seal is attached by SURFACE-PRINTING (which see).

It may be added that the note itself is the joint product of peculiar paper and of impressed designs of the ordinary plate-printing process and of the surface process; the rose-engine work is capable of being worked either way; and by an adaptation of Mr. Casilear the medallion work can be made of a compound series of crossing lines, giving a network appearance and a texture which produces very happy effects. See SURFACE-PRINTING.

The conduct of the bureau, in a commercial point of view, and the security of its plates and impressions, might well form the subject of some paragraphs, but this work deals rather with the mechanical and artistic branches of the subject than with the financial and policing features. In regard to the first it may be stated, as an instance in relation to one series of government issues, that the *greenback* series, so called, of 1869-75, embracing nine denominations, which have never been surpassed in excellence and artistic finish, and which have been six years in circulation, two alone of the notes have been attempted to be counterfeited, and these but rude in comparison. In regard to the latter feature, that of security in the business method, it may be stated that for the entire term of Mr. McCartee's incumbency, the loss to the government, whether from theft, delinquency, or otherwise, has not equalled in percentage the loss resulting from the abrasion of gold coin of an equal amount in a single count.

Steel-press. One for solidifying molten steel. The suggestion is embodied in one of Bessemer's early patents, but has been developed by Sir Joseph Whitworth and by Révollier, Biétrix, & Co., of St. Etienne, who adopted it in 1867, having built steel-works specially arranged for it in connection with furnaces for making steel by the Siemens-Martin process. According to the plans adopted by Révollier & Co.,

Fig. 5747.



Hydraulic Press for Compressing Steel.

the metal was run from the furnace into a ladle, which, by means of a turn-table crane, was conveyed to the ingot-molds, and the metal turned into the latter. The molds were placed on an ingot-carriage, and after filling they were run under an hydraulic press. See also STEEL-CASTING.

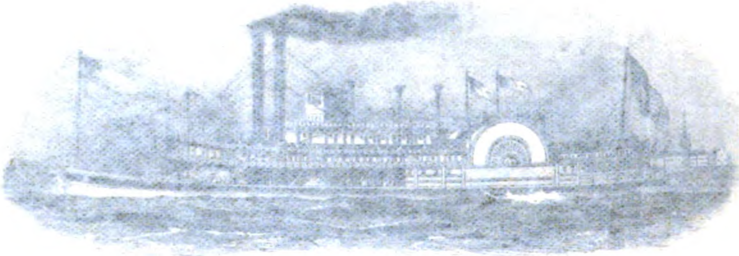
Casting under pressure has been employed to secure compactness and sharpness, and is described in Hollingrake's English patent, 1819. (See also Fig. 1180, which shows a press for casting car-wheels.) Articles of household hardware are cast very sharply and handsomely by Smith's process, described on page 500.

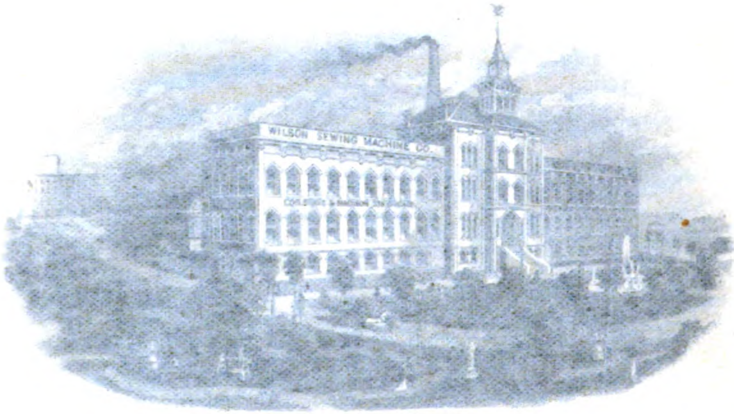
Steel-saw. One saw for cutting cold steel, used in Pittsburgh, is a disk of soft iron 42″ diameter, $\frac{3}{8}$″ thick, driven at a speed of 2,506 revolutions per minute. This is a periphery speed of 25,000 feet. The steel sparks are melted, but the steel bar is not heated sufficiently to draw its temper.

Steel-topped Rail. A railway-rail whose *tread* or upper surface is of steel welded on to an iron body. See RAIL.

Steel-trap. A trap with steel jaws and a spring to catch wild animals.

Steel'yard. A weigh-beam having arms of unequal length. In the usual form (*A*, Fig. 5748), the scale is suspended from the shorter arm, and the weight is adjustable upon the longer arm, which is graduated.





WILSON SEWING MACHINE Co. MANUFACTORY

The most important feature introduced into steel-plate engraving since the invention of the transfer-process by Perkins is an adaptation of the process by G. W. Casilear, the superintendent of engraving, to the reproduction of engraved letters and script by rolling in the separate letters of a word from a roller-die which has all the letters of the alphabet on its periphery. It was formerly the practice to engrave each line of lettering, which was then taken up on a roller and transferred to the plate, as described with artistic designs; but, by Mr. Casilear's method, a complete alphabet of any required style, plain, ornamental, or script, is engraved on a plate and taken up on a roller, which is then used, one letter at a time, to produce any word or line required upon the plate which is to furnish the impressions. A force of two men is now sufficient to do the work formerly done by twelve, and in a more accurately uniform manner.

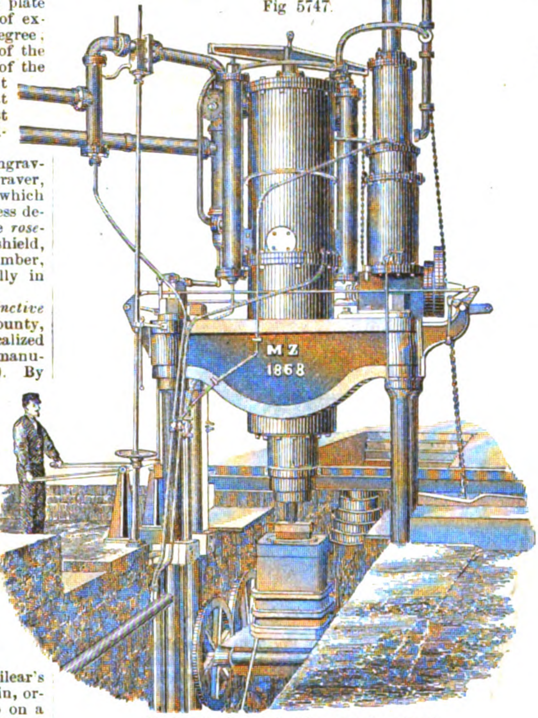
Other improvements have originated in the bureau, among which may be cited devices to prevent the alteration of numbers; an automatic register adjusted to every press and to the paper machinery, to keep an accurate account of every sheet worked; a process for water-proofing notes and fractional currency; the adaptation of power to the numbering-machine; an improved medallion-machine which rules with greater precision and celerity than by previous methods; a peculiar process by which the seal is attached by SURFACE-PRINTING (which see).

It may be added that the note itself is the joint product of peculiar paper and of impressed designs of the ordinary plate-printing process and of the surface process; the rose-engine work is capable of being worked either way; and by an adaptation of Mr. Casilear the medallion work can be made of a compound series of crossing lines, giving a network appearance and a texture which produces very happy effects. See SURFACE-PRINTING.

The conduct of the bureau, in a commercial point of view, and the security of its plates and impressions, might well form the subject of some paragraphs, but this work deals rather with the mechanical and artistic branches of the subject than with the financial and policing features. In regard to the first it may be stated, as an instance in relation to one series of government issues, that the *greenback* series, so called, of 1869-75, embracing nine denominations, which have never been surpassed in excellence and artistic finish, and which have been six years in circulation, two alone of the notes have been attempted to be counterfeited, and these but rude in comparison. In regard to the latter feature, that of security in the business method, it may be stated that for the entire term of Mr. McCartee's incumbency, the loss to the government, whether from theft, delinquency, or otherwise, has not equalled in percentage the loss resulting from the abrasion of gold coin of an equal amount in a single count.

Steel-press. One for solidifying molten steel. The suggestion is embodied in one of Bessemer's early patents, but has been developed by Sir Joseph Whitworth and by Révollier, Biétrix, & Co., of St. Etienne, who adopted it in 1867, having built steel-works specially arranged for it in connection with furnaces for making steel by the Siemens-Martin process. According to the plans adopted by Révollier & Co.,

Fig 5747.



Hydraulic Press for Compressing Steel.

the metal was run from the furnace into a ladle, which, by means of a turn-table crane, was conveyed to the ingot-molds, and the metal turned into the latter. The molds were placed on an ingot-carriage, and after filling they were run under an hydraulic press. See also STEEL-CASTING.

Casting under pressure has been employed to secure compactness and sharpness, and is described in Hollingrake's English patent, 1819. (See also Fig. 1180, which shows a press for casting car-wheels.) Articles of household hardware are cast very sharply and handsomely by Smith's process, described on page 500.

Steel-saw. One saw for cutting cold steel, used in Pittsburgh, is a disk of soft iron 42″ diameter, ⅜″ thick, driven at a speed of 2,506 revolutions per minute. This is a periphery speed of 25,000 feet. The steel sparks are melted, but the steel bar is not heated sufficiently to draw its temper.

Steel-topped Rail. A railway-rail whose *tread* or upper surface is of steel welded on to an iron body. See RAIL.

Steel-trap. A trap with steel jaws and a spring to catch wild animals.

Steel′yard. A weigh-beam having arms of unequal length. In the usual form (*A*, Fig. 5748), the scale is suspended from the shorter arm, and the weight is adjustable upon the longer arm, which is graduated.

A single weight is thus made available for weighing objects having different gravity.

The *balance* with equal arms (*libra*) is more ancient than the steelyard (*statera*). The latter is said to have been invented in Campania, a Greek colony. The balance-beam is the feature of the Egyptian instrument. See BALANCE.

The fundamental principle of the steelyard is given by Archimedes in his book "De Equiponderantibus." He there demonstrates that a balance with unequal arms will be in equilibrio if the two weights in the opposite scales are reciprocally proportional to the arms of the balance.

The *Chinese balance* is a tapering rod of square section, and is suspended by a silk cord. The object depends from the shorter arm, and the *standard* weight is adjustable on the larger graduated arm. Four points of suspension are provided, at different relative distances from the ends, so as to increase the range of the instrument. A corresponding set of graduations is marked on each of the four sides.

The *Danish balance* (*B*) is the inverse of the Chinese or Roman balance. The weight being attached to one end, and the object being suspended from the other, a loop forms the means of suspension of the beam, and is passed backward and forward until the equilibrium is obtained. The weight of the goods is then to the weight of the lead reciprocally as their respective distances from the loop.

Fig. 5748.

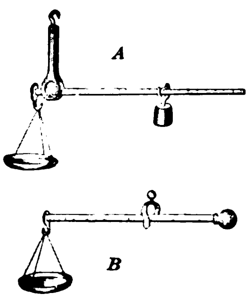


Fig. 5749.

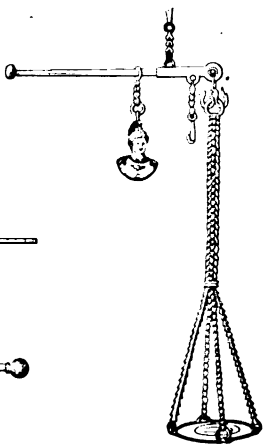


Steelyard and Danish Balance. *Roman Statera.*

The *Roman balance* (*statera*), Fig. 5749, is mentioned 315 B. C., and had the center of gravity of the lever immediately over the point of support, so that the beam was equally balanced on its axis, the effect of the weight of the longer arm of the lever being neutralized by the addition of metal to the shorter arm. The longer arm was then divided into parts, each equal to the length of the shorter arm, and these portions were again subdivided.

A Roman balance found at Pompeii shows that they also had two centers of suspension for varying grades of weights.

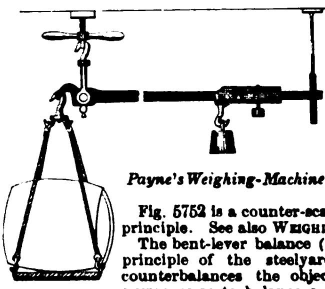
The modern *steelyard* is substantially similar to the Roman balance, but it is not regarded as essential that the unweighted beam should balance at its fulcrum. The commencement of the divisions begins at that point where, the weight being placed, equilibrium is established. To increase the range of the steelyard, the Chinese plan has been adopted of increasing the number of points of suspension. The upper and lower sides of the longer arm are graduated in accordance with the proportions which exist between the points of suspension of the beam and the load. The beam is suspended by one or the other of the hooks; the end hook swings over, so as to be in place for weighing in either case.

Beranger (France) makes a steelyard in which the weight traverses along a screw the length of the graduated arm, and parallel to it. The head of the screw is 4 inches in diameter, and divided into 100 parts, which permits the weight to be adjusted to a distance equal to $\frac{1}{100}$ part of the pitch of the screw.

Dearborn's steelyard (Massachusetts, 1800) has the center of motion, center of gravity, and point of suspension adjustable, so that it vibrates like a scale-beam when unloaded and when loaded in equilibrium.

Fig. 5750 is Payne's weighing-machine. The weights are attached to a graduated box, which slides with some friction on the beam. The larger weight is used for the hundred weights and quarters, which are indicated by the graduations on the beam. The smaller weight is employed for determining the pounds and ounces, which are shown by the graduations on the upper part of the sliding-box.

Fig. 5750.



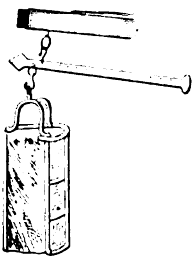
Payne's Weighing-Machine.

Fig. 5751 shows a convenient application of the steelyard to weighing bags of grain, and to articles contained in a pan.

Fig. 5752 is a counter-scale, on the steelyard principle. See also WEIGHING-MACHINE.

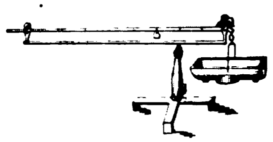
The bent-lever balance (Fig. 5753) is on the principle of the steelyard; the arm which counterbalances the object exerts a greater power, so as to balance a greater weight as it approaches a horizontal position. It is a combination of the bent-lever balance and steelyard. The cast-iron frame *a b c* is heavier toward *a*, and is pivoted at *f*; *e h* is a movable suspender, which may be applied at either of the three points *e k g*. The instrument has three scales, *l m n*; the first indicates to single ounces the weight of a body not exceeding 2 pounds when the suspender is placed at *g*; when the suspender is at *k*, any quantity between 2 and 11 pounds may be weighed on the scale *m*, which is divided into parts showing 2 ounces. The third scale *n*, with the suspender at *e*, is employed for bodies weighing from 11 to 30 pounds; it is divided to quarter-pounds. The principle may, of course, be applied to balances of greater capacity.

Fig. 5751.



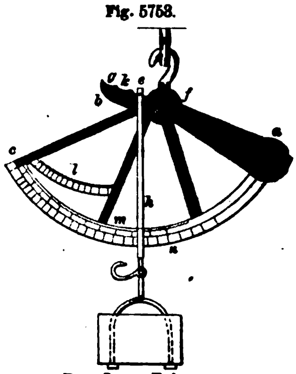
Bag-Weigher.

Fig. 5752.



Counter-Scales.

Fig. 5753.

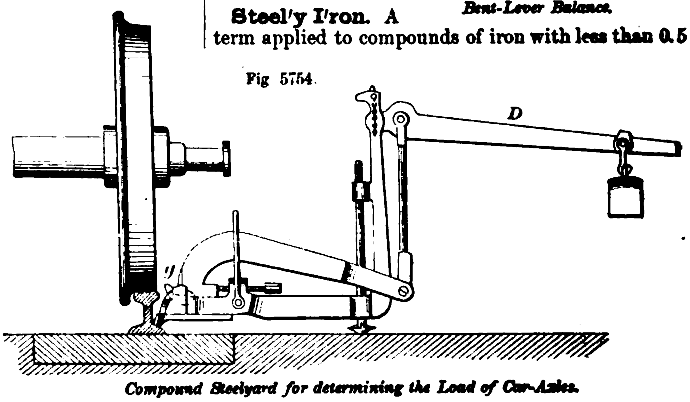


Bent-Lever Balance.

Fig 5754 is an apparatus for determining the load of car-axles. The prong *g* is introduced beneath the tread of the wheel, and the weight transferred through the compound system of levers to the graduated bar *D*.

Steel'y I'ron. A term applied to compounds of iron with less than 0.5

Fig 5754.



Compound Steelyard for determining the Load of Car-Axles.

per cent of carbon. The quality is intermediate between steel and iron. *Semi-steel.*

Steen'ing. (*Masonry.*) A well-wall, half a brick thick. *Steining.*

Steep'er. A vat in which the indigo-plant is soaked for maceration, previous to soaking in the beating-vat.

Steep'ing. The watering or wetting of flax haulm, to facilitate the separation of the woody matter (*shives*) from the fiber (*hare*).

Also to soften and remove the mucilage.

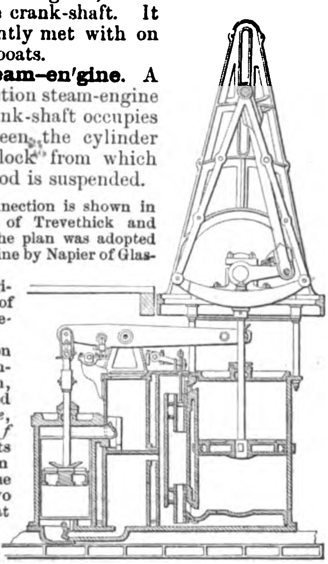
The flax-straw is tied in bundles and placed in ponds or rivers from 8 to 12 days, when it is taken out and spread on the grass. *Grassing.* See FLAX.

Stee'ple. (*Architecture.*) A spire or lantern. The superstructure above the tower of a church. See TOWER.

Stee'ple-en'gine. (*Steam-engineering.*) A form of marine engine, deriving its name from the high erection on deck required for the guides to the connecting-rod, which works above the crank-shaft. It is not unfrequently met with on American river-boats.

Stee'ple Steam-en'gine. A form of direct-action steam-engine in which the crank-shaft occupies a position between the cylinder and the slide-block from which the connecting-rod is suspended.

Fig. 5755.



Steeple-Engine.

The mode of connection is shown in the steam-carriage of Trevethick and Vivian, 1802, but the plan was adopted into the marine engine by Napier of Glasgow (Fig. 5755).

Fig. 5756 is a longitudinal section of Maudslay's steeple-engine.

a is the cast-iron frame; *b*, the cylinder; *c*, the piston, connected by the rod *d* to the cross-head *e*, guided by the wheel *f* between the uprights *g g*; rods *h*, one on each side, connect the cross-head *e* with two cranks, one shown at *i*, to which the fly-wheel shaft is connected. Two eccentric wheels *n* on the fly-wheel shaft give motion to the levers *v t* by means of connecting-rods *p*. The lever *o*, turning on the bearing *q*, works the cold-water pump *s* by the rod *r*; the lever *t*, supported on the center *v*, works the air-pump *j* and the hot-water pump; the condenser *j'* surrounds the air-pump, and is itself surrounded by one of the cold-water cisterns *k k*, which are connected by the pipe *k'*. The steam-passages are opened and closed by an eccentric *u* on the crank-shaft, through the medium of the rod *u'*, bent lever *w*, and connecting-rod *x* and lever *x'*, operating the steam-cock *y*. The valve *z* in the steam-pipe is opened or closed for a longer or shorter time, depending on the velocity of the engine, by a cam-piece on the governor spindle, operating through connecting levers. *w'* is a lever for working the engine by hand.

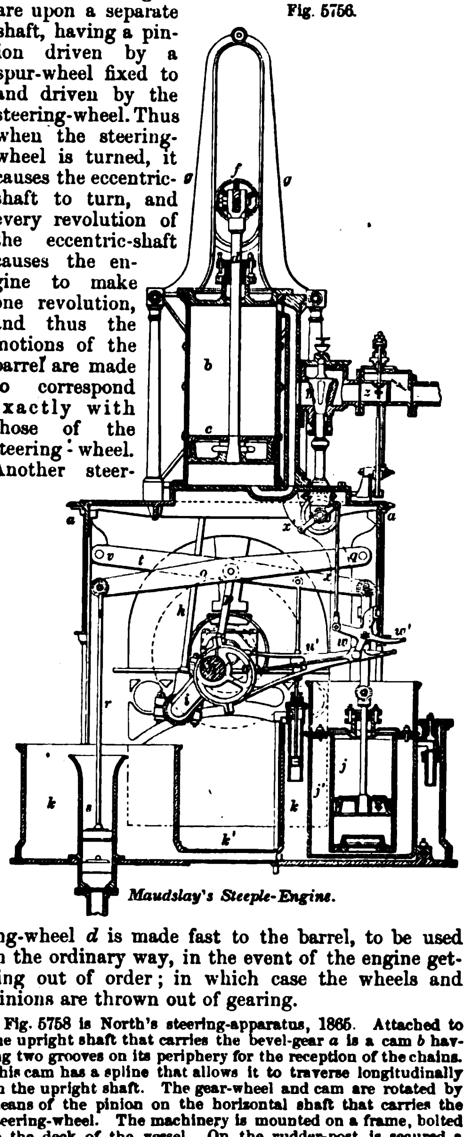
Steer'age. (*Nautical.*) The part of a 'tween-decks just forward of the cabin.

Steer'age-way. (*Nautical.*) Motion of a vessel sufficient to enable her to feel the effect of the rudder.

Steer'ing-ap'pa-ra'tus. A device in aid of the steersman, being interposed between the tiller or tiller-wheel and the rudder-head. See also STEERING-WHEEL.

In Sickel's steam-steering apparatus (Fig. 5757), in use since 1860, the steering-wheel *a* and the barrel *c* for the steering-chains are upon separate shafts, in a line with each other. On the shaft *b* of the steering-barrel is a toothed wheel, gearing with a pinion upon a crank-shaft, which is driven by a small steam-engine having two cylinders working at a right angle to each other. The eccentrics which work the slide-valves of that engine are upon a separate shaft, having a pinion driven by a spur-wheel fixed to and driven by the steering-wheel. Thus when the steering-wheel is turned, it causes the eccentric-shaft to turn, and every revolution of the eccentric-shaft causes the engine to make one revolution, and thus the motions of the barrel are made to correspond exactly with those of the steering-wheel. Another steering-wheel *d* is made fast to the barrel, to be used in the ordinary way, in the event of the engine getting out of order; in which case the wheels and pinions are thrown out of gearing.

Fig. 5756.



Maudslay's Steeple-Engine.

Fig. 5758 is North's steering-apparatus, 1865. Attached to the upright shaft that carries the bevel-gear *a* is a cam *b* having two grooves on its periphery for the reception of the chains. This cam has a spline that allows it to traverse longitudinally on the upright shaft. The gear-wheel and cam are rotated by means of the pinion on the horizontal shaft that carries the steering-wheel. The machinery is mounted on a frame, bolted to the deck of the vessel. On the rudder-post is secured a quadrant *d*, so depressed in its periphery to correspond with the eccentric action of the cam *c* in its rotation as always to present the same face to its action. The periphery of the segment has two grooves for the reception of the chain. When the rudder is "hard up" the quadrant presents its longest radius to the shortest radius of the cam, thereby increasing the power upon the rudder at the time when it is most required.

In Fig. 5759, the tiller-wheel shaft has a right and left handed screw which passes through nuts which are connected by arms to the gudgeons of the rudder-head. The rotation of the shaft draws the nuts simultaneously toward or from the rudder, and rotates the latter on its axis.

Hunt's steering and propelling apparatus (English patent) combines the two operations in one, the axis of the screw being made to oscillate in a horizontal plane by means of the tiller, while the rotation of the axis by the engine is not affected. *a* is a driving-shaft rotated by the steam-engine; *b*. a bearer; *c e d m n*, the gearing and shafting connecting the shaft *a* with the short shaft *i* of the propeller. The shaft *d* is carried down to the step *z* projecting from the stern-post, and is inclosed by a case *f* which has independent motions thereon by means of

the tiller w. The trunk g is formed by an enlargement of the case f, and incloses the lower pair of bevel-gears m and n, and the short shaft i, to whose end the propeller p p' is attached by a coupling o. This arrangement is used in the propulsion.

The steering part of the apparatus consists of a tiller-wheel w, shaft q, bearing r, and bevel-wheel t gearing into a similar bevel-wheel (see the other figure) on the end of a short screw-shaft v which takes into a quadrant x attached to the top of the case f above the plate on which the vertical plate q is stepped. When the steersman turns the wheel w, motion is communicated to the quadrant x and the case f, thereby rotating the propeller-shaft i o in a horizontal plane, and thereby varying the angle of presentation of the axis of the propeller to port or starboard, as the case may be, giving a positive lateral propulsion to the stern of the vessel.

Blackie's electric signal for steering-apparatus is to enable the pilot of a vessel to communicate with the engineer or helmsman. When the pilot sends an order he presses a knob, and a bell rings, meaning attention. The engineer looks to the index, which resembles a clock face, on which are printed the 5 general orders used, namely, *stop; ahead easy; ahead full speed; back easy; back full speed*. The pointer indicates the order, and always remains at the last, and is locked. The device by which the pilot transmits his orders to the engineer is constructed as follows: First, there is a dial on which the five orders described are printed. A pointer, like the hand of a clock, moves at the will of the pilot from order to order. The pointer is attached to a cylinder of iron 4½ inches long, ½ inch diameter, which leads from the center of the dial backward at right angles, and is supported at each end eccentrically. On each side are two electro-magnets and one underneath; there being one magnet for each order. A wire from each magnet leads to the pilot-house, and all wires are connected with a battery. By means of five knobs in the pilot-house the connections are made; one on each wire. The iron cylinder, or keeper, moves from side to side, or downward, according to the attraction of the magnet; and as the pointer is attached to the keeper or cylinder, the movements on the dial will correspond with movements of the keeper, by reason of its eccentric motions. By a double arrangement of wires in connection with a galvanometer, the rudder is made to indicate its position on a dial for the observation of the captain and pilot.

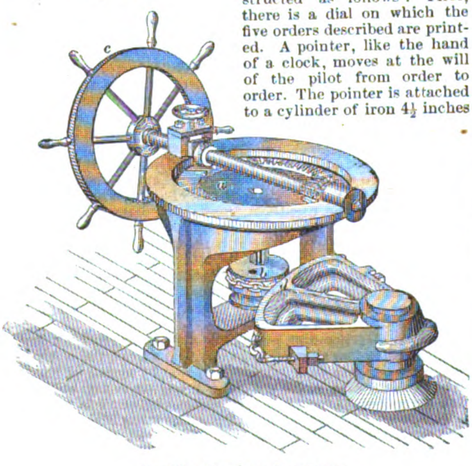
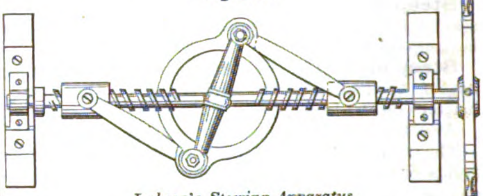
Sickel's Steam-Steering Gear.

Fig. 5758.



North's Steering-Apparatus.

Fig. 5759.



Jackson's Steering-Apparatus.

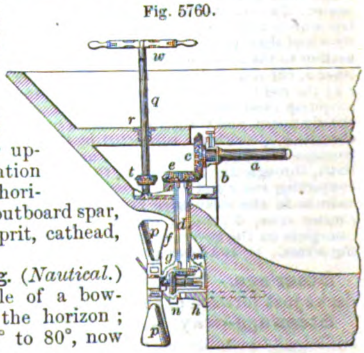
Steer'ing-wheel. (*Shipbuilding.*) A wheel by which a rudder is turned through the medium of a tiller-rope winding on the axis of the wheel.

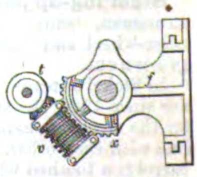
In the cut, Fig. 5761, — x is the *rudder-head*; x t the *tiller*, having a pair of blocks fixed to its forward end t. e e are a pair of eye-bolts in the deck, to which are made fast the ends or standing parts of the steering-chains or wheel-ropes. The chains are led through the blocks of the tiller, then through a pair of fixed blocks b b attached to the deck, and then through a pair of fixed blocks beneath the barrel of the steering-wheel w, and hidden by the latter in the figure. The chains then pass through holes or tubes in the deck or decks that lie between the tiller and the wheel, and then pass round the barrel, to which they are fastened at the middle of its upper side.

The steering-wheels are from 3 to 6 feet in diameter, and one may be placed at each end of the barrel.

The lower rim of the wheel must move in an opposite direction to the rudder, that is, in the same direction as a *tiller* pointing forward.

Fig. 5760.





Hunt's Propeller and Steerer.

Steeve. (*Nautical.*) The slope or upward deviation from the horizontal of an outboard spar, as the bowsprit, cathead, etc.

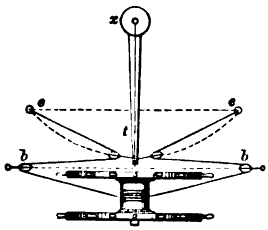
Steev'ing. (*Nautical.*) *a.* The angle of a bowsprit with the horizon; formerly 70° to 80°, now much less.

b. Stowing bales in a hold by means of a jack-screw.

Steg'a-nog'ra-phy. The art of writing in cipher.

Stein'ing. (*Masonry.*) Lining a well with bricks. The wall may be carried up on a curb which is lowered by under cutting, the wall re-

Fig. 5761.



Steering-Wheel.

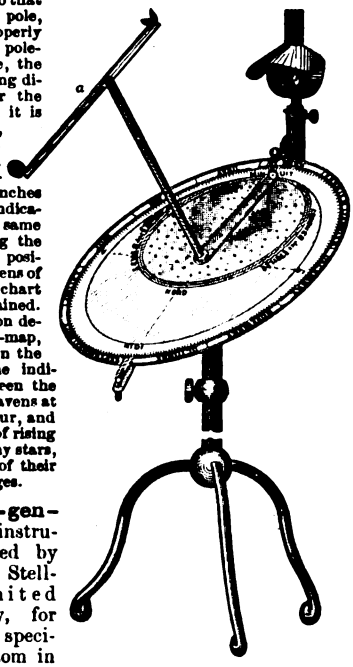
ceiving additions at top as it sinks. See CURB.

Stel'la. (*Surgical.*) A star-shaped bandage crossed like the letter X, applied to the shoulder in cases of fracture of the clavicle or scapula, or dislocation of the humerus.

Stel'lar In'di-ca'-tor. An instrument for enabling an observer to recognize the different stars and point out their positions in the heavens.

It consists of a stand carrying a table, on which is a celestial chart, and having its circumference graduated to show the days and months. The table is inclined at an angle equal to that of the elevated pole, and being properly set, using the pole-star as a guide, the sight-bar *a* being directed to a star the name of which it is desired to know, the star and its name are found on the chart between the branches of the alidade indicator *b*. In the same way, by setting the indicator, the position in the heavens of any star on the chart may be ascertained. From the portion devoted to the star-map, included between the branches of the indicator, may be seen the aspect of the heavens at any day and hour, and also the hours of rising and setting of any stars, and the times of their meridian passages.

Fig. 5762.



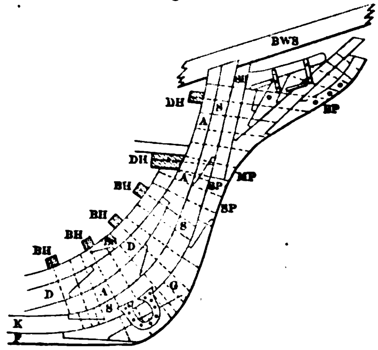
Stellar Indicator.

Stell'wa-gen-cup. An instrument invented by Lieutenant Stellwagen, United States Navy, for bringing up specimens of bottom in sounding. It consists of a hollow cone attached to the bottom of the sounding-lead, and having a flexible cap over which may be an inflexible disk, rising and allowing the mud, sand, etc., to enter the cup when the lead strikes the bottom, but falling and preventing it from being washed out when drawn up.

Stem. 1. (*Shipbuilding.*) The upright piece of timber or bar of iron at the fore end of a vessel, to which the forward ends of the stakes are united. With wooden stems, the lower end is scarfed into the keel. The upper end supports the bowsprit, and in the obtuse angle is the *figure-head*. The advanced edge of the *stem* is the *cut-water*.

S, stem.
K, keel.
A, apron.
D, deadwood.
SS, stemson.
DH, deck-hooks.
BH, breast-hooks.
SP, stem-piece, or independent piece.
MP, main or lace piece.
BP, bobstay-piece.
BWS, bowsprit.
G, gripe.
F, false keel.

Fig. 5763.



Stem and Allied Parts.

2. (*Vehicle.*) The bar to which the bow of a falling hood is hinged.

3. (*Mining.*) A day's work.

4. (*Valve.*) The projecting-rod which guides a valve in its reciprocations.

5. Of a thermometer, hydrometer, etc. The narrowed part, usually graduated or having a graduated scale beside it.

Stem-knee. (*Shipbuilding.*) One uniting the stem with the keel.

Stem'mer. (*Mining.*) A piece of iron with which clay is rammed into the blasting-holes to make them water-tight.

Stem'ming. (*Mining.*) The stuff beaten down upon a charge of powder.

Stem-piece. (*Shipbuilding.*) A piece in front of the stem, into which the main piece of the head is stepped. See STEM.

The stem-piece is sometimes called the *independent piece* (SP in Fig. 5763).

Stem'ple. (*Mining.*) One of the cross-bars of wood placed in the shaft of a mine and serving the purpose of steps.

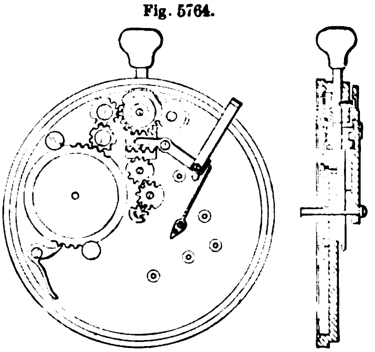
Stem-post. (*Shipbuilding.*) The vertical timber forming the prow of a vessel. The *stem*.

Stem'son. (*Shipbuilding.*) A knee-piece whose horizontal arm is scarfed to the keelson and vertical arm fayed into the throats of the transoms.

Stem-wind'ing Watch. A watch having a stem or pendant which may be thrown into engagement with a winding wheel so as to wind up the spring without the intervention of a key.

Its use is to avoid the trouble of carrying a watch-key, and to prevent the access of dust to the works. Some act by merely pushing the pendant in, and some by turning it round. Some of the *stem-winders* are so constructed that by pushing in the

Fig. 5764.



Howard's Stem-Winding Watch.

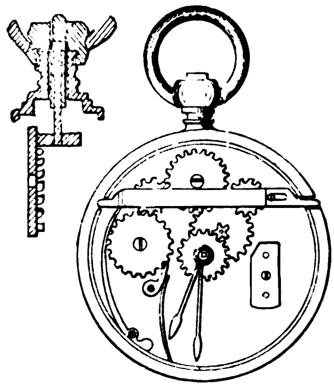
pendant it is brought into relation with the hand-setting mechanism, and by pushing it to another certain distance, it is brought into connection with the winding portion.

In other devices the winding is accomplished by means of a fluted knob at the end of the pendant. The arbor of the winder has a ratchet and click, so that it cannot be turned in the wrong direction. Like a *Breguet key* in this respect.

Berollas's stem-winding watch (English) has a chain which makes one turn around the pulley of the going-barrel and terminates in a button at the end of the pendant, so that it may be grasped by the finger and thumb. To wind the watch, the button and chain are drawn out, giving the barrel-pulley one rotation; a recoil-spring draws in the chain, allowing a second pull to the winding work. This is repeated till the watch is fully wound.

Howard's stem-winding watch has a double-contrate wheel which is splined upon the stem, and is engaged with a train of gears to either wind the watch or set the hands. The barrel is fitted into an opening in the dial-plate, and is supported therein by a toothed flange resting on and attached to the dial-plate, so as to allow the winding of the barrel. A spring pawl prevents the barrel from turning in a contrary direction when the watch is running down.

Fig. 5765.

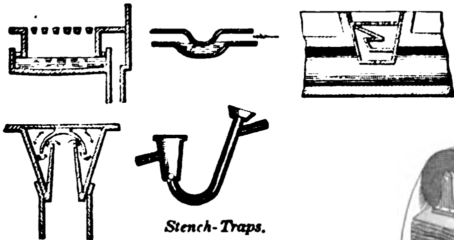


Wadsworth's Stem-Winding Watch.

In Wadsworth's stem-winding watch, by the arrangement of the bar carrying the gears, the main-spring can be wound by turning the pendant, whether the case is open or closed. To set the hands, the bar is first pressed inward to establish the necessary connection between them and the pendant, and disconnect the pendant and main-spring, and then, by turning, regulate the hands.

See also patents to Smith and Folsom, 1873; Rice and Gerry, 1868; Jacob, 1869; Himmer, 1869.

Fig. 5766.



Stench-Traps.

Stench-trap. A depression in a drain in which water collects, to prevent the reflex passage of air. The figure shows various forms for sinks and pipes. See also WATER-CLOSET.

Sten'cil. A thin plate out of which patterns or letters have been cut. The plate being laid on the object, the pattern is made thereon by brushing on the color.

In early times playing-cards were thus made. Chatto, in his "History of Playing-Cards," London, 1848, states that the earliest cards he has noticed are of the year 1440, and were made by stencils. Cards was an Oriental game, and was introduced into Europe about 1360–1390. Covellusso states that three packs of cards were made for Charles VI. of France in 1393. Laws in relation to their manufacture and use were passed in Italy, France, Germany, and England, from the fourteenth to the sixteenth centuries.

Theodoric, king of the Ostrogoths (Eastern Goths), who founded a kingdom in Italy A. D. 493, was so illiterate that he could not write four letters at the foot of his edicts, but had them cut out of a plate of gold, and traced out the letters with a *quill*. It is inferred by some that he used the quill as a pen, which would be the first recorded use of it as a writing instrument; but it is most likely that he used the feather as a brush and the plate as a stencil-plate.

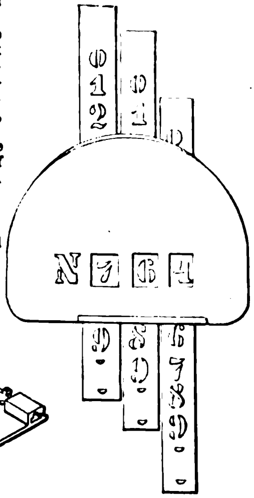
The Emperor Justin, about the same time, used a wooden stamp.

Stencil-plates are now made of thin sheets of brass; they were formerly made of pasteboard, tin, or sheet-iron. The ink used is known as *stencil-paste*, and is essentially a water-color, as ordinary paint or printer's ink does not dry fast enough. It is put up in boxes, like blacking. The indelible ink used for clothes-marking stencil-plates is of a different character, and comes in bottles, at the rate of 25 cents an ounce, or $ 20 per thousand vials.

For many purposes it is more convenient to have a set of letters which can be arranged to form a name or direction. Fig. 5767 shows one form, a *combination stencil*, in which the letter-plates are latched together.

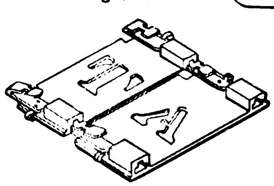
In Fig. 5768, the frame has a series of apertures, and the numbers on the slides are brought into consecution thereat as required.

Fig. 5768.



Stencil-Numbering Plate.

Fig. 5767.



Stencil-Plate.

Sten'cil-cut'ter. (*Metal-working.*) A tool or instrument for cutting letters out of stencil-plates. The tools used in cutting stencil-plates are dies, chisels, compasses, and lignum-vitæ blocks.

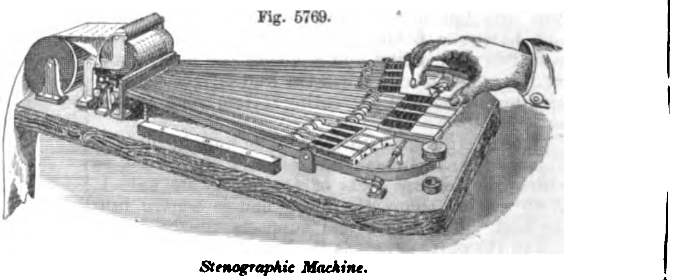
Sten'cil-plate. A thin plate of brass in which letters are cut, used in marking boxes and merchandise. See STENCIL.

Sten'o-graph'ic Ma-chine'. A mechanical writer.

A French form of the instrument is shown in Fig. 5769. It consists of a keyboard operated as shown by the hand of the reporter, and composed of twelve black and an equal number of white keys. On each side of the instrument is a large key moved by a pressure of the wrist, and serving to give supplementary signs which simplify the reading of the characters printed.

All the keys, when operated, produce indications in ink on a roll of paper, which is taken from a reel in manner similar to

Fig. 5769.



Stenographic Machine.

that on the Morse telegraphic apparatus. The black keys, however, give long marks, while the white ones cause simple dots to be transcribed. At each pressure of the fingers on the keyboard, the paper is automatically unrolled for about .02 of an inch, so that on each line any combination of twelve double signs may be imprinted, and these signs are arranged in three groups of four each, and read from left to right in the ordinary manner.

The number of characters which may be made on each division of four is more than sufficient to require a single movement to form a single letter. In other words, with practice, three letters or less can be written at once. If the useless letters be suppressed, such as double letters, e mute, etc., frequently a single movement will produce an entire word. In case, however, the word is to be continued to the next line, a movement of one of the wrist keys makes a character indicating the fact.

The manipulation of the keyboard requires great skill. Learning to read the characters is very easy, but at least six months' practice is necessary for one to become an expert operator capable of following every word as it is uttered in a large assembly.

The paper roll is of no great length. About sixty or seventy feet, four inches in width, is required for an hour's continuous writing. See also TYPE-WRITER.

Stent'er. A *tenter;* the term may be deemed a corruption from *tenter.* It is common in Scotland and in the North of England. Various inflections are found: *stent, stenter, stenter-hook, stenting-machine.* See TENTER.

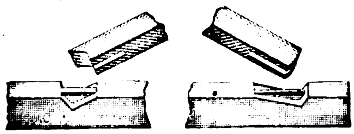
Stent'ing. (*Mining.*) An opening in a wall in a coal-mine.

Sten'ton. (*Mining.*) A passage between two winning headways.

Sten'ton Wall. (*Mining.*) The pillar of coal between two winning headways.

Step. 1. (*Carpentry.*) *a.* The foot-piece of a

Fig. 5770.



Rafter Stepped into a Beam.

timber, as in the example, in which the foot of a principal rafter is stepped into a tie-beam.

b. The *tread* of a stair.

c. A *round* or *rung* of a ladder.

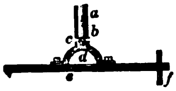
2. (*Vehicle.*) A foot-piece for ascending a carriage.

3. (*Shipwrighting.*) The block in which the foot of a mast is placed.

4. (*Machinery.*) *a.* The lower brass of a journal-box or pillow-block.

b. The socket for the lower pivot of a spindle or vertical shaft. An *ink.* Sometimes called a *breast.*

Fig. 5771.



Adjustable Step for Millstone-Spindle.

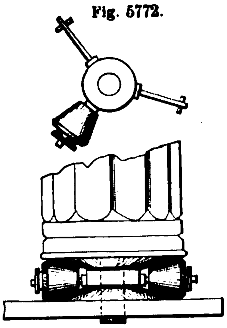
a, foot-stalk.
b, toe.
c, step.
d, foot-bridge.
e, bridge-tree.
f, lighter-screw.

A device similar in principle is used for a step-bearing. The rollers in this case are necessarily conical, as the portion of each more distant from the center of revolution traverses a greater space than that nearer to the axis of the vertical shaft. The three rollers are frustums of cones, and are axled upon radial arms, which keep them in their relative position. The pivot of the vertical shaft passes through the annular piece from which the radial axles diverge. Each roller rotates on its own axle, and the system revolves around the pivot of the shaft. Conical bearings on the end of the shaft and on the bed-plate have a conformity of outline with the rollers.

Gardner's step for vertical shafts (Fig. 5773) may have balls in a cylindrical recess, upon which a conical shoulder near the foot of the shaft rests (*A*); or the recess may be of conical form, and the friction-rollers conical frustums (*B*).

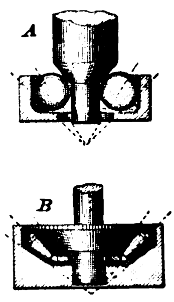
Fig. 5774 is a self-oiling step for vertical spindles. The step *b* rests in a counter-box in the chamber *a*. The end of the spindle is somewhat tapering, and, as it rotates, creates a centrifugal action in the oil, which flows over the edge at *c* into the chamber *d*, and rises through the hole *e* beneath the step to renew the lubrication of the spindle.

Fig. 5772.



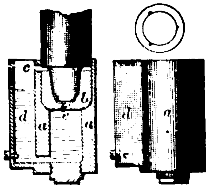
Step-Bearing.

Fig. 5773.



Gardner's Shaft-Step.

Fig. 5774.



Self-Oiling Step for Vertical Spindles.

Step-bit. (*Locksmithing.*) A notched key-bit.

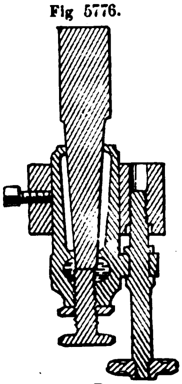
Step-box. (*Machinery.*) A case for a bearing surface at the lower end of a vertical spindle or shaft.

Fig. 5775.

Step-Bit.

In the example, the adjusting-screw may be made to adjust the spindle, together with the socket-sleeve, to different hights, and by the same adjusting-screw — the step-screw being backed out and the spindle fixed — the spindle can be tightened in its socket.

Fig. 5776.



Step-Box.

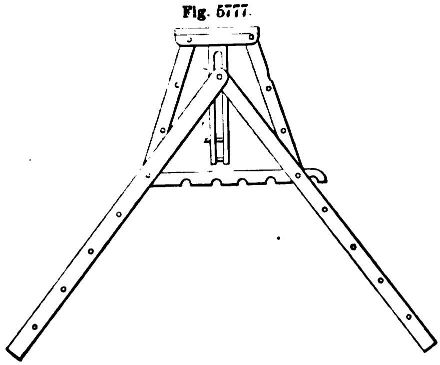
Step-cov'er. (*Vehicle.*) A lid to cover a carriage-step when the door is closed, to prevent the accumulation of mud thereon. When the door is opened it is retracted, and sometimes acts as a protector, to keep the dress from contact with the wheel.

Step-grate. A furnace-grate in several successive hights, like a stairs. See *e, f,* Fig. 2304, page 1012.

Step-lad'der. A portable ladder usually having flat steps, and its own means of support by struts or posts.

In Fig. 5777, the ladder is stayed at the required extension by a notched brace, which catches upon a round; the feet of the upper platform rest upon the rounds of the ladder.

Fig. 5777.



Orchard-Ladder.

In Fig. 5778, the brace and stay-rods slide on the staples, so as to allow of folding together or spreading apart of the sides and legs in position for use.

Fig. 5778.

Step-Ladder.

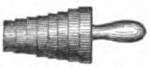
In Fig. 5779, the notched pivoted side pieces are braced together, inclosing the hinged supporting legs and folding together for removal.

Fig. 5779.

Library-Ladder.

Stepped Gage. One having a series of notches which may fit varying sizes of holes.

Fig. 5780.

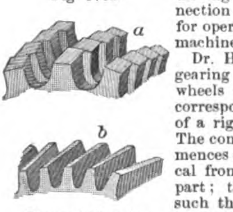


Stepped Gage.

Stepped Gear'ing. (*Machinery.*) An invention of Dr. Hooke for obtaining a continuous bearing between the meshing surfaces of gear-wheels.

Each wheel is composed of two, three, or more separate sets of teeth, which, instead of being in line, are arranged in steps (*a*, Fig 5781). It is sometimes used for driving screw-propellers, and in connection with a rack of similar character for operating the beds of large planing-machines.

Fig 5781.



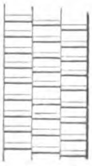
Stepped Gearing.

Dr. Hooke also invented the screw-gearing *b*. This consists of a pair of wheels whose teeth are of helical form, corresponding respectively to the threads of a right-hand and a left-hand screw. The contact of each pair of teeth commences at the foremost end of the helical front, and terminates at the back part; the pitch of the helices being such that the contact of one pair of teeth does not terminate until that of the next pair has commenced, thus causing great uniformity and smoothness of motion.

Stepped Key. The stepped key was shown in Rountree's lock, English patent, 1790. See BIT-KEY.

Fig. 5782. Fig. 5783.

Stepped Key.



Stepped Rack.

Stepped Rack. A rack having teeth arranged in several rows, which alternate with each other so as to produce the uniformity of motion due to smaller teeth, without sacrifice of strength. The teeth of the pinion with which it gears are, of course, correspondingly arranged.

Step'ping-line. (*Ship-building.*) The bearding line or trace of the inner surface of the ship's skin, at the points where it rises toward each end of the vessel.

Steps. A ladder for in-door use, such as for a library or for house-cleaning purposes. See STEP-LADDER.

Ste're-o-bate. A base; the lower part or basement of a building or column. A *stylobate.*

Ste're-och'ro-my. The name is derived from words signifying solid color, the binding material being soluble glass. This silicious material protects the colors against atmospheric influences.

From Ott we learn that Echter and Kaulbach, the artists of Munich, proceed as follows: —

The wall to be painted is first coated with a layer of ordinary lime mortar, to equalize the surface, which must be exposed to the air for several days, so as to become entirely dry and carbonated, as the soluble glass afterward employed would be immediately decomposed by caustic lime. Professor Fuchs, the inventor of stereochromy, recommends moistening the wall with a solution of carbonate of ammonia, so as to accelerate the saturation of the lime. When dry, it is washed several times with a moderately diluted solution of double water-glass, allowing it to dry each time. See SOLUBLE GLASS.

The ground being thus prepared, the upper layer may be added soon after. This also consists of lime cement one tenth of an inch thick. The sand employed must be of a grain not exceeding a certain size, and fine powder must be rejected. A rough grain is rather advantageous, and, as Kaulbach says, it ought to feel like a rasp. For a picture to be viewed at a long distance a less fine grain is required than for a picture to be viewed at a short distance.

This coat being dry, it is moistened with a solution of one part of phosphoric acid in six parts of water, the object being to remove the thin layer formed of carbonate of lime, which would prevent the absorption of the soluble glass subsequently spread over it. The soluble glass here referred to must be the double water-glass, clarified with *liquor silicum.* It is diluted with an equal bulk of water, and the operation has to be repeated twice. Too much water-glass prevents the ground from taking the colors. Rain-water is used exclusively throughout the operation.

The ground being thus completed, the painting may be proceeded with, although some delay increases the capacity of absorption. The colors to be used are ground in pure water, and the wall has to be frequently but carefully sprinkled with water, in order to displace the air from the pores, and insure the adhesion of the colors.

The colors are fixed with a solution of soluble glass. They do not admit of being wet with a brush, and the solution is therefore sprinkled upon the painting in a fine shower or mist by a syringe. The operation of alternate sprinkling and drying is continued till the colors adhere so firmly that by rubbing them with the finger they are not disturbed.

Ste're-o-graph. The representation of a solid on a plane.

Ste're-om'e-ter. 1. An instrument for measuring the solid or liquid contents or the capacity of a vessel.

2. An instrument invented by M. Say, a French officer of engineers, for determining the specific gravity of porous bodies, powders, etc.

It consists of a long glass tube, whose upper and lower portions are separated by a partition, but communicate through an aperture so small as to prevent the passage of fine solid particles, and provided with an air-tight cover. The substance to be examined is placed in the upper part and the lower end of the tube plunged into mercury, until this fluid rises to a certain mark on the tube; the air-tight cover is then placed on, and the tube raised until the contained air is expanded to twice its original bulk. The porous substance is then removed, and the operation repeated. This gives the bulk which it would occupy in a solid state, and from its weight compared with that of an equal volume of water its specific gravity is deduced.

Owing to the variations in bulk of the included air under different conditions of atmospheric pressure and temperature, the instrument requires too much care to be taken in order to produce accurate results to render it practically useful.

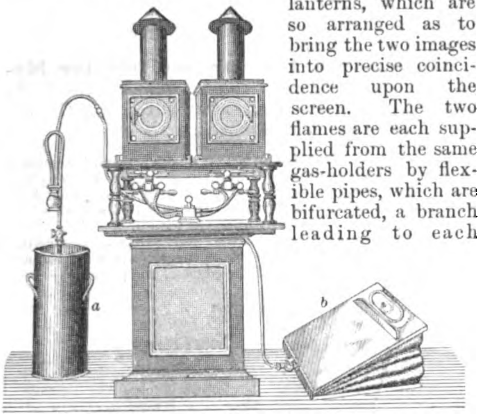
An instrument afterward constructed on the same principle by Sir John Leslie was by him termed a *coniometer.*

Ste're-o-mon'o-scope. A contrivance of M. Claudet, by which a stereoscopic effect is produced by receiving the image of an object on a plate of unpolished glass. The glass is set in a black screen, and the image is projected through a lens, and may be viewed, thus magnified, with the naked eye or with lenses. — COSMOS, Vol. XII. p. 493.

Ste're-op'ti-con. An instrument for exhibiting photographic pictures greatly magnified upon a screen or wall with stereoscopic effect. The oxy-

calcium or oxy-hydrogen lights are preferably employed for illuminating the two magic-lanterns, which are so arranged as to bring the two images into precise coincidence upon the screen. The two flames are each supplied from the same gas-holders by flexible pipes, which are bifurcated, a branch leading to each

Fig. 5784.



Stereopticon.

flame. *a* is the hydrogen and *b* the oxygen gas-holder.

Ste'reo-scope. An instrument employed to represent solid figures, by combining in one image two representations of the object as seen by each eye separately. Two pictures of an object or scene taken from different points of view are seen in a single picture of that object, having the actual appearance of relief or solidity.

"The stereoscope consists of two mirrors placed each at an angle of 45°, or of two semi-lenses turned with their curved sides toward each other. To view its phenomena, two pictures are obtained by the camera on photographic paper, of any object, in two positions, corresponding with the condition of viewing it with two eyes. By the mirrors or the lenses these dissimilar pictures are combined within the eye, and the vision of an actually solid object is produced from the pictures represented on a plane surface." — HUNT.

Euclid, 300 B. C.; Galen, A. D. 131; Leonardo da Vinci, died A. D. 1519; and Baptista Porta, A. D. 1600, each noticed the fact that in viewing an object the eyes received dissimilar impressions, owing to the difference in position of the eyes relatively to the object.

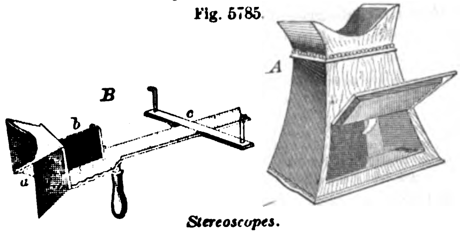
As the vision of an object is compounded of two dissimilar images, an instrument is required to take two pictures, and another instrument is required to optically combine them. One instrument is the binocular photographic camera, and the other instrument is the stereoscope.

The following story is told of the first introduction of the stereoscope to the *savants* of France. "The Abbé Moigno took the instrument to Arago, and tried to interest him in it; but Arago unluckily had a defect of vision which made him see double, so that on looking into the stereoscope he saw only a medley of four pictures. The Abbé then went to Savart, but he was quite incapable of appreciating the thing, for he had but one eye. Becquerel was next visited, but he was nearly blind, and consequently cared little for the new optical toy. The Abbé, not discouraged, called next upon Puillet, of the Conservatoire des Arts et Métiers. He was a good deal interested in the description of the apparatus, but unfortunately he squinted, and therefore could see nothing in it but a blurred mixture of images. Lastly, Biot was tried, but Biot was an earnest advocate of the corpuscular theory of light, and until he could be assured that the new contrivance did not contradict that theory, he *would* not see anything in it. Under the circumstances, the wonder is that the stereoscope ever got fairly into France." — *American "Journal of Chemistry."*

The reflecting form was contrived by Wheatstone in 1838; the lenticular was subsequently devised by Brewster, and is that now in general use.

Brewster's lenticular stereotype consists of a pyramidal box, blackened on the inside, and having a lid for the admission of light, when the pictures are opaque. The box is open below, in order to let the light pass through the pictures when they are transparent. The top of the box consists of two portions, in one of which is the right-eye tube, containing a semi-lens or quarter-lens, and in the other portion is the left-eye tube, similarly furnished with a semi or a quarter lens. The two dissimilar pictures (or slide) are placed in a groove in the bottom of the box (*A*, Fig. 5785), when, on looking through the eye-tubes, the pictures are seen united into one single picture, the objects standing out with an almost magical appearance of relief and solidity. By means of the semi-lenses the two dissimilar stereographs are transferred to a middle point, where they are united to produce the stereoscopic effect.

Fig. 5785.



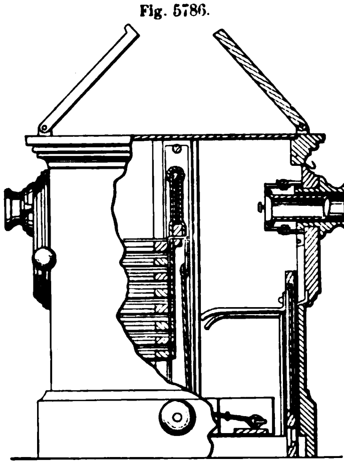
Stereoscopes.

Fig. 5785, *B*, also represents a common form. The box *a* through which the pictures are viewed contains the two semi-lenses, one on each side of the plate *b*, which is designed to prevent each eye from seeing the picture intended for the other. The card on which the pictures are mounted is held by the slide *c*, which may be adjusted to suit the proper visual distance for each individual.

Numerous minor improvements have since been made on the original instrument of Brewster.

Stereoscopes are also made on a larger scale, to hold from 48 to 600 pictures, which are arranged on a chain so as to be revolved and brought consecutively into view. These stereoscopes are adapted to stand on the floor or table, according to size and capacity for pictures.

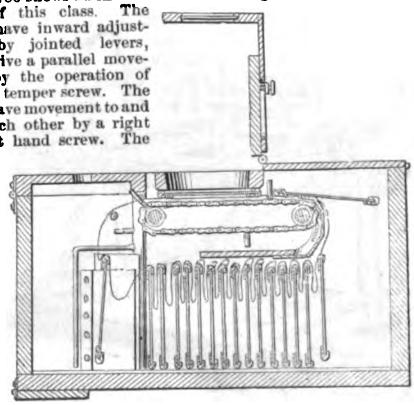
Fig. 5786.



Stereoscope.

Fig. 5786 shows an instrument of this class. The lenses have inward adjustment by jointed levers, which give a parallel movement by the operation of a single temper screw. The tubes have movement to and from each other by a right and left hand screw. The

Fig. 5787.



Stereoscope.

pictures are held by spring clamps which are strung upon cords and brought up to view by turning a shaft in the usual manner.

In Fig. 5787, the pictures are attached to endless ribbons, and by the revolution of a shaft are fed consecutively into position to be viewed. Retiring from this position they are arranged in a rank, ready for the next presentation.

Ste're-o-scop'ic Lens. A combination of two semi-lenses used in the lenticular stereoscope of Sir David Brewster.

The two are placed at such a distance apart that each eye views the object through that one of the semi-lenses which is opposite to it, the visual lines from the object to each eye passing through points equidistant from the margin of each semi-lens, and at a distance apart equal to that between the two eyes, usually about $2\frac{1}{2}$ inches. The two images are thus visually combined and magnified at the same time.

Ste're-o-stat'ic Arch. A linear arch sustaining the pressure of a material in which at any given point there are a pair of conjugate pressures, one vertical and the other in a fixed direction horizontal or inclined. The conditions involve the symmetrical distribution of the vertical load on either side of a vertical axis traversing the crown of the arch.

Ste're-o-type-block. (*Printing.*) A block on which a stereotype is mounted to make it type-high.

Important works are generally stereotyped, and the plates stored; to meet this use blocks are made

Fig. 5788.

Stereotype-Block.

with clasps, and are adapted to hold plates within a given range of sizes.

In Fig. 5788, the stereotype plate is mounted upon quadrats set up in a chase; the clamps which hold the edges of the plate are inserted among the quadrats.

Fig. 5789.

Stereotype-Plate Holder.

In Fig. 5789, the frame is formed of separate pieces clamped in the chase, and has catch-plates and screw-adjusted catches to clamp the plate.

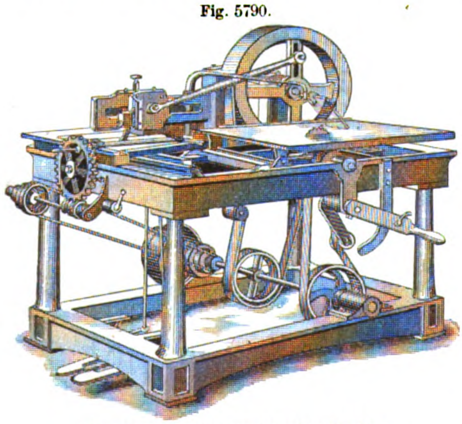
Ste're-o-type Ma'trix-ma-chine'. See TYPOGRAPHIC MACHINE.

Fig. 5790.



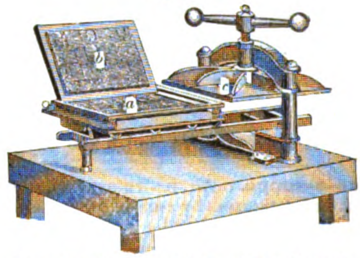
Stereotype Planing and Sawing Machine.

Ste're-o-type-met'al. The alloy for stereotype-plates is composed of the same materials as ordinary type-metal. An alloy composed of 500 lead, 300 tin, and 225 cadmium, has, on account of its hardness, been proposed for stereotype-plates and backing for electrotypes.

Ste're-o-type Plan'ing and Saw'ing Machine'. A machine for roughly planing the backs of stereotype-plates previous to submitting them to the action of the shaving-machine.

The plate is laid face downward on a table, which is advanced by a worm and worm-wheel, and, as it passes beneath two rollers which hold it firmly down, the back is traversed by a tool similar to the ordinary lathe-cutter, fixed in a head which is reciprocated by pitman connection with a fly-wheel. The tool cuts only in one direction; the carriage has a quick return motion. A circular saw and table at the other end of the machine are used for dressing off the edges of the plates.

Fig. 5791.

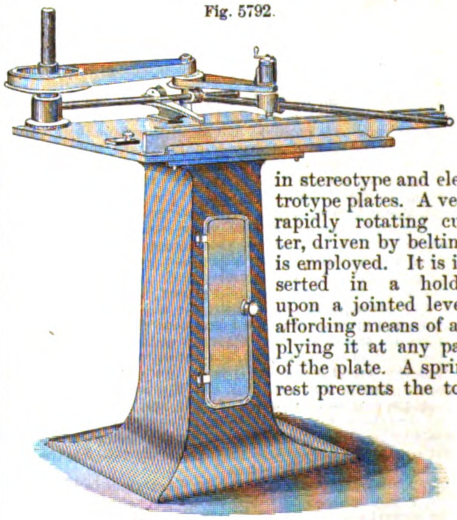


Press for Stereotype-Molding (Clay Process).

Ste're-o-type-press. A small press for use in the clay process. (See STEREOTYPING.) *a* is the bed; *b* is the tympan, which may be large enough to cover the form, or consist only of hinges and clamps for holding a metallic plate; *c* is the platen.

Ste're-o-type Rout'ing-ma-chine'. (*Printing.*) A machine for deepening the blank spaces

Fig. 5792.

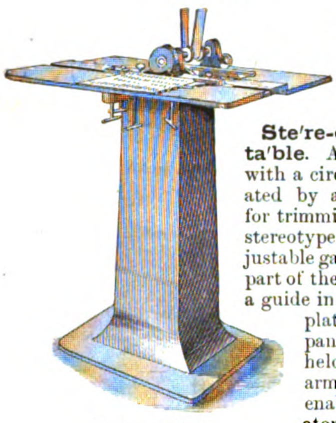


Stereotype Routing-Machine.

in stereotype and electrotype plates. A very rapidly rotating cutter, driven by belting, is employed. It is inserted in a holder upon a jointed lever, affording means of applying it at any part of the plate. A spring rest prevents the tool from touching the plate until pressed down by the operator.

Ste're-o-type-saw. A circular saw used for trimming the edges of stereotype plates. It is mounted on a stand having a table, on which the plate is laid and advanced by hand to the Hoe saw,

Fig. 5793.



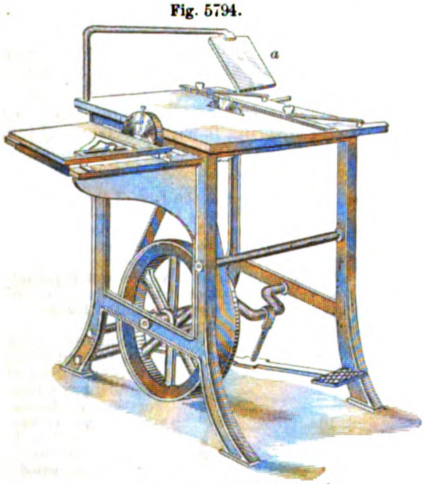
Stereotype-Saw.

which is driven by belt and pulley connection with the other machinery, or with a treadle.

Ste′re-o-type Saw-ta′ble. A table provided with a circular saw operated by a treadle, used for trimming the edges of stereotype-plates. An adjustable gage on the upper part of the table serves as a guide in presenting the plate to the saw. A pane *a* of glass, held by a crooked arm over the table, enables the operator to view the work without being struck by the flying particles of metal. At one end of the saw-mandrel is a cutter-head, with a sliding table for squaring up metallic blocks, etc.

Ste′re-o-type Shav′ing-ma-chine′. A machine for planing the backs of stereotype-plates. The plate is laid face downward on a traveling-bed, and is held by a ledge while it is drawn forward under a stationary knife, which takes off a shaving of the requisite thickness. Motion is imparted to the bed

Fig. 5794.



Stereotype Saw-Table.

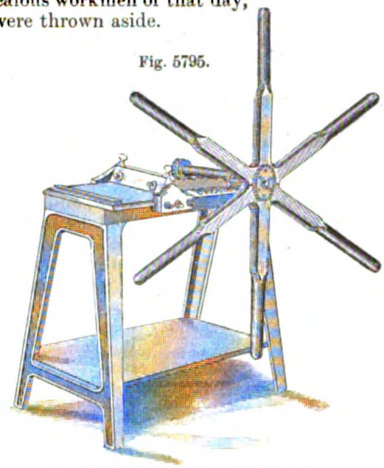
by turning the spoke-levers, which turn a pinion gearing with a rack.

Ste′re-o-type Shoot′ing-board. The shooting-board used in stereotyping is a cast-iron plate *d* with a planed upper surface, having ledges for holding a stereotype-plate firm while its edges are dressed off with a side-plane *c*. The lower figures *a a* show the positions of the stereotype-plates when *squaring* or *beveling* the edges.

Ste′re-o-typ′ing. The art of making solid plates forming an exact fac-simile of the page of type as set up by the compositor, and from which impressions are taken in the usual manner.

The *plaster process* was invented by William Ged, a goldsmith of Edinburgh, who was employed by the University of Oxford in 1731 to manufacture plates for Bibles and prayer-books. These were injured by the jealous workmen of that day, and were thrown aside.

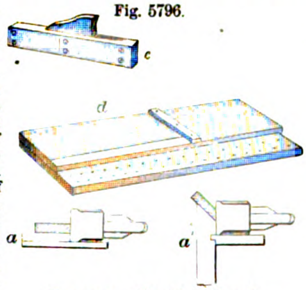
Fig. 5795.



Stereotype Shaving-Machine.

In 1698, J. Van der Mey, in Holland, had printed a quarto Bible and some other books from pages of type soldered together at the back, but this was not true stereotyping.

Fig. 5796.



Stereotype Shooting-Board.

About 1779, Van der Mey's process was revived by Dr. Alex Tilloch of Glasgow, but it still does not seem to have come into general use, as we hear little of it until it was taken up by the French printers.

Carey's method of stereotyping, France, 1793, was as follows: The form was attached to a block suspended face downward from a beam, and was suddenly allowed to fall upon a surface of hot lead, just in the act of solidifying. The matrix thus obtained was used in a similar manner to obtain a relief cast or *cameo* impression, by dropping upon another surface of hot lead.

Didot (France) modified the plan by casting his types with a harder alloy, consisting of lead 30, antimony 30, tin 30, copper 10, and a form of such type was pressed by a fly-press into a surface of pure lead.

The matrix thus obtained was attached to the hammer of a stamping-press, on the bed of which was a paper-frame inclosing type-metal in a state of fusion. When on the point of setting, the metal was rolled up into a mass, and the matrix of the page brought down upon it, flattening it out and giving a stereotype-plate suitable for printing. This plan was adopted in Didot's edition of 200 vols

Herhan's plan (French) was to set up the form in copper matrixes, intaglio, and take a casting in type-metal therefrom, procuring a cameo impression at one operation.

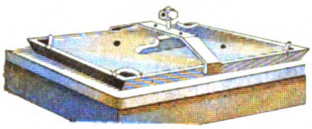
"The invention of solid types by the Parisian printers, Didot and Herhan, is thought a great improvement. These types, instead of being detached characters, like the common, form a solid mass for each page, which, being incapable of derangement, fixes forever the purity of the text. A great saving of paper results, as it is not necessary to take off a greater number of impressions than are wanted at one time." — *Monthly Magazine*, January, 1799.

Ged's process was substantially the "plaster" process as used at the present day.

In this the type is set up in the usual way, except that shoulder-high *spaces* and *quadrats* are employed. The face of the form is thinly and evenly oiled with a brush, and it is surrounded by a rectangular frame termed a *flask*. Plaster of Paris mixed with water is then poured upon it, forming a mold corresponding to the face of the form. When this has sufficiently hardened, it is withdrawn by turning screws at the four corners of the flask, and it is afterward

dried in an oven until all the moisture is driven off. The mold is then placed face downward upon a cast-iron plate, termed a *floating-plate*, and this is placed within a cast-iron tray, termed a *dipping-pan*, having a lid

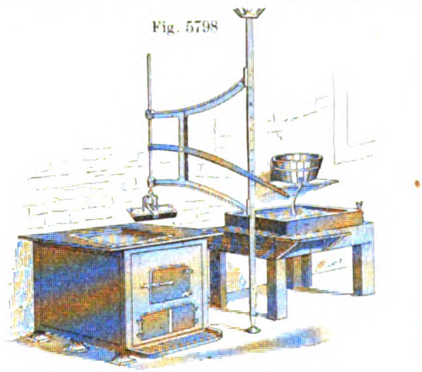
Fig. 5797.



Dipping-Pan.

which is secured by means of a screw, and the whole is heated to about 400° Fahr., lifted by means of a crane suspended over a pot of molten metal, and gently lowered into the bath, where it is immersed to near the bottom, the metal flowing in and filling

Fig. 5798.



Stereotyping Apparatus.

up all the cavities in the face of the mold, though forming but a thin film on the back. After remaining 8 or 10 minutes in the metal, the arrangement is lifted therefrom by the crane, swung over the cooling-trough, and lowered upon a stone, so that the bottom part just comes in contact with the water; the face part is first cooled, and as shrinkage takes place it is filled up from behind. The pan is then opened, the mold separated from the cast by beating with a mallet, and the face examined, to see if there are any irremediable defects; if not, the plate is planed on the back and dressed on the sides, to adapt it to fit the *block* on which it is placed for printing. (See STEREOTYPE PLANING-MACHINE; STEREOTYPE SHAVING-MACHINE.) The planing is effected by a peculiar machine, worked in a manner analogous to the engravers' plate printing-press, and the sides are squared by a saw (see STEREOTYPE-SAW; STEREOTYPE SAW-TABLE), and beveled by a plane while held on the shooting-board (see STEREOTYPE SHOOTING-BOARD). Any flat shallow places into which the paper might be pressed and gather ink are worked deeper by the STEREOTYPE ROUTING-MACHINE (which see).

Stereotyping was introduced into the United States by David Bruce, of New York, in 1813; the first work cast in America was the New Testament, in bourgeois, in 1814.

The curving of stereotype-plates to adapt them to a cylinder printing-press was patented in England by Cowper in 1815; but was not practiced with any great success until of late years, when it was introduced upon daily newspapers in connection with the revolving type-cylinder of Hoe.

Clay, or Clay-and-Plaster Process.

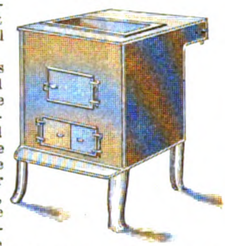
The form is locked up with *high furniture* and *slugs*, and placed on the bed *a* of the press shown in Fig. 5791 (STEREOTYPE-PRESS). The face of the type is brushed over with benzine or naphtha, and covered with a cloth or paper.

A detachable plate is hinged like a tympan to the press-bed. On the face of this plate a mixture of equal parts ground potter's clay and gypsum, moistened to the consistency of mortar, is spread with a trowel to the depth of about ¼ of an inch.

The tympan is now turned down on the form, the bed runs under the platen, and a partial impression is taken, sufficient to give the general outline of the *form* to the clay coating. The press is then opened, the cloth removed, and also any surplus material which has been thrown up by the first pressure, and would be likely to bind. The press is again closed, and a complete impression taken, imbedding the type in the plastic material to the desired extent.

The metallic plate carrying this mold is then removed from the press, and hardened by drying. When dry, it is set afloat face upward in a vat of melted type-metal, as the most convenient means of bringing mold and metal to a uniform temperature.

Fig. 5799.



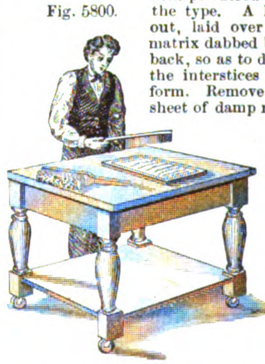
Stereotyping-Furnace and Metal-Pot.

A wire bent like a horseshoe is then put on the plate, around three sides of the mold. The wire is somewhat thicker than a completed stereotype-plate. A second sheet of metal is clamped over the wire, as in a molder's flask. The plate is then put in a rack or trough with its open edge upward, and the metal poured in. The cooling may be hastened by turning water on the outside of the flask. When the casting is removed the clay adheres to the face of the plate, and is removed by washing. The plate is then planed, trimmed, and dressed up for use. Curved plates for cylinders are made from a flat form by using a sheet of spring steel of the desired curvature, for a base plate, which is spread flat on the tympan and the plastic material is applied to what is to be the concave side. After the impression is taken the sheet is released, and resumes its normal curvature, bending the plastic mold with it. The face of the plate is of course somewhat distorted, the stereotype appearing as if taken from type a little more condensed one way than that actually employed in the form.

The *papier-maché* process was invented by Wilson, in Scotland, in 1823. It is a very expeditious process, and is generally used on the daily papers of large circulation. A paper matrix is formed by spreading paste over a sheet of moderately thick unsized paper and covering it with successive sheets of tissue-paper, each carefully patted down smooth, and the pack then saturated.

The face of the type is oiled, the face of the paper treated with powdered French chalk and laid upon the type. A linen rag is wetted, wrung out, laid over the paper, and then the matrix dabbed by a beating-brush from the back, so as to drive the soft paper into all the interstices between the letters of the form. Remove the cloth, lay a reinforce sheet of damp matrix paper upon the back of the matrix, and beat it again without the cloth, to perfect the impression and establish a junction. For large establishments a matrix-rolling machine is used. Put a double thickness of blanket upon the matrix, place form and matrix in a press, and screw down tight. The lighted gas heats the press and the form, and dries the paper matrix. The press is unscrewed, the matrix removed, its edges pared, and it warmed on the molding-press. The matrix is then placed in the previously heated iron casting-mold; a casting-gage to determine the thickness of the stereotype is placed round three sides of the matrix, the other side being left open for a gate, at which the molten metal is poured in. The cover is screwed tight, the mold tipped to bring the mouth up, and the metal poured in. When the metal is *set*, the mold is opened and the matrix removed. The plate is then trimmed and otherwise prepared in the usual manner.

Fig. 5800.



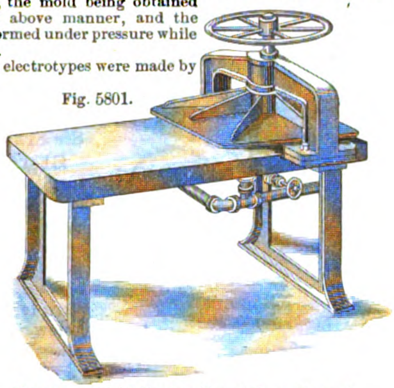
Beating-Table (Papier-Maché Process).

Mr. Muir, of Glasgow, employed gutta-percha slabs for forming stereotype-molds; the process consisted simply in applying the slab while hot to the form of type, and subjecting it for some 15 minutes to the action of a screw-press. The face of the mold being afterward black-leaded, an electrotype cast was

taken. He also made stereotype-plates from the same substance, the mold being obtained in the above manner, and the plate formed under pressure while heated.

Iron electrotypes were made by

Fig. 5801.



Stereotype-Mold Drying-Press (Paper Process).

Klein, a Russian, and the process patented in the United States, September 29, 1868. See also "Scientific American," November 18 and November 27, 1868.

In Joyce's process for obtaining plates in relief from intaglio molds, patented July 14, 1874, a smooth plate of iron, such as is used in the clay process of stereotyping, is covered with a thin layer of suitable composition, ordinary thin clay and pulverized plaster. When dry, the design or writing is cut into the composition by means of pointed or sharp-edged graving-tools, so as to expose the face of the plate at those parts which are to show black in the print. The nature of the material enables a skilled draftsman to cut his design in the matrix without the necessity of previously making a drawing on the surface, or of transferring from a drawing on paper. In case a design is to be copied, the paper is laid directly on the face of the mold, and the lines traced through with a blunt-pointed instrument, the composition being sufficiently yielding to receive and retain the impression; its texture also admits of erasures and corrections being made. When the design is finished, the plate and matrix are heated, and a cast is made with stereotype-metal in the manner usual in the clay process, a somewhat higher temperature, however, being required to ensure the perfection of the face which is formed by the mold-plate. The stereotype-plate thus formed is trimmed, planed, and finished in the usual way, the depressions being deepened by routing, if necessary.

This process enables cuts, maps, autographic or fac-simile writings, etc., to be produced in a form suitable for working on an ordinary letter-press in a very simple and expeditious manner.

ELECTROTYPING.

Electrotyping is an application of the art of electro-plating which originated with Volta, Cruickshank, and Wollaston, about 1800-1801. In 1838, Spencer, of London, made casts of coins and cast in intaglio from the matrixes thus formed; in the same year Jacobi, of Dorpat, in Russia, made casts by electro deposit, which caused him to be put in charge of the work of gilding the dome of St. Isaac, at St. Petersburg.

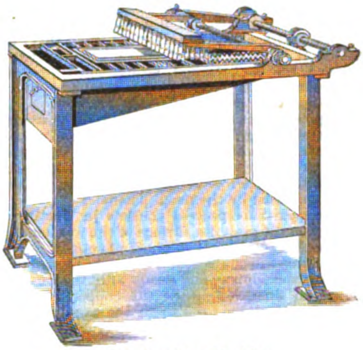
Electrotyping originated with Mr. Joseph A. Adams, a wood-engraver, of New York, who made casts (1839-41) from wood-cuts, some engravings being printed from electrotype-plates in the latter year. Many improvements in detail have been added since in the processes as well as the appliances. Robert Murray introduced graphite as a coating for the forms and molds. He first communicated his discovery to the Royal Industrial Institution of London, and afterward received a silver medal from the Society of Arts.

The process of electrotyping is as follows: The form is locked up very tightly, and is then coated with a surface of graphite, commonly known as *black-lead*, but it is a misnomer. This is put on with a brush, and may be done very evenly and speedily by a machine in which the brush is reciprocated over the type by hand-wheel, crank, and pitman. A soft brush and very finely powdered graphite are used; the superfluous powder being removed and the face of the type cleaned by the palm of the hand.

A shallow pan, known as a molding-pan, is then filled with melted yellow wax, making a smooth, even surface, which is black-leaded. The pan is then secured to the head of the press, and the form placed on the bed, which is then raised, delivering an impression of the type upon the wax.

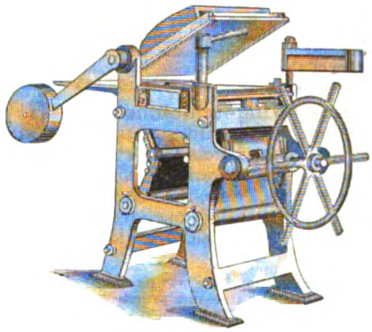
The pan is removed from the head of press, placed on a table, and then *built-up*, as it is termed. This consists in running wax upon the portions where large spaces occur between type, in order that corresponding portions in the electrotype may not be touched by the inking-roller, or touched by the sagging down of the paper in printing.

Fig. 5802.



Black-Leading Machine.

Fig. 5803.

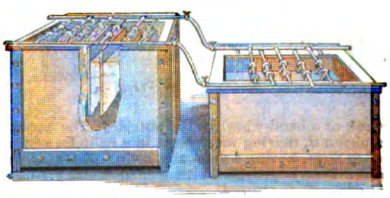


Electrotype-Press.

The wax mold being *built* is ready for black-leading, to give it a conducting surface upon which the metal may be deposited in the bath, superfluous black-lead being removed with a bellows. Black-lead, being nearly pure carbon, is a poor conductor, and a part of the metal of the pan is scraped clean, to form a place for the commencement of the deposit. The back of the molding pan is waxed, to prevent deposit of copper thereon, and the face of the matrix is wetted, to drive away all films or bubbles of air which may otherwise be attached to the black-leaded surface of the type.

In the much-improved wet process of *black-leading*, invented by Silas P. Knight, of Harper Brothers' establishment in New York, the wax mold is laid face upward on the floor of an inclosed box, and a torrent of finely pulverized graphite suspended in water is poured upon it by means of a rotary pump, a hose, and a distributing-nozzle, which dashes the liquid equally over the whole surface of the mold. Superfluous graphite is then removed by copious washing, an extremely fine film of graphite adhering to the wax. This answers a triple purpose; it coats the mold with graphite, wets it ready for the bath, and expels air-bubbles from the letters. This process prevents entirely the circulation of black-lead in the air, which has heretofore been so objectionable in the process of electrotyping.

Fig. 5804.



Electrotyping Bath and Battery.

The mold is then placed in the bath, containing a solution of sulphate of copper, and is made a part of an electric circuit, in which is also included the zinc element in the sulphuric-acid solution in the other bath. A film of copper is deposited on the black-lead surface of the mold; and when this *shell* is sufficiently thick it is taken from the bath, the wax removed, the shell trimmed, the back tinned, straightened, backed with an alloy of type-metal, then shaved to a thickness, and mounted on a block to make it *type-high*.

Adams's process consists in adding finely pulverized tin to the graphite for facing the wax mold: the effect in the sulphate-of-copper bath is to cause a rapid deposition of copper by the substitution of copper for the tin, the latter being seized by the oxygen while the copper is deposited upon the graphite. The film is after increased by the usual means.

Knight's expeditious process consists in dusting fine iron filings upon the wet graphite surface of the wax mold, and then pouring upon it a solution of sulphate of copper. Stirring with a brush expedites the contact, and a decomposition takes place; the acid leaves the copper, and forms with the iron a sulphate solution, which floats off, while the copper is freed and deposited in a pure metallic form upon the graphite. The black surface takes on a ruddy tinge with marvelous rapidity.

The electric-connection gripper is designed to hold and sustain the molding-pan and make an electric connection with the prepared conducting-pan of the mold only, while the metallic pan itself is out of the current of electricity and receives no deposit.

The galvanoplastic process of M. Coblence for obtaining electrotypes of wood-engravings is as follows: A frame is laid upon a marble block, and then covered with a solution of wax, colophane, and turpentine. This mixture on the frame, after cooling, becomes hard, and presents a smooth, even surface. An engraved wooden block is then placed upon the surface of the frame and subjected to a strong pressure. The imprint, or matrix in cameo, having been coated with graphite, is then placed vertically in a galvanoplastic bath, and a cast, an exact reproduction of the wood-engraving, is obtained. The shell is then backed with type-metal and finished in the usual way.

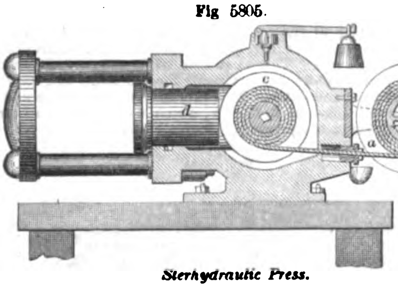
Ste're-o-typ'ing-ma-chine'. One in which type are brought forward seriatim to impress the material for a matrix from which a stereotype-plate is to be cast. The operation is similar to that of a type-composing machine, the letters, spaces, punctuation-marks, etc., being operated by keys, on a manual like a piano-forte. See also TYPOGRAPHIC MACHINE.

Nelson's stereotype-machine was exhibited in New York in 1867. An apparatus on the same principle was also exhibited at the Paris Exposition in 1867. In this but one type of each sort was used, which was arranged at the end of a key-lever, and imprinted itself in the proper place on a bed of clay moving automatically. This, when completed, was served as the ordinary plaster casts for stereotyping, the liquid metal being poured in, and in a few moments producing complete stereotype-plates.

Ster-hy-drau'lic Press. A press in which a powerful hydrostatic pressure is obtained by introducing into the cylinder of a hydraulic press already filled with liquid, not an additional amount of liquid by successive impulses, as in the case of the hydraulic press, but a solid substance, usually a solid cord, by a steady, uninterrupted movement.

The cord *a* is wound from an exterior pulley *b* on to a pulley *c*, which is inclosed within the apparatus, while it is operated

Fig 5805.



Sterhydraulic Press.

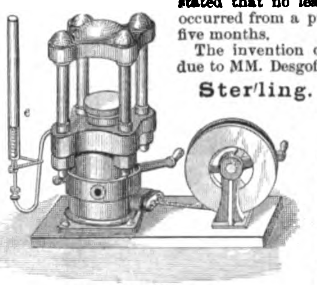
by a crank or a band-wheel on the outside. The pressure acts upon a piston *d*, moving water-tight in a cylinder as usual.

Another form, having a vertically acting piston, is shown in Fig. 5806. This is provided with a manometer *e*, to show the amount of pressure exerted.

The liquid employed for filling the chamber is oil; the rope, about 4/10 inch in diameter, is of catgut; the packing, combed hemp; this in time becomes compacted to a horny consistency, and it is stated that no leakage whatever has occurred from a press in daily use for five months.

The invention of this apparatus is due to MM. Desgoffe and Ollivier.

Fig. 5806.



Sterhydraulic Press.

Ster'ling. (*Engineering.*) See STARLING.

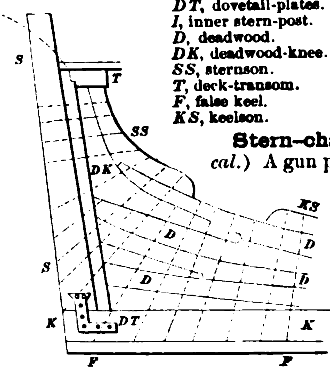
Stern. (*Shipwrighting.*) The *after part* of a vessel. The rail around the upper edge is the *taffrail*. The *stern* terminates below at the junction of the *stern-post* with the keel. Sterns are *round* or *square*.

A ship is said to be *down by the stern* when drawing more water aft than forward.

Of the parts in a vessel's stern, —

Fig. 5807.

S is the stern-post.
K, keel.
DT, dovetail-plates.
I, inner stern-post.
D, deadwood.
DK, deadwood-knee.
SS, sternson.
T, deck-transom.
F, false keel.
KS, keelson.



Parts in a Vessel's Stern.

Stern-chas'er. (*Nautical.*) A gun pointing through a stern-port.

Stern-fast. (*Nautical.*) A warp mooring the after part of a vessel to a wharf or quay.

Stern-frame. (*Shipbuilding.*) That composed of the *stern-post*, *transom*, and *fashion-pieces*.

Stern-knee. One uniting the stern-post and keel.

Stern-port. (*Nautical.*) An opening in the stern of a ship. A *cargo*, *light*, *air*, or *gun* port, as the case may be.

Stern-post. (*Shipbuilding.*) A slightly raking straight piece, rising from the after end of the keel, to which it is secured by tenons and dovetail-plates. See STERN.

Stern-sheets. (*Nautical.*) That part of a boat which is included between the stern and the aftermost thwart.

It is the place of honor in the boats of a government or other vessel, and for passengers in ferry-boats and wherries.

Stern'son. (*Shipbuilding.*) A binding-piece above the deadwood in the stern, and practically forming an extension of the keelson, on which the stern-post is stepped.

Ster'ro-met'al. An alloy invented by Baron Rosthorn of the Imperial Arsenal, Vienna, and used as a gun-metal.

It has, —

Copper	55.04	or	57.63
Tin	0.83		0.15
Zinc	42.36		40.22
Iron	1.77		1.86

It differs from *Keir's metal*, English patent, December 10, 1779, mainly in having a small quantity of tin.

Keir's metal is, —

Copper	100
Zinc	75
Iron	10

See ALLOY.

Stet. (*Printing.*) *Let it stand.* A marginal mark directing attention to a portion of the matter, and countermanding an order to expunge it.

A series of dots made below the matter has the same effect.

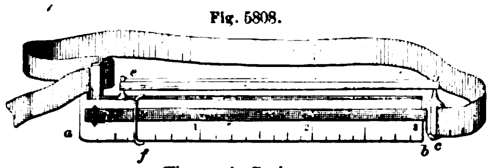
Ste-thom'e-ter. (*Surgical.*) An instrument for measuring the external movement in the walls of the chest during respiration, as a means of diagnosis in thoracic disease.

In one form a cord is extended round the chest, and its extension, as the thorax is expanded, works an index-finger on a dial-plate. It thus becomes a measure of the expansive power and capacity of the lungs.

The *spirometer* measures the quantity of air inhaled, but is the measure of the *thoracic* and the *diaphragmatic* breathing; the latter is that of tranquil respiration, known as *tidal* breathing; the former comes in as auxiliary, is the result of volition, or results from the impeding of abdominal expansion, and is known as *complementary* breathing. The stethometer measures the costal expansion.

Tiemann's stèthometer consists of an outer case marked with a scale of three inches *a b*, within which moves a slide *c d* bear-

Fig. 5808.



Tiemann's Stethometer.

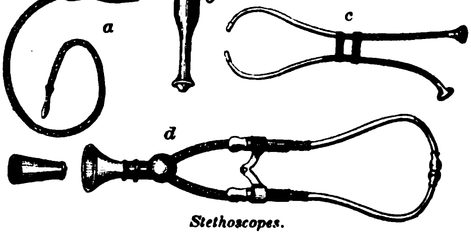
ing an indicator *d*. To the end of this slide is attached an ordinary measuring-tape, the first three inches being cut off, so as to render the scale continuous; this is passed around the chest and drawn through the catch at the opposite end of the instrument. As the lungs are inflated the slide is drawn out, and the indicator shows the exact amount of expansion. A hard rubber ring *f*, sliding easily over the scale, may be used to render the stethometer self-registering; *e e* is an elastic band to draw the two portions of the instrument together.

Dr. J. C. Draper states that in ordinary respiration, on making sixteen respirations in the minute, and continuing the experiment for twenty minutes, the average of five different series of experiments gives 622 cubic inches of air expired each minute (38 7/8 at each expiration).

Steth'o-scope. (*Surgical.*) An auscultation-instrument, invented by Laënnec for exploring the chest. It is a hollow cylinder of wood with a funnel-shaped end, which is placed upon the chest, while the operator listens at the other end to the audible murmurs of the thoracic viscera.

It is variously constructed of cedar or metal, with horn, hard rubber, or ivory mountings. Flexible instruments of rubber

Fig. 5809.



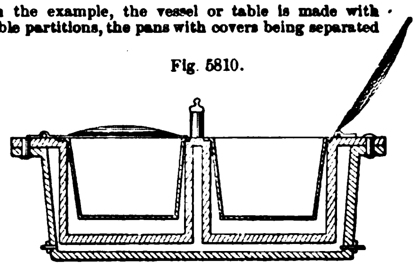
Stethoscopes.

are also used, and are provided with one or two ear-tubes. In the latter case, the pulsation or murmur being appreciable by both ears, a more definite impression is attained. When the bi-tubular stethoscope has distinct mouths and ear-pieces it is termed *differential*, as the comparative conditions of the respective sides of the chest may be examined thereby. *a b c* (Fig. 5809) are various forms. *d* is Camma's double-tube stethoscope.

Stew-pan. A cooking-utensil for exposing meats to a prolonged gentle heat; usually in well-appointed kitchens a charcoal-furnace or steam-bath.

In the example, the vessel or table is made with double partitions, the pans with covers being separated

Fig. 5810.



Stew-Kettle.

by a double jacket, leaving a space for steam to enter and pass around a pipe in each end at the bottom.

Stib'i-um. A name for antimony ore. Its abbreviation *Sb* is used in chemistry as the symbol for metallic antimony.

Stic-ca'to. (*Music.*) An Italian instrument having bars of wood of gradual size and depth of tone, suspended in a box and played by percussion. Resembles a dulcimer. The *lapideon* or *wood-harmonicon.* See also XYLOPHONE.

Stick. 1. (*Wood-working.*) To plane the moldings on sash-bars and rails. See SASH-STICKING MACHINE.

2. A rammer used in filling cartridges.

3. (*Pyrotechnics.*) The slat which trails behind a rocket and directs its flight.

4. (*Printing.*) *a.* A compositor's hand-tray for holding type. (See COMPOSING-STICK.) A *stick-ful* is as much as the *stick* will hold, and the *matter* is then lifted and placed in the *galley.*

b. Furniture for locking up a form in a chase or galley. Known according to position as *head*-stick, *foot*-stick, *side*-stick, or *gutter*-stick, the latter being between the pages. *Quoins* driven around the *sticks lock* the *matter* in the *chase.*

5. A walking-cane. (See CANE, page 443.) For the ethics and romance of the subject, see "The Story of the Stick in all Ages and Lands." Translated and adapted from the French of Antony Real (Fernand Michel). New York: J. W. Bouton.

Stick-chim'ney. One made with sticks laid crosswise and plastered with clay inside and out. Common in the West with log-cabins.

Stick'er. (*Music.*) A rod connecting the far end of the key of an organ-manual with the lever by which the valve is opened, to allow the wind to pass from the chest to the appropriate reed or pipe of the organ.

Stick'ing. 1. (*Mining.*) A narrow vein of ore.

2. (*Carpentry.*) *Running* or *striking* a molding with a molding-plane.

Stick'ing-plas'ter. Two solutions are first made: one, an ounce of isinglass in eight ounces of hot water; and the other, of two drachms of gum benzoin in two ounces of rectified spirits. These solutions are to be strained and mixed. Several coats of this mixture kept fluid by a gentle heat are then to be applied with a camel's-hair brush to a piece of silk stretched on a frame, each coat being allowed to dry before the next is applied. A layer of a solution composed of one ounce of Chian turpentine in two ounces of tincture of benzoin is then to be applied to the other side of the silk and allowed to dry.

Stiff-bit. (*Harness.*) A bit without a joint, like a snaffle; or branches, like a curb-bit.

It is a stiff bar with rings at the end as cheek-bars

to keep the rings out of the horse's mouth. It is usually of round iron.

Hale's *driving-bit*, September 10, 1867, is of round iron, and is covered with a rubber tube.

Dawson's *bit*, September 24, 1867, has a bar of twisted wire with a soft rubber covering.

Arnold's *stiff-bit*, August 7, 1866, is tubular. Metallic straps are passed around the bridle-rings and are screwed into the ends of the bit.

Stiff'en-ing-gird'er. A truss girder which distributes the weight of the platform and load upon the suspension-chain and prevents undulations.

Sti'fler. (*Military Engineering.*) A small mine made for the purpose of interrupting the operations of the enemy's miners. A *camouflet*.

Sti'fle-shoe. (*Farriery.*) A horseshoe which has a curved bar beneath it, exposing a rounded surface to the ground, so as to give it an insecure foundation. It is placed on the foot of the sound leg, in order to induce the animal to throw the weight of the hind-quarters upon the foot of that leg which is *stifled*, that is, has a luxated or weak *stifle-joint*.

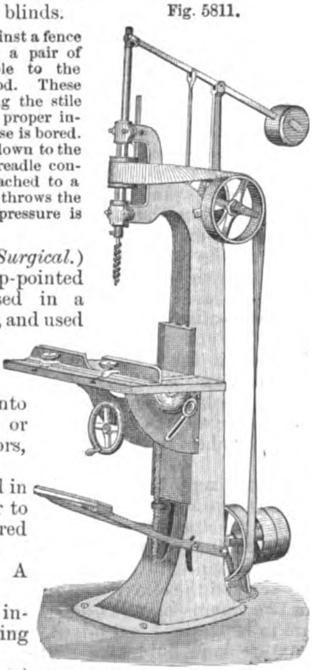
Stile. 1. One of the vertical bars in a wooden frame, as of a door or sash. In the former they receive the *rails* and *panels;* in the latter, the *rails* and *bars*. See DOOR; SASH.

2. A frame of bars and steps, which may be climbed by a pedestrian, but opposes the passage of horses and cattle.

3. The gnomon of a sun-dial.

Stile-bor'ing Ma-chine'. (*Wood-working.*) A machine for boring the circular mortises to receive the tenons on the end of slats for Venetian blinds.

Fig. 5811.



Stile-Boring Machine.

The stile is held against a fence on the feed-table by a pair of gage-wheels adjustable to the thickness of the wood. These turn freely, permitting the stile to be fed forward the proper interval after each mortise is bored. The auger is brought down to the work by pressing a treadle connected with a rod attached to a weighted lever, which throws the auger up when the pressure is withdrawn.

Sti-lette'. 1. (*Surgical.*) *a.* A small, sharp-pointed instrument inclosed in a cannula, or sheath, and used for making openings for the introduction of the said cannula into dropsical tissues or cavities, into tumors, etc.

b. A wire placed in a flexible catheter to give it the required form and rigidity.

2. (*Weapon.*) A dagger. *Stiletto.*

3. A pointed instrument for making eyelet-holes.

Still. In its most general sense, an apparatus by which the volatile matters which enter into the composition of certain substances are eliminated by means of heat, being usually recondensed in their own proper form. This includes apparatus for extracting tar, etc., from wood.

In a more restricted sense, it is applied to apparatus for extracting and condensing the more volatile parts of liquids, as alcohol from saccharine solutions which have undergone the vinous fermentation.

The volatilization and recondensation unchanged of such substances as mercury, sulphur, or zinc, is, properly speaking, *sublimation*.

Though the decomposition of sulphuret of mercury by distillation, or rather sublimation, is mentioned by Dioscorides, yet the first distillation of a fluid, that of fresh water from sea-water, is to be found in the commentary of Alexander of Aphrodisias in Caria, to Aristotle de Meteorol. Alexander lived under the reigns of Septimius Severus and Caracalla.

"Zosimus the Panopolitan" (about A. D. 400) "had described in former times the operation of distillation by which water may be purified; the Arabs called the apparatus for effecting it an *alembic*." In his treatise, the process is concealed in mythical language.

Djafar (Gebir), who lived toward the end of the eighth century, was the first to describe nitric acid and aqua regia. The former he obtained by distilling in a retort Cyprus vitriol, alum, and saltpeter. The latter made gold potable, and no doubt induced the worthy Arabian to think that he was on the eve of the discovery of the transmutation of metals.

To Rhazes, born A. D. 860, physician-in-chief to the great hospital at Bagdad, is due the credit of the discovery of *absolute* alcohol, which he obtained by distilling spirit of wine from quicklime. He also prepared sulphuric acid.

Achild Bechil obtained phosphorus by the distillation together of urine, clay, lime, and powdered charcoal.

"The preparation of nitric acid and aqua regia by Djafar (whose proper name was Abu-Mussah-Dschafar, and also known as Gebir) is more than 500 years anterior to Albertus Magnus and Raymond Lully, and almost 700 years anterior to the Erfurt monk, Basilius Valentinus. Nevertheless, the discovery of these dissolving acids, which constitutes an epoch in chemical knowledge, was long ascribed to the three last-named Europeans. Respecting the rules given by Rhazes, see Hofer, Hist. de la Chimie, I. 325. Although Alexander of Aphrodisias, properly speaking, only describes circumstantially distillation from sea-water, yet he also indicates that wine may also be distilled. This is the more remarkable, because Aristotle had put forward the erroneous opinion that in natural evaporation fresh water only rose from wine, as from the salt water of the seas.

"The Arabians are to be regarded as the proper founders of the *physical sciences*, in the sense which we are now accustomed to attach to the term." — HUMBOLDT.

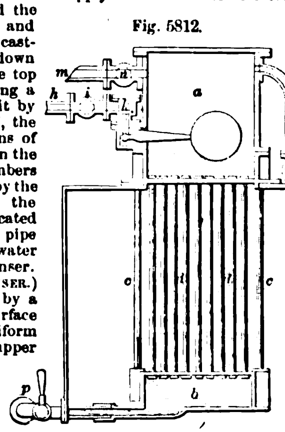
Europe unquestionably owes its knowledge of the art of distillation to the Arabs. Arnold di Villa Nova, 1318, practiced distilling spirits of wine. The use of wines and spirits being prohibited to the Mohammedans, alcoholic spirit was never common among them, and we find that long after its introduction into Europe it was regarded rather as a sovereign remedy, as its Latin name *aqua vitæ*, perpetuated in the French *eau de vie*, implies. It was originally derived from wine or the marc of grapes; the distillation from grain was of later origin.

Quiros distilled fresh from salt water on his ship on a considerable scale, and this has been frequently done since.

Perhaps the simplest apparatus for this purpose is that employed in the Polar expedition of Captain Phipps, in 1773, otherwise principally noted from the fact that Nelson, then a boy, served on one of the vessels. It consisted simply of a caldron having a spout, at the end of which a large swab or bunch of rope-yarns was suspended; this condensed the vapor free from salt, the water dripping into a vessel beneath. It is said, to have furnished a sufficient supply for the ship's company.

Hall's *sea-water still* for the supply of fresh water to steam-boilers, to make good the loss by the safety-valve and leakage, consists of a cast-iron vessel *a* bolted down over an aperture in the top of a boiler, and having a vessel *b* connected to it by rods *c c* and tubes *d d*, the latter forming a means of communication between the upper and lower chambers *a b*. Sea-water enters by the pipe *h* and stands in the still to the hight indicated in the illustration; the pipe proceeds from the cold-water chamber of the condenser. (See SURFACE-CONDENSER.) *k* is a valve governed by a float by which the surface of water is kept at a uniform level. From the upper part of the chamber *a*, a pipe *m* proceeds to the upper chamber of the SURFACE-CONDENSER (which see), and a stop-cock *n* gov-

Fig. 5812.



Sea-Water Still.

erns the passage. *p* is the blow-off cock by which the water is expelled when it has attained a given degree of saturation.

When the water in the boiler has sunk below the desired level, the engineer opens the cock *n* leading to the refrigerator of the condenser, and the steam in the chamber *a* rushes through the pipe *m* and reaches the condenser, where it is condensed and passed to the boiler along with the water resulting from the condensation of the steam from the cylinder. The partial vacuum in chamber *a* causes the water to boil rapidly, and the evolution of steam followed by its condensation and subsequent propulsion to the boiler by the action of the air-pump, restores the proper water-level in the boiler, which is observed by the engineer, and the cock *n* closed.

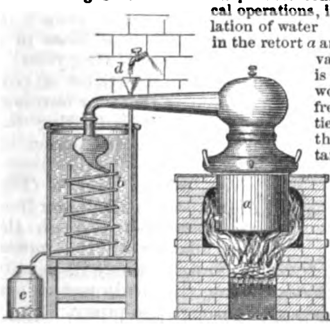
i is the stop-cock in the water-supply pipe.

When the salt water reaches the point of saturation, the cocks *n i* are shut, and the cock *p* opened; the latter connects with a discharge-pipe passing through the side of the vessel, and the water and sediment are driven out.

By means of this still, fresh water evaporated from sea-water is obtained to compensate for losses by leakage and escape. This still was employed upon the "Sirius," 320 horse-power, which crossed the Atlantic in 1838. The "Great Western" and "Sirius" were 19 years behind the steamer "Savannah," which crossed eastward in 1819. See STEAMBOAT.

The common still consists of a retort, or still proper, in which the substance is heated, and a condenser, called a worm, on account of its usually having a spiral shape. The retort is generally made in two parts; the *pan* or *copper*, to which heat is applied, and the *head*, which is removable. (See ALEMBIC.) It is made in some cases of earthenware, but more generally of copper, plain or electro-plated with silver; for some special purposes of platinum, and for others it may be of iron or glass.

Fig. 5813.



Fresh-Water Still.

Fig. 5813 is a simple form of still, adapted for common pharmaceutical operations, including the distillation of water. This being placed in the retort *a* and heat applied, the vapor passes over and is condensed in the worm *b*, the water freed from its impurities being received in the vessel *c*. The tank surrounding the worm is constantly supplied with cool water, which enters by the pipe *d*, having its outlet near the bottom, and is discharged near the top.

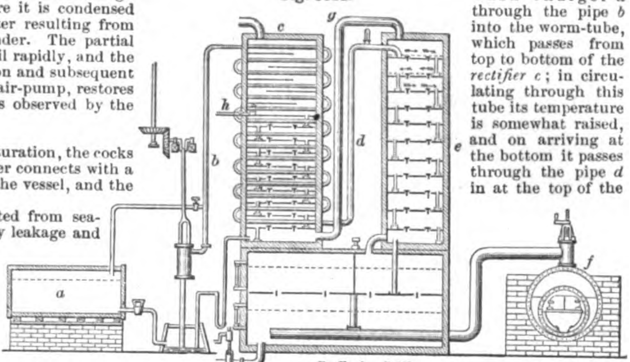
The mode of obtaining the attar of roses at Ghazepore on the Ganges is thus described by Hooker, the naturalist: —

"The rose-gardens surround the town: they are fields, with low bushes of the plant, grown in rows, red with blossoms in the morning, all of which are, however, plucked long before midday. The petals are put into clay stills, with twice their weight of water, and the produce, distilled over, exposed to the fresh air, for a night, in open vessels. The attar is skimmed from the exposed pans, and sells at £10 ($50) the rupee weight (silver coin worth nearly 50 cents). To make this weight twenty thousand flowers are required. The attar is frequently adulterated with sandalwood oil."

Continuous distillation was first carried out by Baglioli, and afterward much improved by Blumenthal and Derosne. See Muspratt, page 75, *et sequitur*. The process is now very generally adopted for distillates which are to be produced in large quantities, high and low wines, and the various grades of petroleum oils being procured from the mash or wine and from crude petroleum respectively at one operation. The forms of apparatus employed are very numerous, many being specially adapted for petroleum. See PETROLEUM-STILL.

In the manufacture of ardent spirits, the alcoholic liquor is obtained from the fermentation of a saccharine solution, derived generally from grain, potatoes, grapes, or sugar. The alcohol, being more volatile than water, passes over first, but with it a large proportion of water is always condensed. To separate this water and obtain spirit of the required strength, it is necessary to redistill the product or return it to the still, and proceed with the operation until the required strength is attained. Dorn's still, yet employed in Germany, was one of the earliest invented for this purpose. Of the improvements on this, Derosne's is generally used in France, while Coffey's (Fig 5814) is preferred in England. In this the saccharine solution, or *wash*, is pumped from the wash-charger *a* through the pipe *b* into the worm-tube, which passes from top to bottom of the *rectifier c*; in circulating through this tube its temperature is somewhat raised, and on arriving at the bottom it passes through the pipe *d* in at the top of the *analyzer e*. Here it falls successively from one to another of a series of shelves, perforated, and having valves for the entry of steam from the boiler *f*, by which they are heated. As the wash gradually descends in the analyzer, it becomes rapidly weaker, partly from condensation of the steam which passes into it, and partly from the loss of alcohol either evaporated or expelled by the steam, till when it arrives at the bottom it has parted with all its spirit. At the same time, the vapor as it rises through each shelf of the analyzer becomes richer in alcohol. On arriving at the top it passes through the pipe *g* in at the bottom of the rectifier; here it ascends in a similar way through the descending wash until it arrives at *h*, above which it merely circulates around the upper convolutions of the wash-pipe, the low temperature of which condenses the spirit, which, collecting on a shelf, flows off by a tube into the finished-spirit condenser, and is finally conveyed to the receiver.

Fig. 5814.



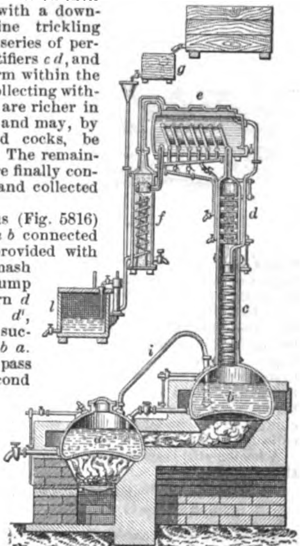
Coffey's Still.

In order to economize heat, the water-supply pipe of the boiler is of spiral form, and is immersed in a trough which receives the boiling-hot spent wash.

Cellier Blumenthal's apparatus, improved by Derosne (Fig. 5815), consists of two stills *a b*, a first rectifier *c*, a second rectifier *d*, a warmer and dephlegmator *e*, a condenser *f*, a regulator *g*, and a contrivance for regulating the flow of wine from the cistern above.

The stills *a b* are filled with wine, the first acting as a boiler; the low-wine vapors pass through the pipe *i* to the bottom of the still *b*, and the vapors from this on their upward course meet with a downward current of wine trickling through and among a series of perforated disks in the rectifiers *c d*, and are condensed in a worm within the fore-warmer *e*; those collecting within the first of the coils are richer in alcohol than the rest, and may, by appropriate pipes and cocks, be drawn off separately. The remaining alcoholic vapors are finally condensed in the worm *f* and collected in the cistern *l*.

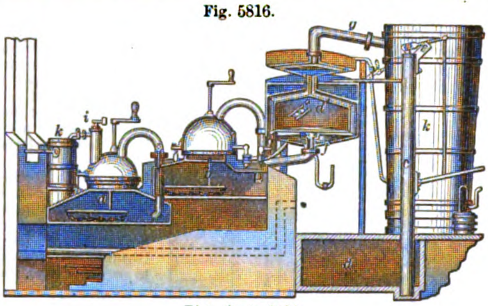
Fig. 5815.



Cellier Blumenthal's Still.

Pistorius's apparatus (Fig. 5816) consists of two stills *a b* connected by pipes, and each provided with mash-stirrers. The mash is transferred by the pump *c* from the mash-cistern *d* to the fore-warmer *d'*, whence it is conveyed successively to the stills *b a*. The alcoholic vapors pass from the first to the second still, and sometimes to a third, then entering the rectifier *e* above the mash fore-warmer, and in part being condensed in the low-wine cistern *f* beneath, finally pass by the pipe *g* into the condenser *h*. The pipe *i* is provided with an inwardly opening safety-valve, and connects with a small cistern *k*, from which samples, showing the progress of the operation, may be taken.

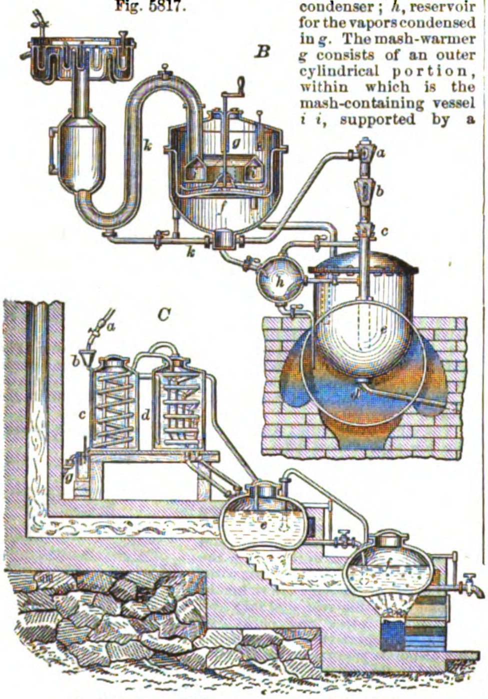
Fig. 5816.



Pistorius's Still.

Siemens's apparatus (*B*, Fig. 5817) comprises two mash-stills set in a boiler and capable of being alternately used by means of the three cocks *a b c*. *d* is the boiler; *e*, one of the mash-retorts; *f*, low-wine receiver; *g*, fore-warmer; *h*, reservoir in which the condensed water for boiler-feed is collected; *g*, dephlegmator, or water-condenser; *h*, reservoir for the vapors condensed in *g*. The mash-warmer *g* consists of an outer cylindrical portion, within which is the mash-containing vessel *i i*, supported by a flange and provided with a rotary stirrer: it is heated by vapors entering through the pipe *k*, which afterward pass into the lower cylinder of the dephlegmator.

Fig. 5817.



B, *Siemens's Still.* *C*, *Langier's Still.*

In Langier's apparatus *C*, the fluid to be distilled flows from the tube *a* into the funnel *b*, and thence into the vessel *c*, entering its lower part and serving to condense the alcoholic vapor. From thence it passes through another tube to the lower part of the vessel *d*, whence it is successively conducted to the upper and lower stills *e f*; the vaporized portions return through the stills and condensers in a reverse direction, undergoing a final condensation in the worm *c*, and the alcohol is collected in the receiver *g*.

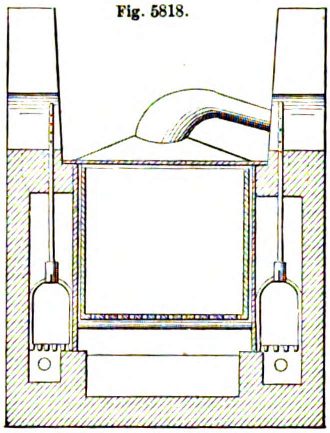
A leaden still is used for obtaining fluoric acid, from the distillation of

Fluoride of calcium	1 part.
Sulphuric acid	2 parts.

The result of the process is a vapor of hydrofluoric acid which is condensed in the worm, sulphate of lime remaining in the still.

The still or retort for distillation of sulphuric acid is made either of platinum or glass, according to the manner in which the process is conducted. See SULPHURIC-ACID APPARATUS.

Fig. 5818.



Still for distilling Pine Wood.

Fig. 5818 is a still for distilling tar from pine wood. The billets of wood are packed vertically in a box, which is then placed in the retort; the grate is vertically adjustable, to act first upon the wood and afterward upon the tar.

Still'age. A low stool to keep cloths off the floor of a bleachery.

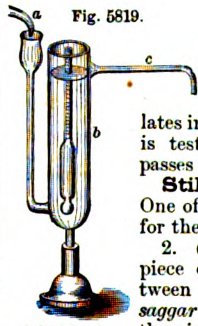
Still'ing. A stand for casks. A *stillion.*

Stil'lion. A stand for casks. The *rounds* or *cleansing vats* of a brewery stand on *stillions* in a trough which conveys away the overflowing yeast.

Stillions are also used to support articles of pottery in the drying kiln to prepare them for burning.

Still-watch'er. A device for indicating the progress of a distillation by the density of the liquid given over. Mohr's (Fig. 5819) receives the liquor from the condenser through the bent adapter *a*. It accumulates in the vessel *b*, where its density is tested by the hydrometer, and passes off through the pipe *c*.

Fig. 5819.



Still-Watcher.

Stilt. 1. (*Hydraulic Engineering.*) One of a set of piles forming the back for the sheet-piling of a *starling.*

2. (*Pottery.*) A little, pointed piece of pottery, used to place between pieces of biscuit ware in the *saggar* to prevent the adherence of the pieces.

3. (*Husbandry.*) A term sometimes applied to the handles of a plow; the word "handles" being confined to the upper end of the stilts, where they are grasped by the hands. The term "stilts," in this sense, is regarded by Webster as an English provincialism. They are usually termed handles in this country.

4. A stave with a foot support; a pair of them being used to raise a person above the ground in walking. In England and the United States stilts are but a sport or exercise, but in the Landes, a flat pasture-country of Southwestern France, the shepherds use them habitually.

Stink-ball. A nasty pyrotechnic, which makes a suffocating smoke and odor, to be thrown among working parties, or on an enemy's deck at close quarters. It is composed of pitch, rosin, niter, gunpowder, colophony, assafœtida, sulphur, etc. Used by the Chinese and Malay pirates.

Stink-pot. A vessel used by the Chinese and Malay pirates to throw on board a vessel to suffocate the crew.

Stink-trap. A device for preventing the passage of mephitic air and gases from the receiving openings of drains. See AIR-TRAP; STENCH-TRAP.

Stint. (*Mining.*) A given quantity of work to be performed.

Stip'ple. Another name for *chalk* engraving; so called because it consists of dots, and resembles chalk-drawings made upon rough paper.

Dots are made instead of lines, and these are closer, deeper, and larger, in accordance with the depth of color desired.

The chalk-drawings of Sir Thomas Lawrence were much admired, and the style became fashionable. This mode of engraving originated with Jacob Bylaert, of London, in 1769, and was practiced in France during the early part of last century, but did not arrive at the greatest excellence until early in the present century. It does not fall within the scope of this work to enumerate the masters in this style of the art of engraving, but the softness and beauty of its finish in representing flesh and statuary are very admirable. Bartolozzi is said to have brought it to perfection; more brilliancy and vigor have been attained by later engravers, but not more grace and softness. It is usual to form the basis by etching in the dots, but the beauty of finish, rotundity, and delicacy are the work of the graver.

They are made through a *ground* on the plate, and then *bit-in* by acid. Afterward they are modified, deepened, and enlarged by the action of a graver, whose *belly* is concave, so as to present the point more vertically to the face of the plate than usual in *line* engraving, where the belly is slightly convex.

The *ground* is a resinous mixture, which is spread smoothly upon the heated plate, and then allowed to cool. When this is removed by the etching-needle, the subsequent action of the acid makes little pits in the plate, which hold the ink when printing. See GROUND; ENGRAVING.

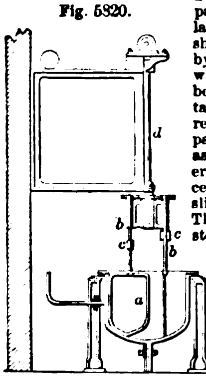
Stip'pling-ma-chine'. (*Metal-working.*) A machine or tool for giving a roughened or, as it is termed, *matted* surface to metal in order that the *dead* portions may form a foil to the more lustrous ones.

See patents 111,086, January 17, 1871; 126,408, May 7, 1872; 128,290, June 25, 1872.

Stir'rer. A mechanical device to keep a solution from settling.

The mechanical stirrer for color-pans in a calico-printing works consists of a brass rod bent into the form shown at *a*. Two of these are suspended in each pan by hooks from the shafts *b b*, collars *c c* slipping over the joints. The shafts *b b* have independent rotation by the spur-wheels meshing with a wheel on the shaft *d*, from which they both depend, and which is itself rotated by bevel gears above. The stirrers are thus revolved around the pan, and rotate around each other, so as to be brought in contact with every part of the color. When the process is finished, the collars *c c* may be slid up and the stirrers unhooked. The pans are supplied by pipes with steam and cold water.

Fig. 5820.



Stirrer.

Stir'ring-bud'dle. (*Mining.*) See BUDDLE.

Stir'rup. 1. (*Manege.*) A loop or ring suspended from the saddle for the foot of the rider.

Fig. 5821 shows several kinds of stirrups.

a is formed of a block of wood, through which the stirrup-leather is rove. *a'* is the block detached.

b has a pair of branches, which, if a rider be thrown and the foot catch in the stirrup, pull apart and release the foot *b'* is a spring which holds the parts in normal position, except when the strain occurs in case of accident.

c is also a safety-stirrup, having a pivoted foot-rest which throws the foot of a dismounted rider out of the stirrup.

d has a roller at the top and joints at the sides, to release the foot.

e has a guard to keep the foot from penetrating so far that it would be jammed in case of accident.

f is the Engle stirrup. It has a bent wooden frame, with arms united at top by a ferrule and stirrup-strap.

g shows the frame detached. *h* is the hood

The ancients mounted their horses in various ways: —

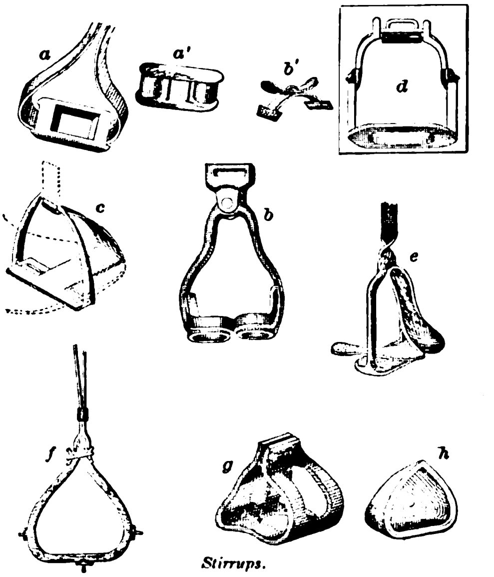
By vaulting.

By short ladders.

By teaching their horses to kneel.

By horse-blocks.

Fig. 5821.



Stirrups.

By grooms, who lifted them on.

By the hands or knees of their servants.

By a step or projecting-bar on their spears.

No traces of the stirrup are found in the old Greek and Latin writings, coins, or statues. The celebrated equestrian statues of Trajan and Antoninus are destitute of stirrups, the legs of the riders hanging down without any support whatever. Xenophon does not mention them in his work on horsemanship and the art of riding. See SADDLE.

Hippocrates and Galen speak of a disease among the Scythians occasioned by long and frequent riding, because the legs hang down without any support. There is no word in Greek or Latin, down to the sixth century, which signifies the stirrup or its use.

The first mention of the stirrup is in the work ascribed to the Emperor Mauritius, in the sixth century. He says, "The horseman must have at his side two iron *scalæ*." Leo VI., in his work on tactics, ninth century, uses the same word and describes the function of the stirrup. In the twelfth century they were common.

The Greek and Roman soldiers were trained to vault on to horseback, but in some cases mounted by a step on the spear which rested against the horse.

Stirrups were introduced into England by the Saxons. Stirrups and spurs appear on seals of the eleventh century.

The Japanese stirrups are of iron or *sappan* wood, very thick and heavy, not unlike the sole of a boot, and open on one side, so that the foot may be easily introduced or withdrawn. The stirrup-leathers are short, the rider's knees being much bent.

2. (*Machinery.*) A band or strap which is bent around one object and is secured to another by its tangs or branches.

Fig. 5822.

Stirrup.

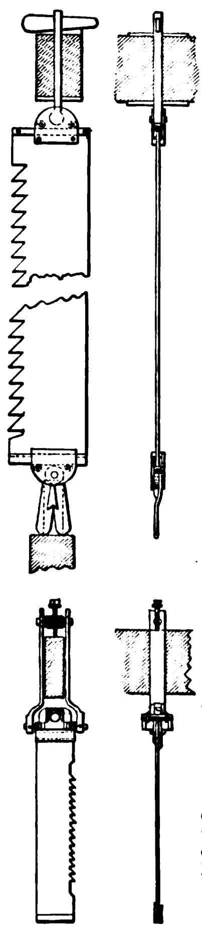
3. The iron loop or clevis by which the mill-saw is suspended from the *muley-head*, or in the sash. A *saw-buckle*. The example (Fig. 5823) shows two forms. The saw-blade may be held by a cotter or key which passes through a hole in the saw and above the bar from which it is suspended; or it may have cheek-pieces riveted to it, which afford hold for clamping devices.

4. (*Carpentry.*) *a.* A device for holding a rafter-post or strut to a tie. In wooden construction it consists of a wrought-iron loop secured by a through bolt to one piece and embracing the foot of the other. Fig. 5824 shows that employed for connecting a principal rafter and tie-beam. In iron framing the stirrup is usually wrought on the tie.

b. An iron strap to support a beam.

5. (*Nautical.*) A rope with an eye at the end for

Fig. 5823.

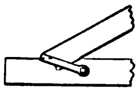


Stirrups for Mill-Saws.

supporting a foot-rope below its yard.

6. (*Shipbuilding.*) A plate which laps on each side of a vessel's dead-wood at the stem or stern, and bolts through all.

Fig. 5824.



Rafter-Stirrup.

Stir'rup-bar. (*Saddlery.*) The part of a saddle to which the stirrup-strap is attached. Some of the patented styles are called spring-bars.

Stir'rup-ir'on. (*Saddlery.*) The ring suspended from a saddle and in which a foot is placed.

Stir'rup-leath'er. (*Saddlery.*) The strap by which the stirrup is attached to the saddle.

Stir'rup-strap. A band by which a stirrup is suspended.

Stitch. A pass of a needle in sewing. The mode of making the stitch and the kind of stitch characterize the various kinds of sewing-machines. See SEWING-MACHINES, pages 2123, 2124, and Plate LVII.

The amount of thread taken by the different kinds of stitch is about as follows: —

Lock-stitch being	=	1
Chain-stitch is	=	1.8
Double-thread chain	=	2.5

Thread to the yard of average goods, depending on thickness of fabric: —

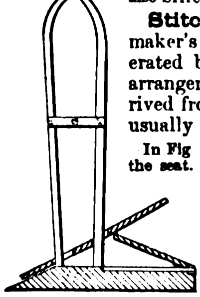
Lock-stitch........ 2.5 to 3 yards.
Chain-stitch....... 4.5 to 5.4 yards.
Double chain-stitch 6.25.

Stitch'ing. (*Bookbinding.*) Fastening the sheets of a pamphlet or book together by threads passed through holes simply *stabbed* through the pile. A cheap substitute for *sewing*.

Stitch'ing-clamp. A work-holder much used by saddlers and harness-makers, and by others stitching stiff material.

In Fig. 5825, the pivoted jaw is opened or closed by pressure on the respective ends of the toggle-treadle, which is pivoted to one leg, and hinged to a plate connecting it with the base-piece. See also STITCHING-HORSE.

Fig. 5825.



Stitching-Clamp.

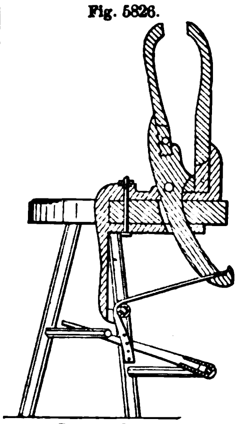
Stitch'ing-horse. A harness-maker's work-holder, having jaws operated by treadle and cord, or similar arrangement. The term *horse* is derived from the fact that the workman usually sits astride of the seat.

In Fig. 5826, the clamp-frame is bolted on the seat. The moving jaw runs beneath the seat, and is actuated by a strap passing over a sheave to a treadle.

In Fig. 5827, instead of securing the clamp rigidly to the frame, it is made vertically adjustable, to suit the varying stature of persons using it. The pin secures it at the required hight to plates depending from the seat.

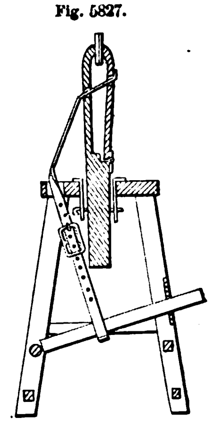
In Depp's stitching-horse, October 27, 1868, the weight of the workman closes the jaws, the seat being connected thereto by lever and cord.

Fig. 5826.



Sewing-Clamp.

Fig. 5827.

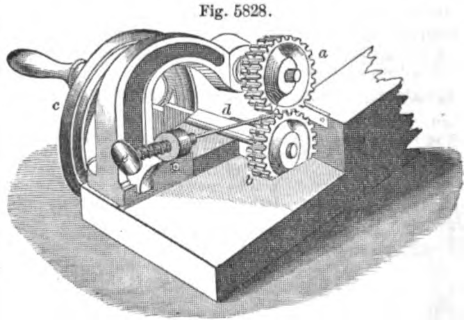


Stitching-Horse.

Stitch'ing-ma-chine'. The stitching-machine used for sewing together the ends of pieces of cotton cloth, for bleaching, washing, singeing, printing, dyeing, etc., was invented by Charles Morey, in England, in 1849.

It has two toothed wheels *a b*, gearing with each other and rotated by a handle on the fly-wheel *c*, the teeth of the wheels are cut away at the center, so as to form a continuous groove,

Fig. 5828.

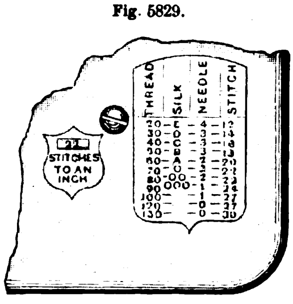


Stitching-Machine.

to which the point of the needle *d* is presented; this has an eye near its point, and is kept to its work by a spring. The cloth is crimped by passing through the rollers, and pushed forward against the needle, which carries the thread through the folds. When the ends of the two pieces have been joined in this way, the crimps are straightened out by pulling upon the edges. When a fresh thread is to be inserted, the needle is drawn back by the button *e* on the end of the holder. See SEWING-MACHINE, Figs. 4852, 4853.

Stitch-reg'u-la'tor. (*Sewing-machine.*) A device to determine the length of stitch according to the quality or thickness of goods, or for other cause. Some devices for this purpose are shown under SEWING-MACHINE. See Fig. 4867.

Fig. 5829.



Stitch-Regulator.

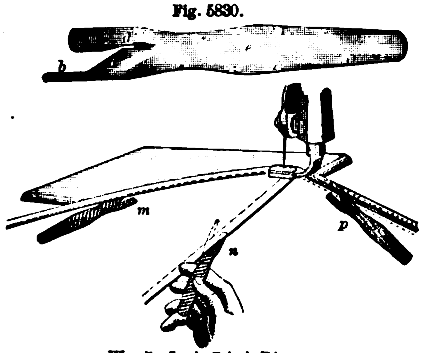
The Willcox and Gibbs machine has a table on its cloth-plate, showing the proper relation of size of thread or silk, size of needle, and length of stitch. The oscillating lever has a segment of a cylinder, attached on the periphery of which are the

various numbers from 12 to 30, representing those numbers of stitches to an inch. As the lever is adjusted, each of these numbers is exposed at an opening in the cloth-plate seen within the shield. The proper thread and appropriate needle being determined, the suitable stitch is indicated and the lever moved until the determined number is exposed at the opening in the plate.

Stitch-rip'per. An instrument for opening a seam by cutting the stitches.

That shown is Wood's stitch-ripper, which is a flat tool with a guide *b*, guard *e*, blade *a*, and eye *d*. The figure shows it in three positions *m n p*, and above is one of the instruments on a larger scale. The guide enters between the folds, so as to bring the blade across the line of stitching.

Fig. 5830.

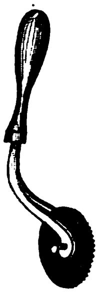


Wood's Lock-Stitch Ripper.

Stitch-wheel. (*Saddlery.*) A pricking-tool for marking out the site for a row of stitches, so as to render them uniform. The wheels are made with 8, 10, 12, or 14 points to the inch, and each fits in the same holder.

Called also *pricking-wheel*, the handle or carrier being called a *pricking-carriage*.

Fig. 5831.



Stitch-Wheel.

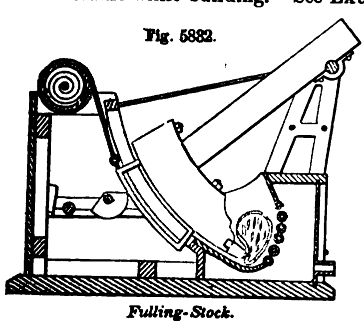
Stock. The term is applied to the principal piece, main frame, or handle of an implement or arm. That to which others are attached, or in which they are inserted, as, —

The barrel and lock to the *stock* of a fire-arm.
The trail to the *stock* of a gun-carriage.
The bit in the *stock* of a brace or a plane.
The shank in the *stock* of an anchor.
The anvil to its *stock* or pillar.
The screw-cutting die in its *stock*, or holder.
The irons to the *stock* of a plow.
The *beater* in a fulling-mill.
The wooden frame which supports the wheel and post of a spinning-wheel.
The *post* of an anchor.

1. (*Nautical.*) The cross-bar at the upper end of the shank of an anchor, which cants the anchor and turns a fluke down.

2. (*Shipbuilding.*) The frame which supports a vessel and its cradle while building. See LAUNCH.

Fig. 5832.



Fulling-Stock.

3. (*Building.*) Red and gray bricks used in party-colored brickwork.

4. (*Fulling.*) The beater of a fulling-mill.

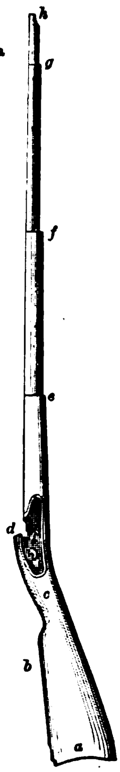
5. (*Husbandry.*) The part of a plow or other implement to which the *irons*, draft, and handles are attached.

6. That part of a fire-arm to which the barrel and lock are attached.

The stock of the United States service musket is made of well-seasoned black-walnut. The different parts are shown by their respective letters in the cut.

a, *butt*; the enlarged rear portion having a *cheek-piece* and *heel-plate*.
b, *comb*.
c, *handle*, *hand*, or *small*; its length and *bend* or *crook* determine the *fall* or *drop*.
d, head, having a *brass* side and *lock* side.
e, shoulder for lower band. At this point is the *thimble* for the ramrod.
f, shoulder for middle band.
g, shoulder for upper band.
h, shoulder and tenon for tip.
i, bed for lock.

Fig. 5833.



Gun-Stock.

7. (*Joinery.*) *a.* That arm of a bevel which is applied to the base or molding side; the *tongue* being applied to ascertain the angle of the meeting surface, or adjustable to test whether the proper bevel has been attained.

The *stock* forms a case for the *tongue*.

b. The *brace* which holds a bit for boring.

c. The block which holds the plane-bit.

8. (*Machinery.*) The handle which contains the screw-cutting die. See *f*, Fig. 4739.

9. Rags and material for making paper. Said also of other material used in business.

10. Lumber of regular market size, as distinguished from *dimension lumber*, which is sawn to specific sizes, to order; and may be beams, scantling, boards, etc. See STOCK-GANG.

The stock-saws of lumber regions are *gang-saws*, a number of saw-blades being arranged parallel in a gate and ripping the log into boards of the usual sizes. See SLABBING-GANG; STOCK-GANG.

11. Formerly, that part of the tally which the creditor took away as the evidence of the king's debt. (See ABACUS; TALLY.) The part retained in the Exchequer was called the *counter-foil*, or *counter-stock*.

Stock'ade. 1. (*Fortification.*) Stout timbers planted in the ground so as to touch each other, and loopholed for musketry.

In its most effective form it is 8 or 9 feet high, has a *ditch* in front, and a *banquette* in the rear.

2. (*Civil Engineering.*) A row of piles, or a series of rows with brushwood in the intervals, driven into a sea or river shore, to prevent the erosion of the banks. See GROIN; SEA-WALL; DIKE; RIVER-WALL; EMBANKMENT.

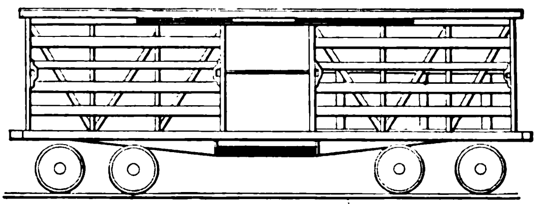
Stock and Die. The screw-cutting die in its holder. See *f*, Fig. 4739.

Stock-board. 1. (*Music.*) The board above the arrangement of register slides by which is regulated the access of air to the respective systems of pipes or reeds which form the *stops* of an organ. The *stock-board* is pierced with holes, in which set the lower ends or *feet* of the pipes.

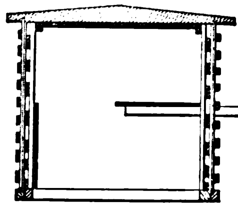
2. (*Brick-making.*) The board over which the brick-mold slips, and which forms the bottom of the latter while the brick is molding.

Stock-brush. For whitening and distempering. The tufts are on each side of a long head.

Fig. 5834.



Stock-car. A railway-car for carrying cattle, horses, sheep, hogs, etc. Some have but one deck, specially adapted for cattle and horses; others have two decks, for smaller stock.

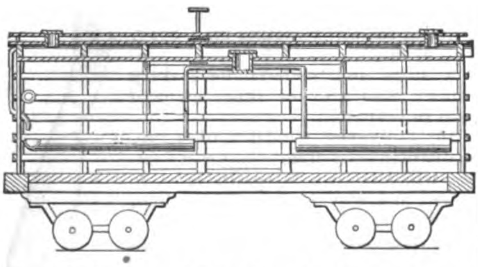


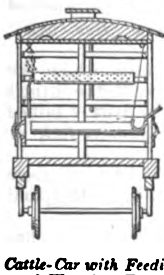
Convertible Stock-Car.

Fig. 5834 is an example of a convertible car. The deck consists of two sections, hinged respectively to the opposite sides of the car. When raised into a horizontal position they meet at the center, and are sustained by a beam or beams inserted in sockets beneath, to form a platform.

Fig. 5835 has an elevated reservoir and a pipe for leading water to the troughs to which the animals have access. Partitions in the reservoir prevent the surging of the water when the train is in motion. A feed-board is used in connection with the troughs, which latter are turned down out of the way when not in use.

Fig. 5835.





Cattle-Car with Feeding and Watering Trough.

Other cars have arrangements for converting the cattle-car into one for ordinary freight, the stalls folding away against the roof and sides, or unshipping, to be laid on the floor.

Stock'er's-saw. A small saw, specifically constructed for the use of the armorer or gun-stocker.

Stock-feed'er. A device for automatically supplying feed to stock in limited quantities at certain times. An ingenious but not commonly adopted device attached to some mangers.

Stock-fowl'er. A *blunderbuss.* A short gun with a large bore.

Stock-gang. An arrangement of saws in a gate, by which a log or balk is reduced to boards at one passage along the ways. The term *stock* is as distinguished from *slabbing ;* the latter reducing the log to a *balk* and to *slab-boards.* (See SLABBING-GANG.) The *stock-gang* makes *stock-lumber*, or regular market lumber, as distinguished from dimension lumber, which is sawn to a specific size, as ordered.

Stock-hole. (*Puddling.*) The opening through which the crude metal, or *stock*, is inserted. It is closed by a door which is counterweighted or raised by a lever.

Stock'ing. 1. A knit covering for the foot and leg.

2. (*Farriery.*) A device for remedying injuries to the tendons, varicose veins, etc., occurring in the lower part of a horse's leg. It has upright braces, to maintain a tension on the part; is perforated, to permit a certain degree of ventilation; and is secured by laces.

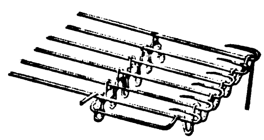
Fig. 5836.

Horse-Stocking.

Stock'ing-frame. The English term for a stocking-knitting machine. The term *frame* is there common, as *spinning-frame*, *warping-frame*, etc.

The stocking-frame was invented by William Lee, of Cambridge, England, 1589. In this machine the thread is first pushed down between each alternate needle of a set by a series of levers with plates, termed *jack-sinkers*, which are depressed successively by a sort of carriage on rollers, the *slur*, operated by the *slur*-bar. Another series of levers with plates, called *lead-sinkers*, is then depressed by a *sinker-bar*, forming a loop between each pair of needles. The loops are then pushed back out of the way of the sinkers and another set formed in the same way, which are then pushed into the open elastic hooks at the ends of the needles; the points of these hooks are then depressed by a *presser-bar*, holding the loops between them, and while thus closed the loops first made are drawn over them. A third set of loops is then formed and the second set drawn through them, and so on, the whole fabric being knit by forming successive series of loops and interlocking them with other loops in this way. See KNITTING-MACHINE.

Fig. 5837.



Stocking-Frame.

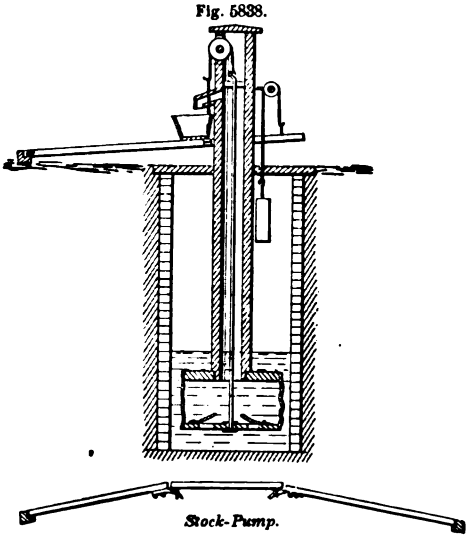
Stock'ing-ma-chine'. See STOCKING-FRAME; KNITTING-MACHINE.

Stock-lock. A lock adapted to be placed on an outer door. It is inclosed in an outer wooden case, and is opened and locked from the outside by the key, and bolted only inside.

Stock-pump. An arrangement in which the weight of the animals coming to drink is made to operate the pump.

In the example, the animal seeking water steps upon the pivoted platform at either side, and by depressing the same

Fig. 5838.



Stock-Pump.

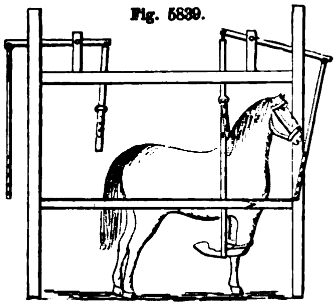
raises the pump-rod, together with the bottom board of the bellows. Water is thus forced into the tub from which animals drink. The flow continues until the bellows is depleted or the animal steps off the platform; in the latter case, the platform being raised by the weight, and the bottom board sinking so as to again fill the bellows.

Stocks. 1. (*Shipwrighting.*) A frame of blocks and shores on which a vessel is built. It declines down toward the water. It is usually a timber frame, which, as the building proceeds, assumes the form of a cradle. The *cradle* rests on ways, on which it eventually slides when the vessel is *launched.* The vessel is laterally supported by *shores;* the cradle is held by *struts* and *chocks.* In launching, the *shores* are removed, so that the vessel rests altogether in the *cradle;* the *ways* are greased or soaped; the *struts* are knocked away; the *chocks* knocked out, and the ship slides down the *ways* into the water, where the *cradle* becomes detached and floats away. See LAUNCH.

2. (*Farriery and Manege.*) A frame in which refractory animals are held for shoeing or veterinary purposes.

In the example, the straps are hitched to the limb of the animal and then attached to the frame above.

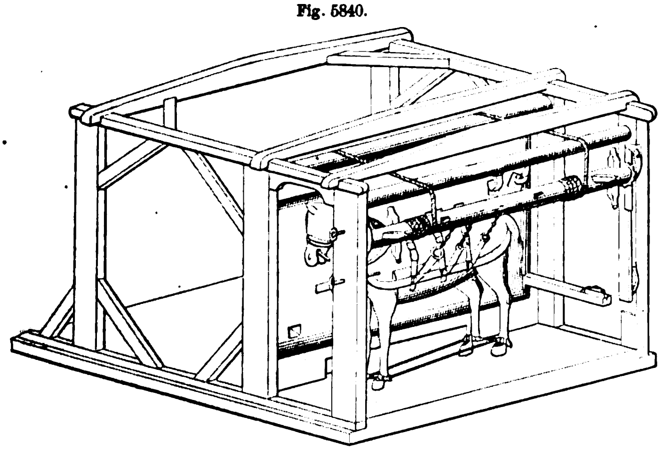
Fig. 5839.



Farrier's Stocks.

In Fig. 5840, the horse is strapped to a shutter, which is then lowered to a horizontal position, the feet being secured by bands. For treating broken limbs, the horse is slung by a belly-blanket and straps, which pass over a roller.

Fig. 5840.



Veterinary Stocks.

Stock-saw. A saw specifically used in gangs for sawing the staple market lumber. Those used in the Ottawa Mills, Chaudiere Falls, are No. 11 gage (Stub's wire-gage), and 4½ feet long.

Stock-shave. A form of shave used by block-makers.

Stock-shears. A shears used in shearing cloth.

Stock-stone. A rubbing-tool used by curriers on the grain side of leather to stretch and straighten it before currying.

Stock-tack'le. (*Nautical.*) A tackle applied to the stock of an anchor, when fished, to rouse it perpendicular.

Stock'trail. This term is applied to gun-carriages which have a *stock* between the cheeks supporting the gun, and the *trail* at the end of the stock rests upon the ground when the gun is in position for firing. When *limbered up,* a loop on the extremity of the trail is passed over the pintle-hook of the limber.

Field and siege gun-carriages are made in this way which have been in use since about 1830, having superseded the Gribeauval pattern (1765), in which the cheeks rested on the ground, and served the purposes of the stock in the stocktrail carriage.

Stock-yard. An inclosure for cattle on the way to or at market.

The Union Stock-yard at Chicago connects with ten different railways. It lies half an hour by rail from the center of the city, contains 345 acres of land, has a capacity for 21,000 head of cattle, 75,000 hogs, and 22,000 sheep, with stalls for 350 horses, — in all, for 118,350 animals. When all the ground is covered with pens, it will accommodate 210,000 head of cattle. The value of the live-stock received and forwarded during the year 1874 was nearly $ 80,000,000. There are now 100 acres of pens for cattle, all floored with three-inch plank, besides a great area in which the cattle stand on the ground. There are 50 miles of underdrainage, 17 miles of streets and alleys, all paved with wood; 5 miles of water-troughs; 15 miles of feed-troughs; 2,800 gates; 1,500 open pens; 800 covered sheds for hogs and sheep; 22,000,000 feet of lumber were used on these structures, and 500,000 pounds of nails; 17 miles of railroad track, with 60 switches and frogs, connect with the stock-yard, by a special track, every railway which runs into Chicago. The water is supplied by two artesian wells, one dug to the depth of 1,082 feet, and another to the depth of 1,190 feet. These send water into tanks 45 feet high, whence it is distributed in all the pens and sheds, there being a hydrant in each of these. The water can be shut off from any or all the divisions at pleasure, and, to guard against loss by fire, 14 fire-plugs are distributed over the grounds, and 1,000 feet of three-inch hose are at hand.

Stoke-hole. 1. (*Furnace.*) *a.* The place beneath the level of a boiler or oven where the furnace fire is fed and tended.

b. The hole in a furnace at which the poker, stirrer, rabble, paddle, or other tool is introduced to stir the charge, as in *puddling, calcining,* or *refining.*

2. (*Nautical.*) A scuttle in a steamer's deck for the admission of fuel.

Stom'ach-piece. (*Shipbuilding.*) A compass-timber fayed to the stem and keel. An *apron.*

Stom'ach-pump. (*Surgical.*) A suction and force pump for withdrawing the contents of the stomach in cases of poisoning, etc., and also used as an injector.

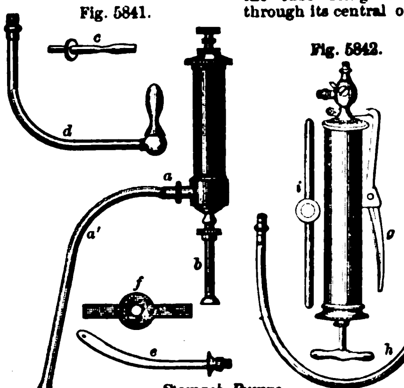
A flexible suction-pipe is attached to the lower opening *b*, and by working the handle the contents of the stomach are withdrawn and ejected through the branch *a*. A quantity of warm water should be first pumped into the stomach. *a' c d e* are tubes for making injections; *f* is a gag or mouth-piece, placed between the teeth, through which the flexible pipe is inserted.

Fig. 5842 is an improved form, having a lever *g* which operates a valve closing either the induction or eduction passages as the instrument may be required for use as a stomach-pump or enema-syringe.

In the former case the flexible tube *h* is screwed to the lower end, and in the latter to the side branch of the instrument.

The mouth-piece *i* is held between the jaws of the patient, the tube being introduced through its central opening.

Fig. 5841. Fig. 5842.



Stomach-Pumps.

Sto-mat'o-scope. (*Surgical.*) *a.* An instrument to keep the mouth open. A mouth-speculum.

b. An instrument invented by Professor Burns, of Breslau, to make critical examinations of the mouth and jaws.

A platinum spiral wire (inclosed in a boxwood cup, to prevent the transmission of heat), brought to a red heat by the passage of an electric current from two of Middeldorpe's elements, is placed in the mouth behind the teeth. The light reflected by a very small mirror is sufficiently intense to render the jaw transparent, so as to allow of the vessel proceeding to the roots of the teeth, the smallest specks of caries, etc., becoming visible. By reason of the transparency, even the labial coronary artery may in some subjects be seen at the level of the commissure, and its course followed.

Stone, Ar-ti-fi'cial. Many kinds of material have been used for the production of artificial stone. That which has been used on the largest scale, and, until a comparatively recent period, exclusively, was cemented by a calcareous substance, as Roman, or, still better, Portland cement, which hardens after being mixed with water. Ordinary *concrete* and Béton (which see) are of this class. *Terra-cotta*, employed for architectural ornaments, statuary, etc., is in the nature of a fine brick.

Cement stones have been largely employed for constructions in the sea, especially for harbor dams, breakwaters, and quay walling. We may cite the moles of Dover and Alderney, in England, of Port Vendre, Cette, La Ciotat, Marseilles, and Cherbourg in France, Carthagena in Spain, Pola in the Adriatic, of Algiers and Port Said in Africa, and Cape Henlopen at the mouth of the Delaware. For the breakwater at Cherbourg artificial stone blocks of 712 cubic feet each were immersed.

The fortifications before Copenhagen are made of a concrete of broken stone and hydraulic mortar. The sluice of Francis Joseph on the Danube, in Hungary, is built entirely of concrete. This work forms a reservoir, the bottom and the sides of which consist of one piece. Its length is 360 feet, and width 30 feet. Its construction, begun in 1854, was completed within 90 days, the work being pushed forward both night and day.

M. Coignet's béton aggloméré was used in the erection of the aqueduct of La Vanne, which now carries pure water from the river of La Vanne in the department of the Aube and of the Yonne to the city of Paris. The distance from Paris to La Vanne is over 135 miles. The section which traverses the forest of Fontainebleau comprises three miles of arches, some of them as much as 50 feet in hight, and 11 miles of tunnels, nearly all constructed of the material excavated on the spot. The monolithic test-arch at St. Denis, Paris, has a span of 196 feet, and an elevation of 19 feet. See Fig. 666.

Coignet's béton is compounded of sand 5, lime 1, and say .25 of hydraulic cement, mixed with an unusually small quantity of water, considerable mechanical exertion, followed by heavy ramming when the concrete is placed in the mold. The reduction of the volume by the ramming is 1.7 to 1, and the weight of a cubic foot becomes 140 pounds. The blocks soon harden in the air, and the resistance to compression is 5,000 pounds to the square inch. An ordinary mortar of the same material will be crushed by a pressure of 500 pounds. See Béton.

Recent French inventions in this line embrace: compacting the particles of which the stone is formed together by the action of a rammer upon successive layers while in a plastic state; forming monolithic buildings of a stone paste, the heating and ventilating flues and also the gas and water pipes being formed within the mass by the introduction of cores, which are afterward withdrawn; a modification of this for wharves, dams, abutment walls, etc., consists in making the walls hollow or honeycombed, and filling in the spaces or cells with earth or other cheap material; iron scraps may be incorporated with the material to bind it together, or a skeleton metallic framework may be imbedded in the walls while being made.

Orsi's *artificial lava* consists of

Stone or gravel	48
Pulverized chalk	32
Tar	16
Wax	1

The solid ingredients are added to the melted tar and wax, and the mixture poured into molds.

Metallic lava consists of

Ground flint	2
Broken marble	3
Resin	1

with small quantities of wax and coloring matter to imitate stone. It is used for tesselated pavements, the slabs being backed with concrete.

Artificial stone, having silica as the cementing material, was first introduced by Ransome.

He originally made this stone by boiling flints, under a pressure of about 60 pounds to the inch, in a solution of soda, to which lime was added to render it caustic. The soluble glass thus obtained, about the consistency of treacle, was mixed in the proportion of about 1 part to 10 of sand, 1 powdered flint, 1 clay; forming a paste which was molded into blocks, afterward dried in a steam-bath, to prevent the formation of a coating of silicate on the outside, which would prevent the escape of the vapor from the interior, and afterward burned in a kiln.

As at present made, the stone consists of clean sand and silicate of lime. It resists boiling, roasting, freezing, pickling in acids, fumigating with gases, soaking and freezing, heating to redness, and then plunging into ice-water.

Flints are digested by boiling in a caustic solution of soda under pressure, giving a silicate of soda (see Soluble Glass). This is added at the rate of one gallon to each bushel of well-dried sand, whose interstices are partially filled with dust of carbonate of lime. After careful mixing, the plastic mass is rammed and molded. The block is immersed in a solution of chloride of calcium. A reaction takes place; the silicate of soda and the chloride of calcium mutually decompose each other and reunite as silicate of lime and chloride of sodium, the former practically indestructible in air, the latter; common salt, perfectly deliquescent and removable by washing, although the stone, *after* the washing, is impermeable to water.

The tensile strength of this, by experiment, was, for a piece 2¼ bore, from 870 to 1,200 pounds. Crushing strength, cubes of 4 inches square, 44 to 48 tons. It has been used for grindstones with excellent effect. The same process forms the basis of several United States patents.

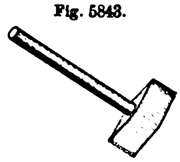
A "silicious varnish" (so called by the narrator) was used to give sharpness and permanency to the tri-lingual cruciform inscriptions on the scarp of a limestone mountain at Besitun, on the Tigris. It has been partially detached by the action of the elements during 23 centuries, and lies in scales at the foot of the precipice. It was cut by the orders of Darius Hytaspes, about 516 B. C., to celebrate a victory over the Magians. We are indebted to Rawlinson for the deciphering of the inscription.

In Sorel's process, natural magnesite — carbonate of magnesia — is first calcined, which reduces it to the oxide of magnesium. In this state it is mixed dry in the proper proportion, by weight, with the powdered marble, quartz, sand, or whatever material forms the basis of the stone. It is then wetted with bittern water, which converts the oxide of magnesium into the oxychloride. The now semi-plastic mixture is rammed into molds, where it speedily hardens, sufficiently to be taken out and laid on skids. In two hours' time the stone will resist rain, and in two weeks the stones may be used. See also Scagliola.

Patent 163,676, May 25, 1875, proposes to render artificial stone impervious to moisture and to prevent efflorescence thereon by mixing with the ordinary constituents in the process of manufacture soluble earthy or metallic sulphates in the form of a powder, and then a solution of the fatty acids.

McMurtrie and Chambers, May 25, 1875, treat the surface of the stone with a solution of earthy or metallic sulphates, and then with a solution of the fatty acids.

Fig. 5843.



Stone-Axe.

Stone-axe. An axe with two somewhat obtuse edges, used in spawling and hewing stone.

Fig. 5844.

Stone-Boat.

Stone-boat. A flat-bottomed sled for hauling

heavy stones for short distances, as in clearing them off the surface of tillable ground.

Planks are sawn from a log having a natural crook, and are united by cleats and bolts. The rise in front enables the stone-boat to ride over small obstacles. See also STONE-VESSEL.

Stone-bow. A cross-bow for shooting stones.

Stone-break'er. A machine for crushing or hammering stone. See ORE-CRUSHER; ORE-MILL.

Stone-break'er's Ham'mer. A hammer having a head of an oblately spheroidal form, with the handle in line of its axis.

Fig. 5845.

Stone-Breaker's Hammer.

Stone Bridge. Stone bridges appear to have originated among the Romans, who were the first to employ the arch on an extended scale. One with six arches, commenced by Augustus and finished by Tiberius, as its inscription indicates, still exists at Rimini. Others, some of which are yet in service, constructed by that remarkable people, are found, touched to a greater or less degree by the hand of time, in different parts of the former Roman Empire. Their stability, no doubt, was in great part due to the massive character of their foundations, as the builders, not employing the coffer-dam, used immense quantities of stone. (See COFFER-DAM.) Trajan (A. D. 105) built a magnificent bridge across the Danube at Gladova; it was 4,770 feet long, and consisted of 22 wooden arches, resting on 23 stone piers. It was destroyed by Hadrian, to prevent the incursions of the Dacians. See *b*, Fig. 924.

The first stone bridge in England was Bow Bridge, built in 1118.

The bridges of the Middle Ages also possess great durability, as those remaining attest. Their piers were founded on piles, the spaces between which were filled in with stone, necessitating, after a time, the driving of other piles outside these, until the substructure frequently, as in the case of Old London Bridge, seriously obstructed the water-way and impeded navigation.

This was built by Peter of Colechurch, 1176 - 1200, with houses on each side, connected by arches of timber, which crossed the roadway. This was burned in July, 1212, and 3,000 persons perished. It was restored in 1300; again partially burned in 1471, 1632, and 1725. The houses were pulled down in 1756, and finally the bridge itself, to make way for New London Bridge, constructed by the Rennies, opened in 1831. On this occasion the original piles, mostly of elm, were found to be but partially decayed, some portions being even used for making articles of utility or curiosity. The new bridge cost £506,000. The daily travel in 1859 was about 20,498 vehicles, carrying 60,836 persons, and 107,074 foot-passengers. This is the spot from which Macaulay's "New-Zealander" is supposed to view the ruins of the old city once known as London.

At a later, though comparatively recent period, the plan of sinking caissons (a kind of wooden case filled with stone) to form pier foundations, was introduced. The coffer-dam succeeded these, to be itself succeeded by the pneumatic caisson, a vast improvement on the unwieldy structure formerly used. See CAISSON.

In the construction of a stone bridge, when the coffer-dam or the pneumatic caisson is used, the river-bed is excavated until firm, hard bottom is reached, the abutments and piers of masonry are built up to the springing points of the arches, which are then turned upon the wooden centerings, which at once serve as a former for the arch and a support for its weight until the keystone course is laid. They thus perform a function of great importance, and great care and skill are required in their construction. When the masonry is complete, the centerings are removed, and the amount of subsidence, when this is done, affords a test of the skill of the architect and the faithfulness of the workmanship. If the piers have been solidly built on a firm foundation, and the arch-work accurately and strongly laid, there should be little or no subsidence. The bridge of Neuilly, by Perronet, settled two feet; Waterloo Bridge but five inches. The spandrels are afterward built up, the spaces between the arches filled in, the roadway and parapet completed. See ARCH; CENTERING; BRIDGE.

The following table embodies some facts in relation to a number of the most remarkable stone bridges in the world.

Name.	River.	Place.	Number of Arches.	Widest Arch. Span. Ft.	Span. In.	Rise. Ft.	Rise. In.	Curve.	Architect.	Date.
Washington Aqueduct	Cabin John Creek	Maryland	1	220	0	90	0	Segment	Meigs	1861

Fig. 5846.

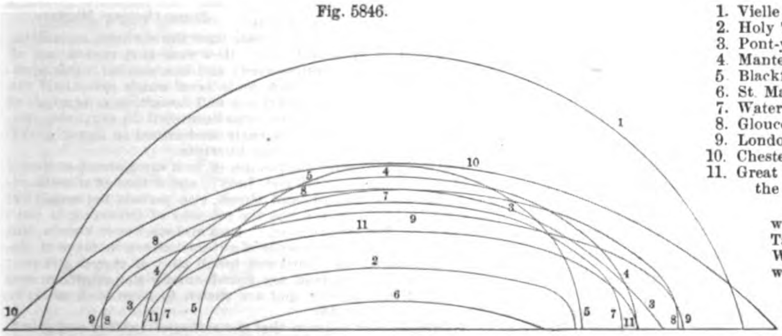

Diagram of European Bridges, showing the Forms and Proportions of Arches.

1. Vielle Brionde, over the Allier.
2. Holy Trinity, over the Arno.
3. Pont-y-Prydd, over the Taaf.
4. Mantes, over the Seine.
5. Blackfriars, over the Thames.
6. St. Mascence, over the Oise.
7. Waterloo, over the Thames.
8. Gloucester, over the Severn.
9. London, over the Thames.
10. Chester, over the Dee.
11. Great Western Railway, over the Thames at Maidenhead.

A remarkable bridge (3) was built in 1751 across the Taaf, in Glamorganshire, Wales, by William Edwards, a country mason. He had previously erected two bridges on the same spot: the first was carried away by a sudden and extraordinary flood;

the second by the crowding up of the crown of the arch by overloading its haunches before the parapet was finished. Peronnet could have taught him better, but Edwards was a skillful and persevering man, and ultimately succeeded.

The present bridge has a span of 140 feet, rise of 35 feet, and is a segment of a circle 175 feet in diameter. To avoid the subsidence of the haunches, Edwards made cylindrical openings through them, 3 in each haunch, the lower opening being 9 feet in diameter, the next 6, and the upper one 3 feet. The bridge is widest at its abutments by the amount of 1 foot 9 inches. The width of the bridge at the crown is 11 feet.

The longest bridge in England is that built by Bernard Abbot of Burton, over the Trent at Burton, in the twelfth century. It is all of squared freestone, is strong and lofty, is 1,545 feet in length, and consists of 34 arches.

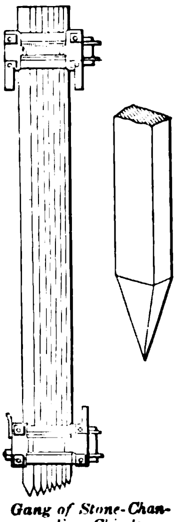
Most of the 339 bridges of Venice are of stone.

The "Union Arch" of the Washington Aqueduct over Cabin John Creek has 220 feet span, is 450 feet long, 20 feet 4 inches wide; the elevation of the roadway above the bed of the stream is 100 feet. Cost to May, 1872, $237,000.

Stone-cem'ent. A hard composition of the nature of mortar, which will harden and form a water-tight joint.

A mineral compound for uniting stone and resisting water is made by mixing 19 lbs. of sulphur with 42 lbs. of powdered glass or stone ware. Over a gentle heat the sulphur melts, and the whole is stirred till a homogeneous mass is obtained, when it may be run into molds. It melts at 248° Fah., and becomes hard as stone, and will resist boiling at 230° Fah. It may be re-formed indefinitely by remelting. See HYDRAULIC CEMENT, page 1144; MORTAR, *b*, pages 1477, 1478; and other compositions under various sub-heads: *Alabaster*, *Granite*, *Hydraulic*, *Marble*, *Mastic*, *Mortar*, *Slate*, *Stone*, article CEMENT, pages 507, 508. See also ARTIFICIAL STONE, where a number of compositions are cited which form good mortars and cements.

Fig. 5847.



Gang of Stone-Channeling Chisels.

Stone-chan'nel-ing Ma-chine'. A machine for cutting gains or grooves in stone, usually in the quarry, but also applicable to dividing large blocks.

The gang of chisels is operated by steam, and moves automatically on a track over the rock to be channeled.

Fig. 5847 shows the gang of chisels, and also, on an enlarged scale, one of the points.

Fig. 5848 shows the machine with its gang of chisels in place. A gang of cutters is applied on each side of the frame of the machine, outside the track on which it moves, in such a manner that the cutters may be inclined at any angle. There are devices for feeding the machine up to its work at any desired degree of speed, for stopping and starting the machine, for moving the machine without operating the cutters, and also for elevating and supporting the gangs of cutters when detached from their working-beams. See also Fig. 3054.

Stone-crush'er. A mill for grinding stone or ore. See ORE-CRUSHER; ORE-MILL.

Fig. 5848.

Stone-Channeling Machine.

Hitchcock's quartz-crusher (Fig. 5849) is on the principle of the Chilian mill, but has three wheels instead of two, traveling around in an annular trough. At the top of the frame is a hopper for receiving rock or other heavy material, to give

Fig. 5849.

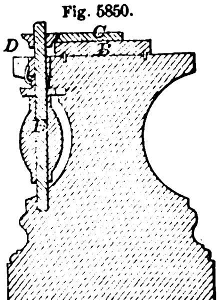
Hitchcock's Quartz-Crusher.

increased weight to the machine. The rotative power is applied outside of the machine instead of at its center, as has always been the case in mills of this class, adding greatly to the crushing force, which may be developed by the application of an equal power.

Stone-cut'ter. A machine for working a face on a stone or ashlar; in other words, a machine for *shaping* stone. It differs from the *stone-dresser*, which may be said to begin its duty after the surface is fairly flattened, or brought approximately to shape. The duty of the *stone-polisher* then commences, being to polish the fair surface left by the *stone-dresser* or *grinder*. The operations are successive, and some machines may be adapted to several, according to the character of the tool employed, or the relative coarseness or fineness of the abradant. In point of mechanical construction, the distinction cannot always be maintained between the stone DRESSERS, GRINDERS, PLANERS, and POLISHERS (which see). See also figures on pages 1391, 1392.

Fig. 5850 is a machine for cutting the molding edge of mantels, tablets, etc. The cutter *D* has the converse of the molding required, and revolves with its vertical shaft *E* operating upon the edge of the slab *C*, which moves with its sliding bed *B*.

Fig. 5850.



Stone-Cutting Machine.

Fig. 5851 is for circular and other curved work. The adjustable spindle, carrying the cutting-tool, is arranged so as to operate on any part of the top or sides of the stone. A pointer is attached to the slide which carries the spindle, and a grooved pattern to the rotating portion of the table, by which the movement of the tool is directed. See also Fig. 3055.

The earliest buildings of stone to which we can assign a date are the pyramids of Ghizeh.

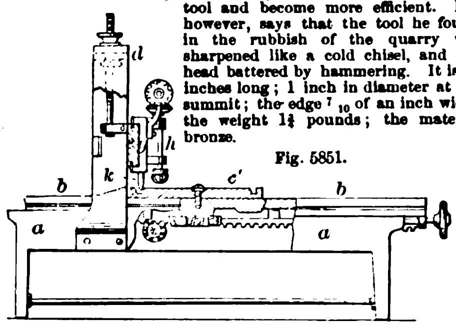
Few of the memorials of bygone ages have excited more surprise or given rise to more debate than the obelisks, monoliths, and colossi of ancient Egypt. How were they carved out of the mountain; how transported; and how erected? Our predecessors of 18 centuries since, an interval which spans half the time separating us from Osertasen and Joseph, were as much at fault as we; and Herodotus, who flourished 23 centuries ago, says that the art was apparently understood in Egypt 10,000 years ago as well as at the time he wrote.

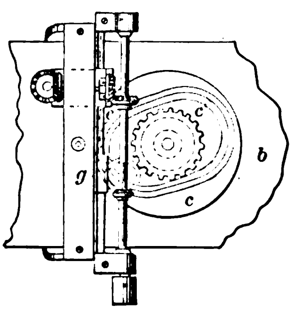
The early indications of the use of iron are glanced at under that caption in this work (see IRON); and a cluster of authorities, Egyptian, Syrian, and Greek, cite periods between 1350 and 1537 B. C.; but how was the colossus of Osymandyas cut? (2100 B. C. LENGLET, USHER) Iron and steel were known, but the inference and the balance of authorities are in favor of the more general use of a hard and tough alloy of copper and tin; bronze tools of this kind are found among the clippings and rubbish of the quarries, and are shown to have been used by the masons of that day.

Wilkinson is of opinion that the action of cutting and grinding the faces and making the ornaments in relief or intaglio was with emery; for which purpose a softer metal than steel

would answer better, as the emery would imbed itself in the tool and become more efficient. He, however, says that the tool he found in the rubbish of the quarry was sharpened like a cold chisel, and the head battered by hammering. It is 9½ inches long; 1 inch in diameter at the summit; the edge 7/10 of an inch wide; the weight 1¾ pounds; the material bronze.

Fig. 5851.

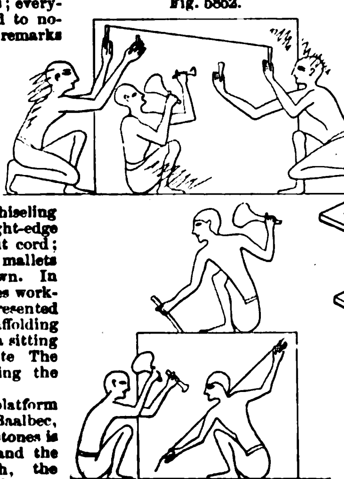




Stone-Cutting Machine.

The obelisks transported from the quarries of Syene, at the first cataracts, to Thebes and Heliopolis, vary from 70 to 93 feet in length. Wilkinson calculates the largest monolithic obelisk in Egypt, that at Karnak, at 297 tons. This was brought 138 miles, from its quarry to its site, and those at Heliopolis were transported over 800 miles. The statues of Amunoph III. are 47 feet in hight, and each made of a single stone, transported from its native quarry. That of Remeses II., when entire, weighed over 887 tons, and was brought from E'Sooan to Thebes, 138 miles. The pedestal of Peter the Great's statue in St. Petersburg is estimated to weigh 1,200 tons. Herodotus describes a block of stone brought from Elephantine to Saïs by Amasis. The exterior dimensions, as stated by him, and, converted into our terms, are 31½ feet × 22 feet × 12 feet. Its interior measured 28¼ × 18 × 7½ feet. Herodotus gives the dimensions of another which would figure out 5,000 tons; everybody feels bound to notice it, but the remarks are always given with a reserve, and often with a ?

Fig. 5852.

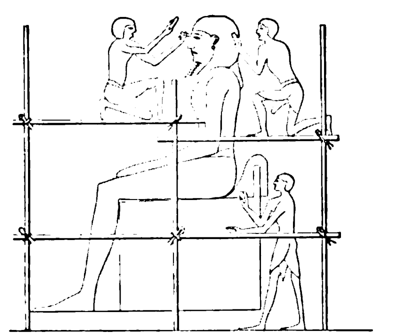


Egyptian Masons.

The annexed representation from paintings at Thebes illustrate the operations of leveling, squaring, and chiseling stone. The straight-edge seems to be a taut cord; the chisels and mallets much like our own. In a tomb at Thebes workmen are represented mounted on scaffolding and working at a sitting Colossus of granite. The men are polishing the figure.

In the large platform of the temple of Baalbec, the first tier of stones is 12¼ feet thick, and the same in width, the length being much greater. In the next tier are three stones, respectively 64 feet, 63 feet 8 inches, and 63 feet long: the hight about 13 feet, and the width no less. One of the same class lies at the quarry, about a mile distant; it is 14 by 17 feet, and 69 feet long. These stones are fitted so that a knife-blade cannot be thrust between. Drs. Robinson and Thompson carefully measured these monsters. See page 1404.

Fig. 5853.



Egyptian Sculptors.

Stone-dress'ing Ma-chine'. A machine for reducing to shape or working the surface of the stone ready for the final operations of grinding and polishing.

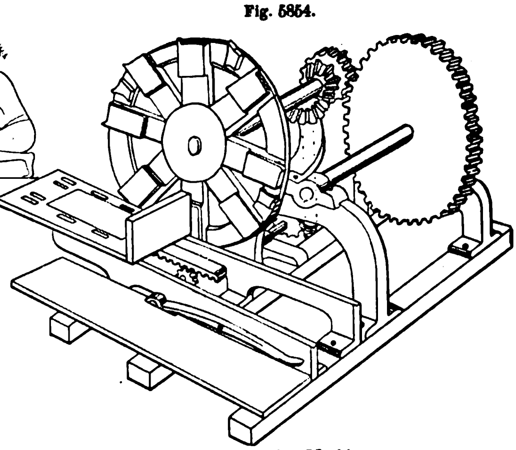
In Fig. 5854, the cutters are attached to a rotating-wheel, and act upon the face of the stone, which rests upon a traversing-table, and is fed along to the cutters by gearing from the main driving-shaft.

In another machine, a frame travels over the stone, being carried on wheels with rubber tires, and may be moved by a hand-crank, which is connected to either the moving or dressing devices. The cutters are clamped at the lower end of a rod, which has adjustable springs to limit its action, and is raised by radial revolving arms, which engage a lever that comes in contact with its tappet.

A machine for working moldings, figures, or ornamental devices upon stone is shown in Fig 5855. A circular tool carrying a number of diamond points is employed. This is journaled vertically in a pivoted frame, admitting a movement of translation in any desired direction, and has rapid rotation by pulleys and belting. The work, with the model or pattern, is clamped upon a table beneath, which may be raised or lowered, and held at any hight, and the tool is, by means of handles, elevated or depressed, as required, to suit the inequalities of the work, while a jet of water is conveyed to the point where it is acting.

Fig. 5856 is a machine for facing grindstones. The carriage slides on horizontal ways, carrying a bar of iron at right angles to its path of movement, the alternating movements and feeding being effected by bevel gears and a screw. The turning of the crank causes the tool to traverse from right to left across the periphery of the stone, and *vice versa*. The carriage is advanced by a sliding tubular shaft.

Fig. 5854.



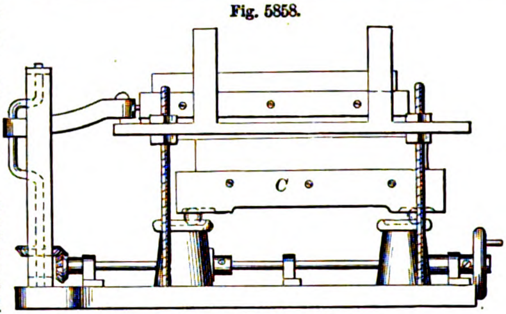
Stone-Cutting Machine.

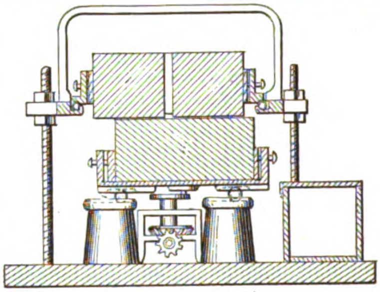
In Fig. 5857, the cutter-wheel is placed in a case which only

allows a segment to protrude, and excludes grit. The traverse sliding surfaces and the long journal-bearings are also encased. The rests of the journal are adjustable toward and from the stone, while the traverse is effected by rack and pinion.

In Fig. 5858, the bed *C* is supported upon friction rollers, and has a rotary reciprocating motion beneath the stones above, which are secured in a frame which has a longitudinal reciprocation.

Fig. 5858.



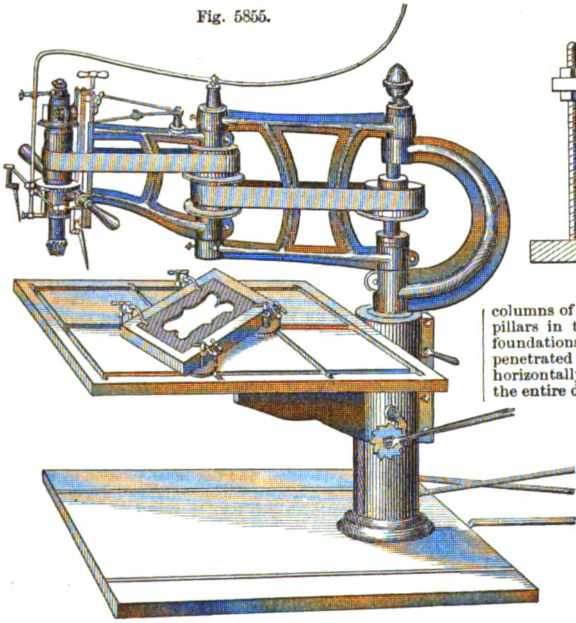


Stone-Facing Machine.

Stone-drill′ing Ma-chine. A machine for drilling holes in stone.

Fig. 5859 shows a hand-machine with one drill. The frame has adjustment on the crank-shaft as a center, and is held in position by the side plates, which have trunnion bearings for the shaft and curved slots as guide-ways for the feet of the frame. The drill-rod is raised by anti-friction rollers upon studs projecting from the fly-wheels; and is adjustable by a screw-sleeve, which is turned upon it by a hand-wheel. The anti-friction rollers act upon the connecting-bars, each of which is pivoted at one end to the sleeve, and at the other end has a cross-pin sliding in the horizontal slot of a fixed frame.

Fig. 5855.



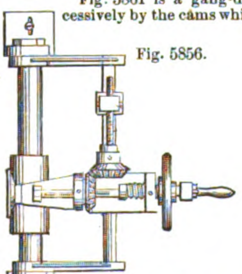
Gear Stone-Dressing Machine.

The application of steam to stone-drilling has worked a revolution in these machines, as in other departments of work.

The drill is now usually placed on the end of the piston-rod, which is reciprocated by steam or compressed air, as in Fig. 5860. See Rock-drill, pages 1956-1958. See also Diamond-drill, page 697.

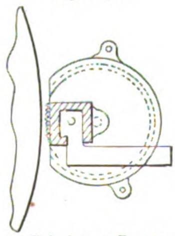
Fig. 5861 is a gang-drill. The drills are raised successively by the cams which are set spirally on the rotary-shaft. On a lower bar are a series of water-cans, whose contents trickle through a spout to the drill-bars. When not in use or moving, a supporting plate is slipped beneath each drill-bar.

Fig. 5856.



Machine for Facing Grindstones.

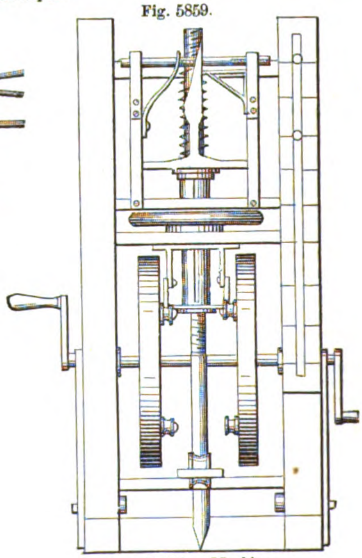
Fig. 5857.



Grindstone-Dresser.

The American Diamond Rock-Boring Company, of Providence, lately finished the job of taking a 24-inch core out of the columns of the State Capitol at Columbus, Ohio, the immense pillars in their solid state being considered too heavy for the foundations. By the use of this annular drill strata can be penetrated 800 to 1,000 feet through solid rock, vertically or horizontally, and perfect samples of ore or mineral taken out the entire depth.

Fig. 5859.



Stone-Drilling Machine.

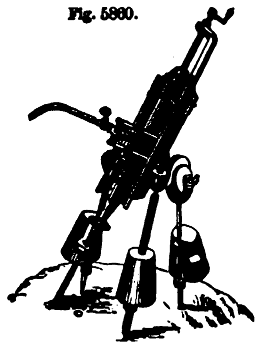
Stone Fou-gasse′. (*Military Engineering.*) A mine covered with stones.

Stone-gath′er-er. A machine for picking up loose surface stones in fields.

Fig. 5862 has a rectangular frame mounted on rollers near the front end of the frame. At about the center of the frame is a cross-bar, having journals which have their bearings in the side pieces of the frame. Curved teeth are secured to this cross-bar, and run upon the ground for the purpose of gathering the stones. When the teeth are loaded, they are thrown back by means of a lever, and the stones deposited upon a platform in the rear.

Fig. 5863 has a revolving toothed cylinder and an endless apron, connected with a stone-receiving box suspended from a mounted frame and provided with a hinged tail-board and hinged bottom, with fastening operated from the driver's seat.

Fig. 5860.

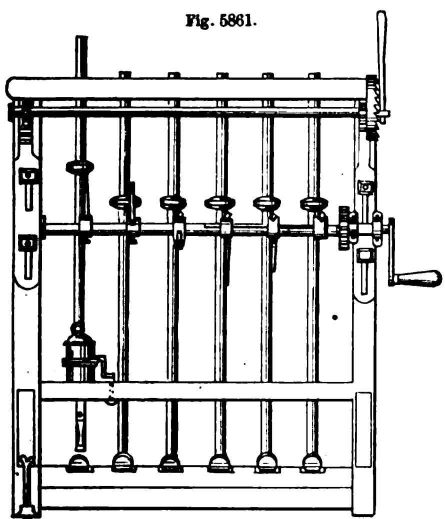


Steam Stone-Drill.

Stone-grind'ing Ma-chine'. One in which the action is due to an abradant or mutual attrition, usually with sand or other grit between the two surfaces. Only distinguishable from the stone-polishing machine by the greater fineness of the abradant used in the latter, and the smoother quality of the resulting surface.

Fig. 5864 is a hand-machine which has a horizontal disk, which, with its holder and standard, is pushed about over the surface of the stone. The hollow standard has a chamber in which

Fig. 5861.

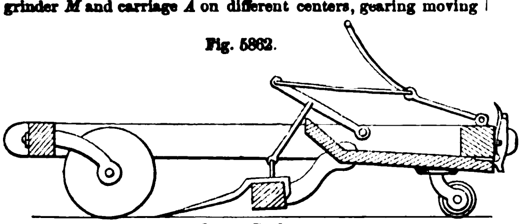


Stone Gang-Drill.

is a beveled pinion. In the standard is a shaft having a universal joint at its lower end for connecting with a rubbing disk or a circular saw. The machine is pushed over the face of the stone as the work progresses, the operator turning the crank with one hand.

In Fig. 5865 an eccentric motion is obtained by placing the grinder *M* and carriage *A* on different centers, gearing moving

Fig. 5862.



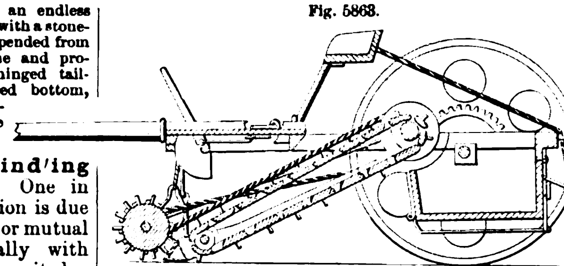
Stone-Gatherer.

the carriage along longitudinally, so as to expose different portions of the length of the stone to the action of the rubber *M*.

In Fig. 5866, the upper and lower stones are made to dress each other by a system of gearing by which the upper stones receive a rotary and the lower one a longitudinal movement.

The details of the invention have reference to the arrangement for adjusting the stones to be dressed so as to hold them steadily in the proper relative position to ensure a perfectly plane surface; the method of supplying sand and water; a peculiarly shaped scroll-grinder; a self-adjusting frame, and manner of raising and lowering the same at will; and an arrangement for relieving the grinders of all weight in excess of that required for grinding purposes.

Fig. 5863.

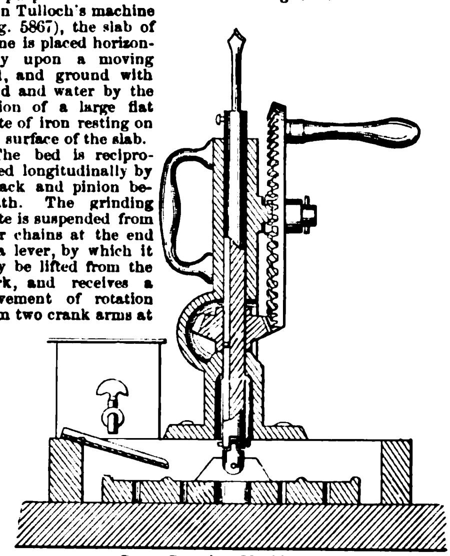


Stone-Gatherer.

In Tulloch's machine (Fig. 5867), the slab of stone is placed horizontally upon a moving bed, and ground with sand and water by the action of a large flat plate of iron resting on the surface of the slab.

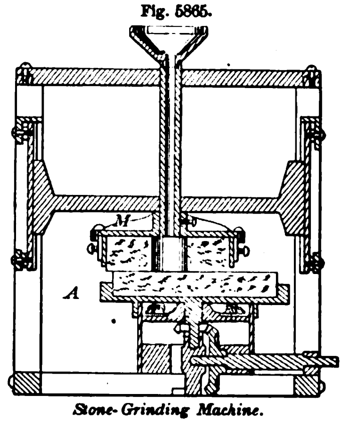
The bed is reciprocated longitudinally by a rack and pinion beneath. The grinding plate is suspended from four chains at the end of a lever, by which it may be lifted from the work, and receives a movement of rotation from two crank arms at the lower extremities of two shafts rotated in opposite directions by spur gears at their upper ends engaging with an intermediate wheel. This, combined with the reciprocating motion of the bed, causes different parts of the two surfaces to be brought in contact at every instant, and ensures the equal grinding of the stone. See also Fig. 3056.

Fig. 5864.



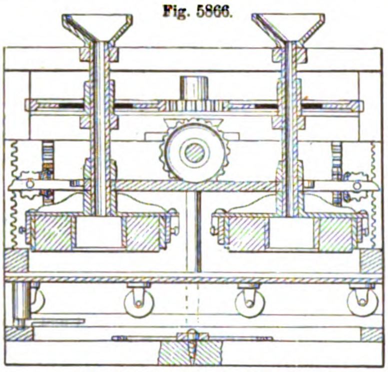
Stone-Scouring Machine.

Fig. 5865.



Stone-Grinding Machine.

Fig. 5866.



Machine for Grinding Stone.

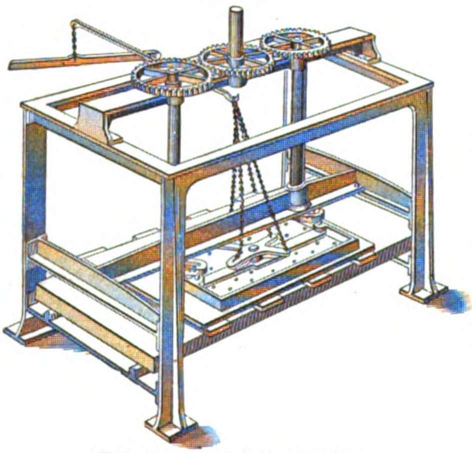
Stone-ham'mer. A chipping hammer used by stone-masons in rough-dressing stone. See STONE-AXE.

The *acisculis* or stone-hammer of the Romans had a rounding head, like an adze (*ascia*); a square face and pointed *peen*.

Stone Har-mon'i-con. A musical instrument consisting of a number of bars or slabs of stone, supported on strips, bundles of straw, or what not, and played like the *dulcimer*. See page 760; see also LAPIDEON, pages 1253, 1254.

Among the ancient musical instruments of the Chinese is the *pien king*, which is an assortment of sixteen stones arranged on strings in two series of eight each, one above the other, and each giving out, when struck successively, a system of sounds employed by the ancient Chinese in their music. The size and shape of these stones have been very carefully determined by

Fig. 5867.



Tulloch's Stone-Grinding Machine.

them after a minute analysis of the sounds peculiar to each one. In order to render the sound graver, the thickness of the stone is diminished to the right amount, and to render it more acute, something is cut off from the length. The stones thus arranged remind one in effect of a series of steel bars, as exhibited in acoustic apparatus to illustrate the fact that vibrations above a certain pitch are inaudible to the human ear. Frequent endeavors have been made to decide what kind of stones are employed in the fabrication of the *pien king*, since they were customarily paid as tribute-money more than two thousand years before Christ by certain provinces of China. Certain authors have thought that they recognized in them a kind of black marble, and the editor of the works of Father Amiote asserts that the *king* or musical stone constructed in France with the black marble of Flanders was quite as sonorous as those of China. Lately a discovery was made at Kendal, in England, of some musical stones, which, when struck with a piece of iron or another stone, gave out sounds of very different pitch, and with eight of which it would be possible to attain a very distinct octave. See also XYLOPHONE; STICCATO.

Stone'head. (*Mining.*) The rock immediately below the alluvial deposit.

Stone-mill. A machine for breaking or crushing stone. See STONE-CRUSHER; ORE-CRUSHER.

A machine for facing stone. See STONE-CUTTER; STONE-GRINDER; etc.

Stone-mold'ing Ma-chine'. A machine employed for working moldings in stone. Its general construction is that of one form of stone-saw, except that the frame carrying the revolving grinders may be adjusted by a screw beneath, to adjust it to the thickness of the slab being worked.

The grinders *a b c* (Fig. 5868) are turned from solid cylinders of cast-iron to the desired shapes. Each has a central hole fitted to the axis of the driving-pulley, and is secured thereto by

Fig. 5868.

Stone-Molding Machine.

a key or a side-screw. The grinder is made to revolve, so as to cut upward toward the surface, and is kept constantly supplied with moist sand. Moldings on the edges of narrow slips are sometimes wrought in pairs, the two pieces being cemented together at their sides, as shown at *c*. See STONE-CUTTER; STONE-PLANING MACHINE. See also Fig. 3055.

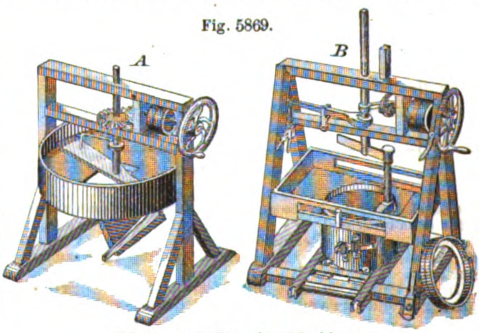
Stone Pipe. Stone pipes have been made by annular drills, being made in concentric nests. The water-pipes of the Flavian amphitheater were hewn from stone blocks.

What are now usually known as *stone* pipes are made of concrete or some other form of artificial stone.

Stone-pipe Ma-chine'.

Fig. 5869 illustrates a stone-pipe machine. It has a rotary-mixer *A* and tamping-machine *B* employed in making artificial

Fig. 5869.



Mixing and Tamping Machines.

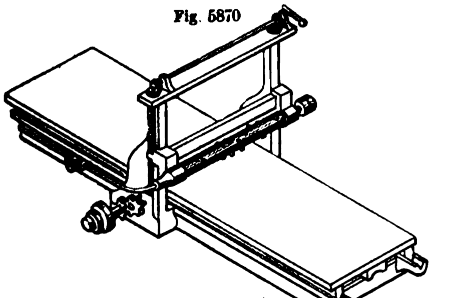
stone pipe. The cement and sand are incorporated together in the former and transferred to a two-part circular mold, having a core, at the lower part of the latter. As each layer of the mixture is placed in the latter, it is compacted by blows from a rammer carried by an arm on a vertical rod, which has a rotary motion and is gradually lifted as the formation of the pipe progresses.

Stone-plan'ing Ma-chine'. A machine in which the surface of a stone slab or block is cut or dressed by tools which act upon it while the stone passes beneath it on a reciprocating bed.

Fig. 5870 has a series of cutters arranged upon a hollow revolving cylinder, which latter is provided with small perforations, opening near each cutter, and also with a stuffing-box and pipe, through which hot or cold water, or steam, may be conducted to the stone, which traverses on a table beneath, in the manner of a planing-machine.

In Fig. 5871, the cutting or dressing wheel has slits across its

Fig. 5870

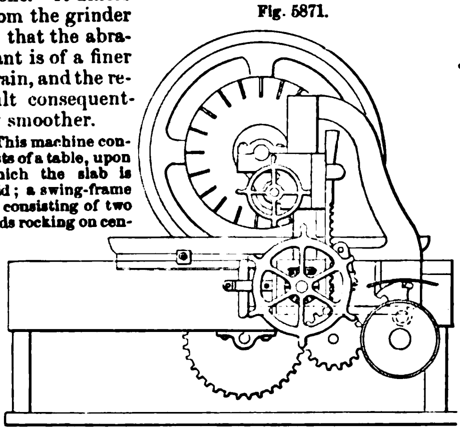


Stone-Planing Machine.

periphery to hold sand, which acts as a cutter upon the stones dogged to the bed which traverses beneath.

Stone-pol'ish-ing Ma-chine'. A machine for giving the final dressing and gloss to the surface of stone. It differs from the grinder in that the abradant is of a finer grain, and the result consequently smoother.

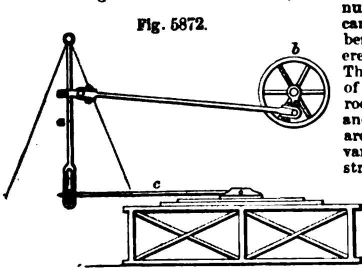
Fig. 5871.



Stone-Cutting Machine.

This machine consists of a table, upon which the slab is laid; a swing-frame *a*, consisting of two rods rocking on centers above, and operated by a rod connected to a crank on the fly-wheel *b*. At the lower end of the swing-frame is a horizontal bar extending the width of the table, and having attached a number of rods *c*, carrying flat rubbers of wood covered with felt. The attachments of the connecting-rods to the crank and rocking-frame are adjustable, to vary the length of stroke. See also page 1393.

Fig. 5872.



Stone-Polishing Machine.

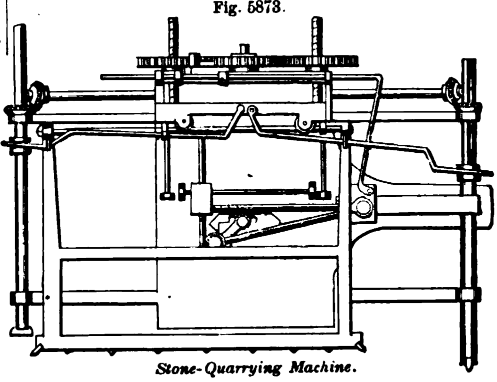
Perhaps the most perfectly polished piece of architecture in the world is the Taj, on the west bank of the Jumna, about 8 miles from Agra. The buildings of the Taj are erected on a platform about 20 feet high, and occupy a space of about 350 feet square. They consist of the tomb itself, which is an octagon, surmounted by an egg-shaped dome of about 70 feet in circumference, and of four minarets, about 150 feet high, which shoot up like columns of light into the blue sky. One peculiar feature is its perfect purity, for all portions of the Taj — the platform, the minarets, the building proper — are of pure white marble. The only exception is the beautiful ornamented work, of an exquisite flower pattern, which wreathes the doors and wanders toward the dome, — one huge mosaic of inlaid stones of different colors.

The screen of the tombs is divided into several compartments and panels; it sweeps around marble cenotaphs that lie within it, and represent the real tombs seen in the vault beneath. It is of purest marble, so pierced and carved as to look like a high fence of exquisite lace-work, but is really far more refined and beautiful; for everywhere along those panels are wreaths of flowers composed of lampis, lazuli, jasper, heliotrope, chalcedony, carnelian, etc., so that to make one of the hundreds of these bouquets a hundred stones are required. The Florence mosaic work does not surpass it.

The father of the builder of the Taj, Jehanghir, was the first ruler in India who received an ambassador from England, Sir Thomas Roe, in the reign of James I. Jehanghir married a famous beauty, Niher-ul-Nissa, the widow of Sher Afgan, who four years previously, had been assassinated by this same Jehanghir. Her name was changed first into Noor Mahal, "the light of the harem," — celebrated by Moore in his "Lalla Rookh," — and afterward to Noor Jehan, "the light of the world." Jehanghir, it may be mentioned, had *impaled* eight hundred of the race of Timour, who were in his way to the throne.

Shah Jehan succeeded him, having murdered his own brother in order to do so. He married Arzumund Banoo, the niece of the "light of the harem," the daughter of her brother. She was a good wife, and brought to her husband several children, among whom was Aurungzebe, who was the last ruler of the united empire of the great Akbar, his grandfather. After 20 years of married life, and burying his wife in the Taj, Shah

Fig. 5873.



Stone-Quarrying Machine.

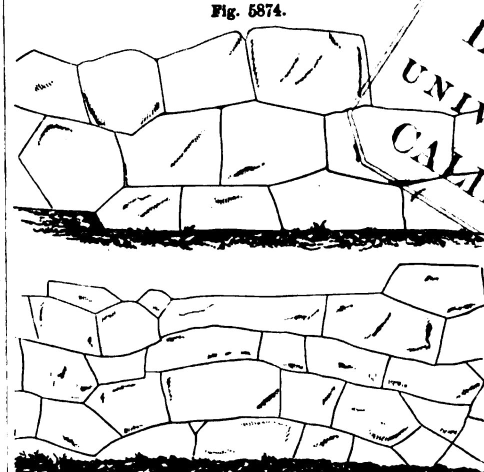
Jehan became a miserable debauchee. He was buried beside Arzumund Banoo, beneath the marble dome.

The cost of the Taj was upward of three millions of pounds sterling. Thousands of workmen were engaged upon it for years.

Stone, Pres-er-va'tion of. A process or composition for facing stone or impregnating it, to prevent its destruction by atmospheric influences.

Szerelmey's plan is to saturate with a silicate and apply asphaltum varnish. It has been adopted on the new Parliament Houses of London.

Fig. 5874.



Cyclopean Masonry.

Ransome's is to saturate with silicate of soda and then with chloride of calcium. The chemical reaction produces insoluble silicate of lime, and chloride of sodium which washes out.

Hibble's plan is to paint with a compound of ground lime, turpentine, flaxseed oil, silicate of lead, and burnt copperas.

Davies proposes sulphur and flaxseed oil.

Barff and Sullivan: treatment with alumina, carbonate of zinc, and silicate of potash.

Hardwicke: potash, alum, fish-oil, and flaxseed oil.

Quarm: oil.

Bernays: fluo-silicic acid, washed with alkaline solution.

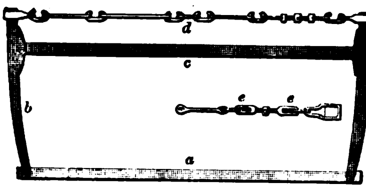
Rust and Mossop: solution of caustic barytes, washed with fluo-silicic acid.

Gros: a paint of wax 10, oil 30, litharge 1, heated to 212° Fah.

Spiller: superphosphate of lime, followed by ammonia (for magnesian limestone).

Crookes: fuller's earth in a dilute solution of hydrofluoric acid.

Fig. 5875.



Stone-Saw.

Stone-quar'ry-ing Ma-chine'. A machine for channeling stone in the quarry, making vertical cuts and grooves, which will enable it to be split off in layers.

Fig. 5873 has a reciprocating saw, armed with diamond points, so formed as to cut from the terminal holes formed by the drills, both saw and drills operating simultaneously. See STONE-CHANNELING MACHINE.

Stone-saw. Sesorthus was called Asclepias by the Egyptians, on account of his medicinal skill. The Greeks derived the name and attributes of their Æsculapius from him. According to Manetho, Sesorthus introduced the art of building with hewn stone. Heavy masonry, previous to his time, is presumed to have been Cyclopean; that is, the heavy blocks were fitted together by adapting to each other in the wall such faces as they already possessed.

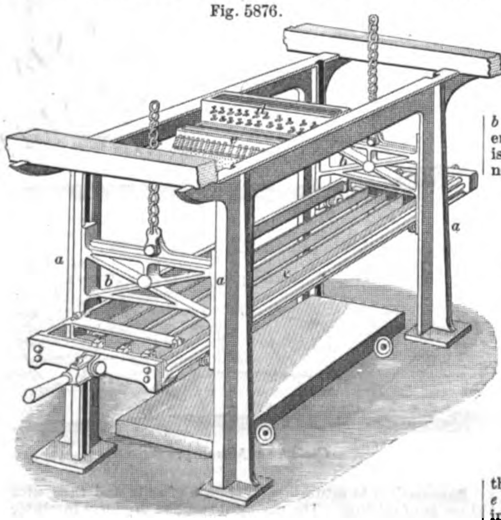
After Sesorthus, if indeed we make this exception, the Phœnicians are entitled to the credit of the use of the stone-saw, for these skillful navigators and mechanics erected the temple of Solomon of stone sawed within and without. This was in advance of the instances which we find described by classic authors.

Pliny informs us that he knew of no building faced with marble of greater antiquity than the palace of Mausolus, king of Caria, described by Vitruvius. This was erected 350 B. C. According to one authority, Crassus was the first Roman who embellished his house with marble, about 90 B. C., but it soon afterward became common, and several of the palaces of the Cæsars were made of it. Cornelius Nepos states that Mamurra (at a little later date) was the first to use marble in this way. Artemisia of Caria antedates both of them several hundred years.

In the time of Henry I. the choir of Canterbury Cathedral was paved with marble. In the sixteenth century marble became common in English architecture.

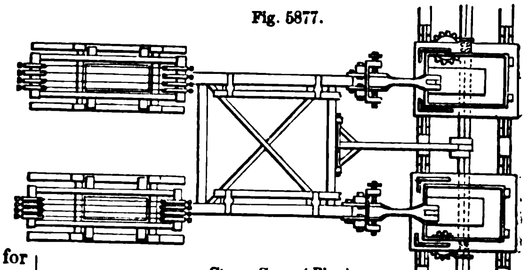
Pliny gives an account of cutting marble with the saw, and states the different kinds of sand used; "for it is the sand," says he, "that does the work, and not the saw." The blocks were cut from the marble quarries of Paros by means of saws. Such is indicated by the sharpness of the edges.

Fig. 5876.



Tulloch's Stone-Saw.

Fig. 5877.



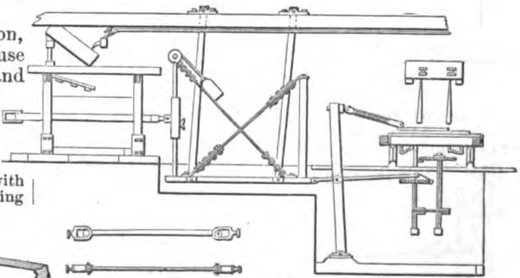
Stone-Saws (Plan).

The first account of staining marble to imitate the variegated varieties is by Kircher. The ancients admired the white, and regarded the veins as a detriment.

Oliver Evans of Philadelphia, in 1803, had a double-acting high-pressure steam-engine at work grinding plaster and sawing stone. He drove with it "twelve saws in heavy frames, sawing at the rate of one hundred feet of marble in twelve hours."

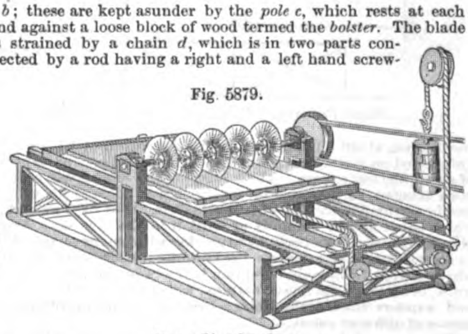
The common stone-saw (Fig. 5875) has a blade *a* of soft iron, $\frac{1}{8}$ to $\frac{1}{6}$ of an inch thick, having a hole at each end for the reception of pins, which fit into notches at the ends of the *heads* *b b*; these are kept asunder by the *pole c*, which rests at each end against a loose block of wood termed the *bolster*. The blade is strained by a chain *d*, which is in two parts connected by a rod having a right and a left hand screw-thread cut upon it, which enter the hollow screws in the nuts *e e*. The screw has holes, into which a lever may be inserted in order to tighten the chain.

Fig. 5878.



Stone-Saws (Elevation).

Fig. 5879.

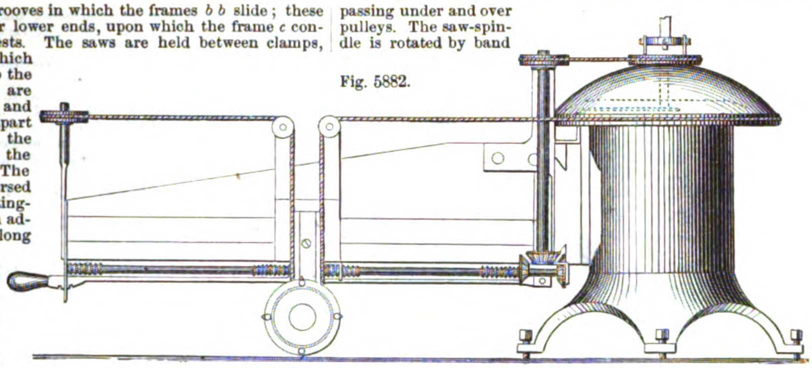


Stone Circular-Saw.

Tulloch's stone-saw (English) has a framework of iron; the

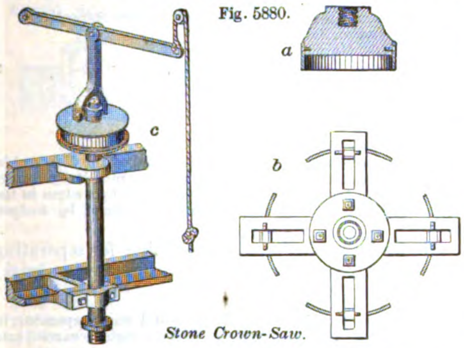
uprights *a a* have grooves in which the frames *b b* slide; these carry rollers at their lower ends, upon which the frame *c* containing the saws rests. The saws are held between clamps, having hooks, by which they are attached to the frame *b*; they are strained by wedges, and kept equidistantly apart by iron blocks of the exact thickness of the slabs to be sawn. The saw-frame is traversed by a jointed connecting-rod, attached by an adjustable loop to a long vibrating pendulum kept in motion by a pair of connecting-rods, one above the other, leading from two cranks driven by the engine.

Fig. 5882.



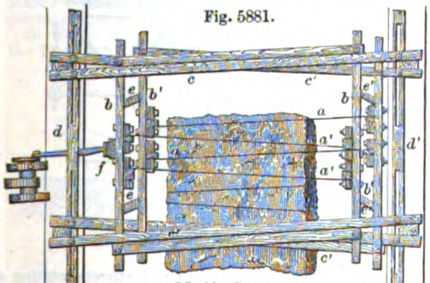
The frames *b b* are suspended by chains, and are counterpoised, they and the saw-frames having sufficient preponderance to descend as the cutting proceeds. The trough *d* contains water, which flows through a number of apertures into the sand-box *e*, where it is conducted through curved channels conveying the sand to openings, whence it may drop into the kerfs made by the saws.

Fig. 5880.



Stone Crown-Saw.

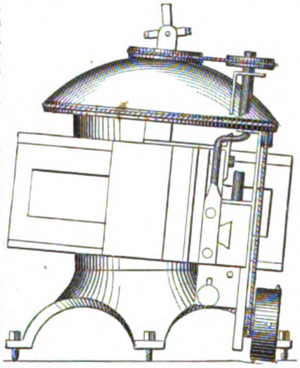
Fig. 5881.



Marble-Saw.

In Figs. 5877, 5878, the saws are arranged in gangs, being adjustable as to distance according to the thickness of slabs required. Each saw is strained between stirrups at the respective ends, attached to the frame, which is suspended by rods in such a manner as to admit of a free horizontal reciprocation. The saw-frame is attached to a cast-iron box, which is movable upon a vertical post, from whence it receives its reciprocating motion. Two sets of saws are shown in the illustration, moved by means of a crank through the intervention of a swinging frame. To the same frame are attached two polishing-blocks, which reciprocate upon the tables, to which is imparted a motion in a direction at right angles to the former. This prevents the *worker* from wearing the marble into grooves. The saws are guided between vertical posts, and receive sand and water from a reservoir and apron above.

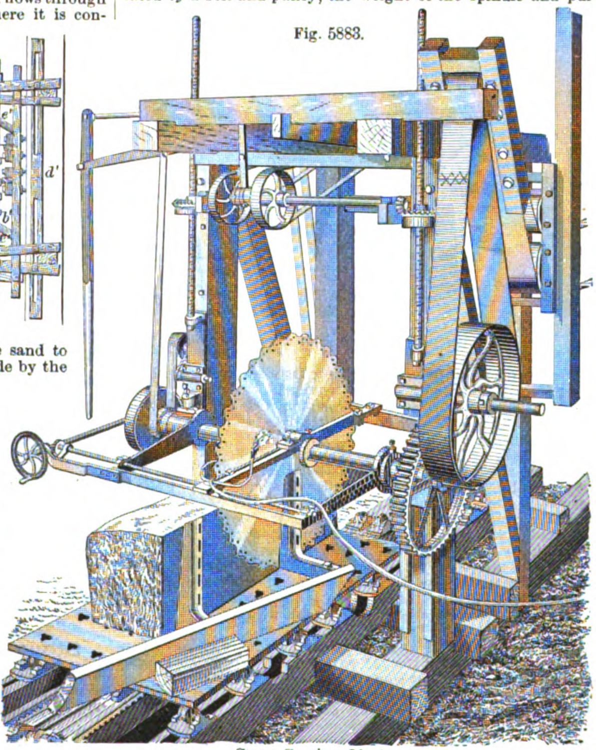
Fig. 5879 shows a gang of circular stone-saws mounted on a bench having rails, upon which a carriage is traversed by a weight and cord passing under and over pulleys. The saw-spindle is rotated by band and pulley in such a direction that the saws may have an upward cut, acting against the end of the stone as it is pressed against them by the forward movement of the carriage.



Gilmore's Millstone Saw-Drill.

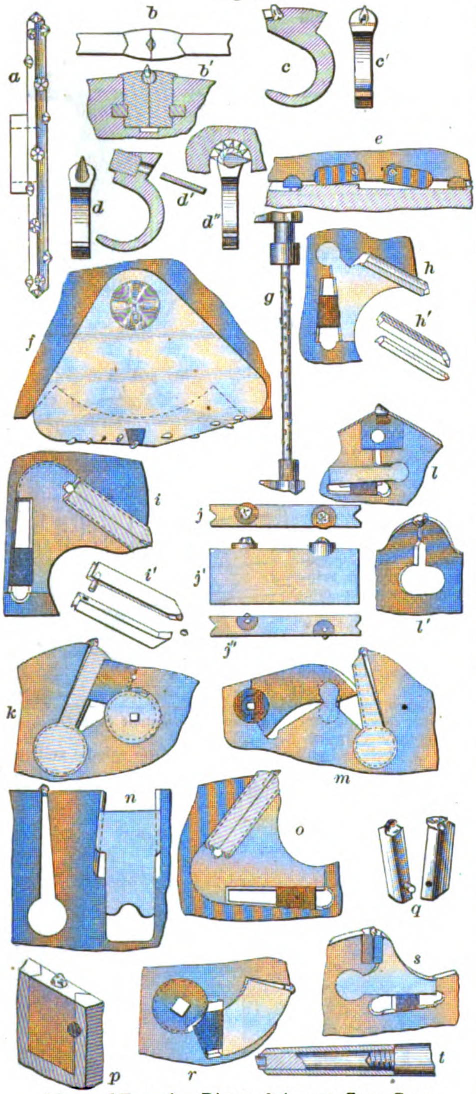
For circular work, such as the tops of circular tables, disks for bosses or ornaments, lamp-bases, etc., a cylindrical saw is employed, similar in principle to the crown-saw. For small work, hollow cylinders of sheet-iron *a* are employed. For large circles, segmental cutters, adjustably fixed upon the arms of a cross piece, are used. In either case, the vertical spindle *c* is rotated by a belt and pulley, the weight of the spindle and pul-

Fig. 5883.



Stone-Sawing Machine.

Fig. 5884.



Modes of Fastening Diamonds in or to Stone-Saws.

ley being relied on to keep the saw to its work, and a cord and lever are employed to lift it when required.

The machine, Fig. 5881, is designed for sawing taper slabs by means of two sets of saws operated from a single crank.

The saws *a a a′ a′* are secured to the fender-bars *b b b′ b′*, and those of the one set are adjusted at any angle with those of the other by the lateral movement of the fender-bars corresponding to the relative inclinations of the guides *c c c′ c′*, which may be secured in the required position by bolts near their ends passing through slots in the rails *d d′*. The two sets of fender-bars are connected by links *e e e′ e′*, so that the adjustment of one determines that of the other, and at the same time motion is imparted to both by the connection of the crank with a post *f* attached to the first set of fender-bars.

Stone-sawing machines of the highest class are made by furnishing the blade with CARBON-POINTS (which see). These saws are usually circular, but some are made reciprocating.

James T. Gilmore of Painesville, Ohio, No. 38,670, May 20, 1863, has a circular revolving plate or disk, armed with diamonds or other hard cutting-points, and used for dressing millstones. A portion of the machine is shown in Fig. 5882. It is described as adapted to leveling the surface of, and cutting the furrows in buhr-stones, dressing building-stones, fluting columns, and making moldings. The view shows side and end elevations.

Diamond-drills are described in Hermann's French patent, March 31, 1855. See DIAMOND-DRILL.

Fig. 5883 shows a stone-sawing machine having a circular blade in a frame, which may be raised or lowered, to bring the saw to cut at the required depth. The stone is dogged upon a reciprocating bed beneath, in the manner of a planing-machine. The various adjustments will be easily understood from the figure.

Fig. 5884 shows a number of ways of fastening the black diamonds to the steel blade.

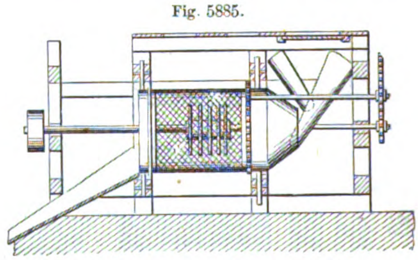
It will be perceived that some of these imbed the diamond in the saw by sockets, rings, or solder; others grasp it by fingers which are clamped in sockets; others grasp it by wedges in the slot, or by clamps which are themselves jammed by wedges, etc.

Stone-sep′a-ra′tor. A machine for separating stones from clay or sand; for concrete or brick-making.

Fig. 5885 shows a dry-clay pulverizer and stone-separator, in which the ground clay from the mill at the right is carried into

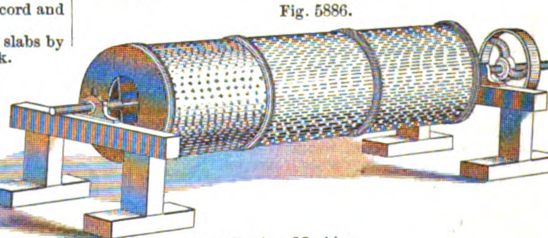
Fig. 5885.



Clay-Pulverizer and Stone-Separator.

a revolving screen, in which is a shaft with stirrers rotating at a different speed. While material of a given fineness passes through the holes in the screen, the stones are discharged at an end spout.

Fig. 5886.



Stone-Sorting Machine.

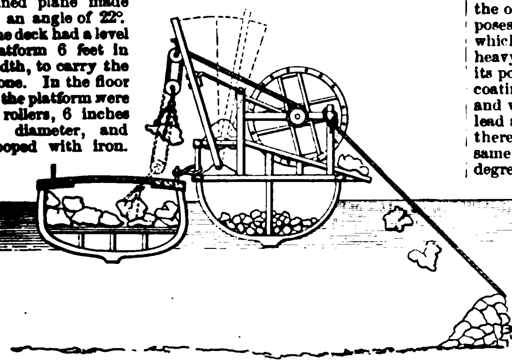
Stone-sort′ing Ma-chine′. A machine having an inclined iron cylinder perforated to allow stones of given sizes to escape. The machine has three sections of varying fineness of mesh, the crushed stone being fed in at the fine end, in the manner of a flour-bolt, and sorts into three sizes the pieces not too

large to fall through. These larger pieces pass all the way through, and are discharged at the end of the cylinder.

Stone-ves'sel. The breakwater of Cherbourg, France, was commenced in 1786, and was never completed according to the original design by De Cessart, but during the nine following years, 100,000,000 cubic feet of stone had been deposited in and around the 18 timber cones which formed the nuclei for the stone piles.

De Cessart's machine for throwing large stones into the sea consisted of a pontoon carrying an inclined plane made at an angle of 22°. The deck had a level platform 6 feet in width, to carry the stone. In the floor of the platform were 8 rollers, 6 inches in diameter, and hooped with iron.

Fig. 5887.



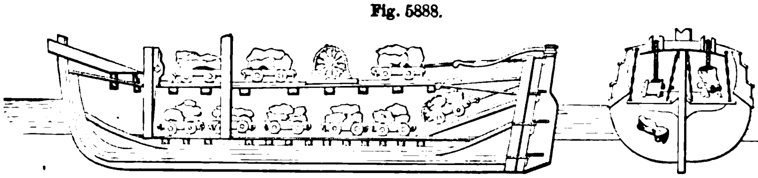
De Cessart's Stone-Boat.

A gib, moving on a pivot and furnished with hoisting-tackle, was employed to hoist the stones from the lighter which carried them to the spot. Two wheels and axles worked the rope. The wheels were 12 feet in diameter, the axles 1.

Iron grapplers and chains first lifted the stone from the lighter, and when the necessary hight was obtained, the gib was swung back into the position shown in dotted lines. By loosening the tackle a little, the stone was deposited on the platform rollers, along which it traveled until it reached the discharging-chute, which precipitated it into the sea.

In transporting and depositing the stones used in making the Plymouth Breakwater, vessels were employed having a pair

Fig. 5888.



Plymouth Stone-Boat.

of longitudinal tracks on each side of the ship, on each deck. On these tracks were trucks which held the stone, which were dumped at the stern, to which the trucks were conducted, one at a time, and tilted by tackle. At the stern of the boat was an inclined plane, by which the loaded trucks reached the lower deck, and another inclined plane led from the upper deck to the opening in the stern, which was exposed when the shutters were lowered. These shutters were supported by chains, and formed chutes.

Stone'ware. A grade of ceramic ware of great hardness and value.

The stoneware of London is made of pipe-clay from Dorsetshire and Devonshire, calcined and ground flint from Staffordshire, and sand from Woolwich and Charlton. The dry clay is pulverized and sifted. The ingredients are compounded in different proportions, according to the fineness of the ware, its size, and purpose. The round articles are turned on a wheel, dried, and shaved in a lathe. Articles of other shapes are molded. The articles are then stacked in the kiln, with pieces of well-sanded clay placed between them, to prevent their adhering. A slow fire dissipates the moisture, and the heat is then raised until the flame and ware have the same color.

The glaze is then added by pouring 20 or 30 ladlefuls of common salt into the top of the kiln. This is volatilized by heat, becomes attached to the surface of the ware, and is decomposed, the muriatic acid flying off and leaving the soda behind it to form a fine thin glaze on the ware, which resists ordinary acids.

The labors of Wedgwood date from about 1762, and the art attained great excellence under his fostering care, ingenuity, and taste. We quote from Aiken: —

"With a liberal ambition far above the mere love of gain, his ruling object was to carry the art that he practiced to the utmost perfection of which it was capable. For this he spared neither time, nor labor, nor expense; and his splendid success, inciting others to follow in the same track, has secured to his country a most important branch of internal and foreign commerce, and has placed his name forever among the worthies of the British nation.

"He perceived that the defects of the delft-ware, at that time the only species of pottery employed for common domestic purposes, were the softness and looseness of texture of its body, which obliged the potter to make it thick and clumsy and heavy, in order to ensure to it a moderate durability; and that its porousness, as well as its dirty gray color, required a thick coating of white enamel, which added still farther to its bulk and weight, and which, containing a large proportion both of lead and arsenic, was hardly safe for culinary use. He began, therefore, by inventing a body for earthenware, which at the same time should be white and capable of enduring a very high degree of heat without fusion, well knowing that the hardness of the ware depended upon the high firing to which it had been subjected. For this purpose, rejecting the common clays of his neighborhood, he sent as far as Dorsetshire and Devonshire for the whiter and purer pipe-clays of those counties. For the silicious ingredient of his composition, he made choice of chalk-flints calcined and ground to powder.

"It might be supposed that white sand would have answered his purpose equally well and have been cheaper; but being determined to give the body of his ware as great a degree of compactness as possible, it was necessary that the materials should be reduced to the state almost of an impalpable powder; and calcined flints are much more easily brought to this state by grinding than sand would be. The perfect and equable mixture of these two ingredients being a point of great importance, he did not choose to trust merely to the ordinary mode of treading them together when moist; but having ground them between stones separately with water to the consistence of cream, he mixed them together in this state by measure, and then evaporating the superfluous water by boiling in large cisterns, he obtained a composition of the most perfect uniformity in every part. By the combination of these and other ingredients in different proportions, and exposed to different degrees of heat, he obtained all the variety of texture required, from the bibulous ware employed for glazed articles, such as common plates and dishes, to the compact ware not requiring glazing, of which he made mortars and other similar articles.

"The almost infusible nature of the body allowed him also to employ a thinner and less fusible glaze, that is, one in which no more lead entered than in common flint-glass, and therefore incapable of being affected by any articles of food contained or prepared in such vessels. With these materials, either in their natural white or variously colored, — black by manganese, blue by cobalt, brown and buff by iron, — he produced imitations of the Etruscan vases and of various other works of ancient art, such as the world had never before seen, such as no subsequent artist had ever attempted to rival.

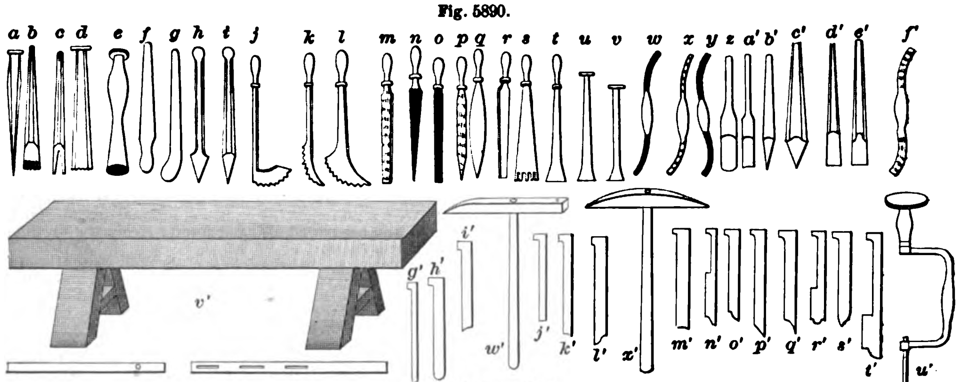
"In table ware, for many years he led the way almost without a rival; but the immense demands occasioned by the successive improvements of this article, which first put down the use of delft, and then of pewter, gave ample room to men of capital and skill to enter the field of profit and competition. Much good has hence resulted; many subordinate improvements have been effected and are almost daily making; but it is to be regretted that many of the most modern ones have reference rather to cheapening the price than improving the quality of the ware or even keeping it up to the original standard."

Fig. 5889.

Stoneware Filter.

Stone'ware Fil'ter. A sim-

Fig. 5890.



Stone-Workers' Tools.

ple filter consists mainly of two stoneware vessels, the one being placed on the other, and the lower on a stand or table. The water is placed in the vessel *a*, and thence percolates through the sponge *b*, which detains large impurities, thence through a perforated earthenware plate, 6 inches of charcoal, and a second plate, reaching the lower vessel, whence it is drawn as required, by means of the faucet.

Stone-work'ing Tools.

Figs. 5890, 5891, show groups of stone-workers' tools.
a, square etching-needle.
b, marteline-chisel.
c, toothed chisel.
d, marteline-chisel.
e, puncheon.
f, *g*, scrapers for sinking flutings.
h, *i*, etching-needles, called *houguettes*, partly flattened, and sharp.
j, hook for leveling cavities.
k, round-nose chisel, for leveling cavities.
l, sharp-edged notched scraper, for sinking flutings.
m, half-round rasp.
n, round file.
o, flat file.
p, German half-round rasp.
q, *r*, safe-side rasps.
s, *t*, marteline-chisels.
u, *v*, puncheons.
w, *x*, *y*, parting-tools, with curved ends in rasp or file.
z, *a'*, gravers and *burins*.
b', *c'*, houguettes, or etching-needles.
d' e', gravers and *burins*.
f', parting-tool, with curved rasps.
g' to *t'*, molding-chisels and scrapers having edges, of varying patterns.
u', *wimble*, for drilling.
v', stone-worker's bench.
w' x', marteline-hammers.
y', square.
z', triangle.
a'', bevel.
b'' c'' d'', rules and straight-edges.
e'' f'' g'', saws of various sizes and construction.
h'' i'' j'' k'', compasses of various sizes and forms.
l'', *sebilla*, or wooden bowl for holding sand and water.
m'', hand-saw.
n'', level.
o'', mallet.
p'' q'', sledges.
r'' s'' t'' u'', chisels of various sizes.
v'', ladle for feeding sand and water to the saw.
w'' x'', hand-saws.

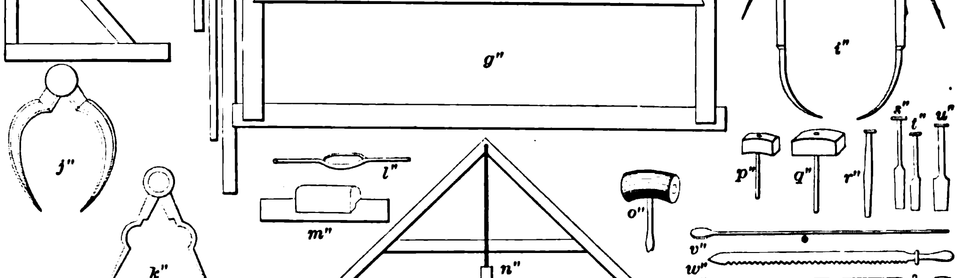
Stook. (*Husbandry.*) A collection of sheaves set up together so as to be mutually supporting. The more usual word in the United States is a *shock*. See SHOCK.

Stool. 1. (*Furniture.*) A kind of seat; usually a circular block supported on three or four legs.

Stools are known by construction, as *folding*; or by purpose, as *camp*, *night*, *foot*, *piano*, etc.

2. (*Agriculture.*) A frame of four growing corn-

Fig. 5891.



Stone-Working Tools.

stalks, tied together to form a support for a corn-shock.

3. (*Shipbuilding.*) *a.* (*pl.*) Chocks beneath the transoms for the attachment of the fashion-pieces.

b. A piece of plank fastened to a ship's side to receive the bolting of the gallery.

c. A small channel on a ship's side for containing the dead-eyes of the back-stays.

4. The sill of a window.

5. A decoy-bird.

Stop. 1. (*Music.*) *a.* A device for changing the tone of a wind-instrument by directing the wind to certain optional series of pipes or reeds of different tones; such as *principal*, *flute*, *diapasm*, etc.

b. A set of pipes in an organ, of given quality and embracing all the tones and semitones within the range for which they are constructed. By means of a variety of stops the organist can change the quality of tone, the power of sound, and the compass of the instrument.

Stops, so called, were first introduced into harpsichords about the middle of the eighteenth century. They were worked by pedals, and known as the *forte*, *soft*, and *buff*. The first lifted the dampers; the second partly stopped the vibrations of the strings; the third interposed a piece of cloth or *buff* leather between the strings and the jacks. This was apparently the origin of pedals.

The *stops* of an organ are *mouth* and *reed*. The *mouth*-stops are divided into *foundation* or *octave* stops and *mutation*-stops. The *foundation*-stops are *open* or *closed*; the latter, called *bourdons*, are an octave above the open pipes of the same size.

The *mutation*-stops have this peculiarity that they give above each sound its third, its fifth, its tenth, in such a way as to represent by the action of several small pipes the aliquot parts or harmonics of the large pipe

The names of the stops of each class, *mouth* and *reed*, and their sub-classes, are numerous. See Rimbault, "On the Organ."

As different stops vary in *pitch* and in *timbre*, a key will sound different notes and tones according as different *stops* are drawn.

The stops which sound the fundamental note are denominated *unison*, and agree in pitch, although they differ in *timbre*.

Stops sounding an octave above the unison are termed *octave*, and those sounding an octave below it are called *double*; as *diapason*, *double diapason*, etc.

Stops with open or closed pipes are so denominated, as *open diapason*, *closed diapason*.

Principal is a stop whose name indicates that it is the first stop tuned, the other stops being tuned from it.

Diapason-stops extend through the whole scale of the instrument, as the name implies.

Some stops are known by the interval which any note of the given stop makes with the fundamental note corresponding to the key struck, as *twelfth*, *fifteenth*, etc.

The following stops are those in common use: —

1. *Open diapason:* has metallic mouth-pipes, open at the upper end.
2. *Stopped diapason:* wooden mouth-pipes, in unison with 1, and having tompions in the upper end.
3. *Double diapason:* wooden mouth-pipes, open, pitched an octave lower than 1.
4. *Principal:* metallic mouth-pipes, pitched an octave higher than 1.
5. *Dulciana:* an open metallic mouth-pipe, tuned in unison with 1, and having relatively long and narrow pipes.
6. *Twelfth:* metallic mouth-pipe, tuned a twelfth above 1.
7. *Fifteenth:* metallic mouth-pipe, tuned an octave above *principal*.
8. *Flute:* wood *or* metal mouth-pipes, in unison with *principal*.
9. *Trumpet:* reed-pipes of metal in unison with 1.
10. *Clarion*, also called *octave-trumpet:* metallic reed-pipes, tuned an octave higher than *trumpet*.
11. *Bassoon:* reed-pipes in unison with 1, but extending only a part of the scale.
12. *Cremona* (krum-horn): reed-pipes in unison with 1.
13. *Oboe:* reed-pipes in unison with 1.
14. *Vox humana:* reed-pipes in unison with 1.

Many others might be mentioned of peculiar tone, as *clarinet*, *cornet*, *vox celeste*, etc.

Compound stops consist of several sets of stops aggregated to form harmonic combinations. Such are the *sesquialtera*, *cornet*, *mixed*.

It will be noticed that a number of the above are described as *reed-pipes in unison with* 1. The cause of the difference in *timbre*, or quality of tone, may be partially in the tongue, but is mainly produced by varying the form of the tube. The tubes have varying lengths and proportions, more or less elongated, with swells and other peculiarities which affect the character of the tone emitted.

Some large church-organs have numerous stops not here enumerated, such as the *tierce*, *larigot*, *nineteenth*, *twenty-second*, *twenty-sixth*, *twenty-ninth*, *thirty-third*, tuned at these intervals above *open diapason*.

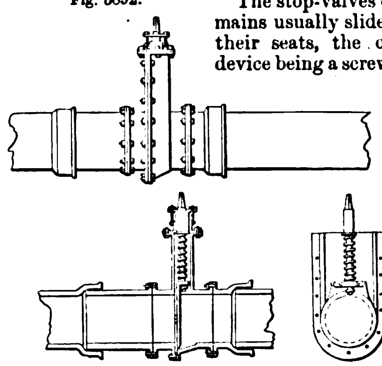
The organ of the church of S. Alessandro, in Colonna at Bergamo, built by Serassi in 1782, has 100 stops and 4 banks of keys. The Boston organ has 120 stops. See ORGAN.

2. (*Nautical.*) A projection at the upper part of a mast, outside of the cheeks.

3. (*Optics.*) A perforated diaphragm between two lenses, to intercept the extreme rays that might disturb the perfection of the image.

Stop-cock. A faucet in a pipe, to open or close the passage.

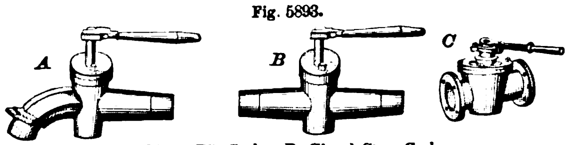
Fig. 5892.



Stop-Valve.

The stop-valves of water-mains usually slide against their seats, the operative device being a screw, turned by a handle. A turnkey inserted from above fits over the square of the screw, whose thread traverses in a nut formed by a projecting flange on the back of the valve. See STOP-VALVE.

Fig. 5893.



A, Gland Bib-Cock. B, Gland Stop-Cock.
C, Smith and Rowe's Patent Stop-Cock.

Stop-cyl'in-der Press. (*Printing.*) One in which the impression-cylinder is stationary during the return of the bed. While the bed returns the next sheet is adjusted. See CYLINDER-PRESS; also LITHOGRAPHIC PRESS, Fig. 2977.

Stope. (*Mining.*) A horizontal bed. To stope; to excavate horizontally layer after layer.

Stop-fin'ger. A device in a silk-doubling machine for stopping the motion of the bobbin if the thread break. See FALLER-WIRE.

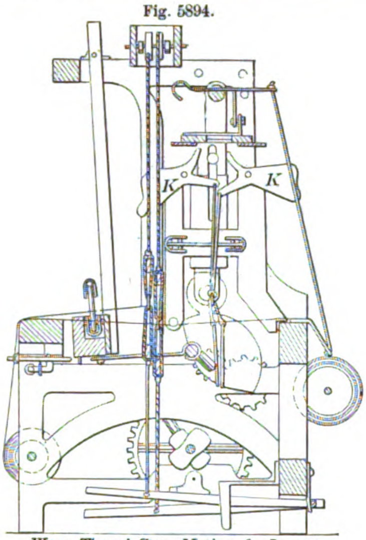
Stop-mo'tion. An arrangement in a machine by which the breakage of material in transitu, or the failure of supply of the material under treatment, causes an arrest of the motion.

Such, for instance, is the attachment in power-looms and knitting-machines, designed instantly to arrest the movement, if at any time the spool become exhausted in the shuttle, or the yarn happen to break. A delicate metallic finger feels for the yarn at the very instant the shuttle completes its course. If the yarn is in its place it rests there, and the work goes on; if not, it makes an electric contact, and the power is paralyzed in an instant. In pattern work the advantage of such an attachment will easily be understood. No time is lost in studying to find where the pattern began to be interrupted, and no trouble is necessary to set backward the Jacquard guides.

Fig. 5894 is a stop-motion for warps of looms.

It has a series of pivoted wings *K K* from which warp-supporting rods or threads are suspended. So long as the warp-supporting rods or threads are kept tense by the warp-thread, they hold the wings in such a position that the same do not in-

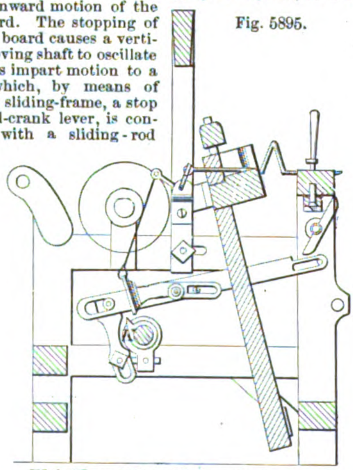
Fig. 5894.



Warp-Thread Stop-Motion for Looms.

terfere with the motion of a rising and falling flat board; but as soon as a warp-thread breaks, it will cause the release of a warp-supporting rod or cord, whereupon the wing from which the same is suspended will swing upon its pivot, so as to arrest the downward motion of the flat board. The stopping of the flat board causes a vertically moving shaft to oscillate and thus impart motion to a lever, which, by means of cords, a sliding-frame, a stop and bell-crank lever, is connected with a sliding-rod

Fig. 5895.



Weft-Thread Stop-Motion for Looms.

which operates the belt-shifting lever. As soon as the rod is released by the withdrawal of the stop, it is moved by the action of a spring, so as to shift the belt to a loose pulley and thus stop the loom, the batten being simultaneously arrested by a stop on said rod.

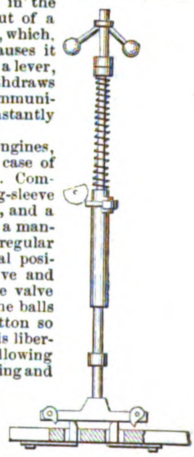
Fig. 5895 shows a set of devices designed to stop the loom when the weft-thread breaks or gives out; in this case the bars of the grid on the lay are allowed to pass the weft-fork, and a lever is thus allowed to drop so low as to be struck by the wiper *K*, which pushes it and the bar forward until the shoulder strikes a lever, and by the intervention of another lever unlocks the shipper.

Stop-motions are also used in *roving*, *spinning*, and *working machinery*. See Fig. 5900.

The stop-motion of *drawing*-machines is contrived to arrest the motion of the machine when a sliver breaks. This is accomplished by causing the slivers from the finishing carding-engine to pass over weighted guide-levers, termed *spoons*, mounted so as to be capable of turning upon centers, and kept in a certain position by the tension of the fibers while being drawn. Should one of the slivers break, or a can become empty, the spoon falls, and a part projecting from its under side intercepts the motion of a vibrating bar, and this acts upon other apparatus which shifts the driving strap from the fast to the loose pulley. See STOPPING MECHANISM.

The electric stop-motion for fabric-machines is so arranged that, on the breaking of a single thread, the emptying of a bobbin, the accidental bending of a needle, or on holes being caused in the work by the knotting or thinning out of a thread, an electric circuit is completed, which, passing through an electro-magnet, causes it to attract an armature, and so releases a lever, which, actuated by a strong spring, withdraws a clutch through which motion is communicated to the loom, and the machine is instantly stopped.

Fig. 5896.



Stop-Motion for Engine.

Fig. 5896 is a stop-motion for steam-engines, to come into action automatically in case of the failure or breakage of the governor. Combined with the governor is a coupling-sleeve with a dog let in crosswise of the same, and a supporting-spring and button in such a manner that when the engine runs at its regular speed and the balls occupy their normal position, the connection between the valve and governor-rod is not disturbed, and the valve remains open; but if from any cause the balls drop down, the dog will strike the button so that it is thrown back, and the sleeve is liberated from the rod of the governor, allowing the same to follow the action of the spring and close the valve, and thus stop the motion of the engine.

Stop'per. 1. (*Nautical.*) A short piece of rope having a knot at one end, with a laniard under the knot; applied to shrouds, cables, etc., for various purposes.

a. Of the anchor; a rope attached to the cathead, and, after passing through the anchor-ring, made fast to a timber-head.

b. Of the cable; a *deck-stopper* is a rope attached to a ring on the deck, and lashed to the cable to prevent the veering of the latter. The cable-stopper has a hook and thimble at one end, and a laniard at the other.

A *dog-stopper* is clinched around the mainmast and secured to the cable.

A *wing-stopper* is clinched to a beam.

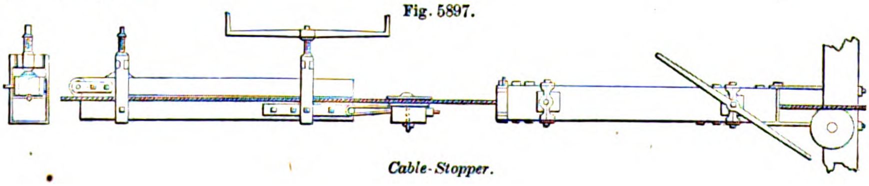
A clamp or stopper is used to secure a cable while *fleeting* it on the capstan, especially in hoisting heavy weights.

The illustration shows the stopper by which the rope was clamped when hoisting the chains of the Menai Suspension Bridge. One end of the chain was carried over the strait, and attached to that which hung perpendicularly from the opposite pier. The hoisting power was 4 capstans, each worked by 32 men, and assisted by powerful tackle. Each chain weighed 242,299 pounds, over 121 tons. As the rope coiled upon the capstan, it was necessary to *fleet* it back every 3 rounds, and the stopper was to prevent the fall of the rope from surging back. See also CABLE-STOPPER.

c. Of rigging; a rigging-stopper secured to standing rigging above and below an injured part, so as to make the piece secure. It may be done by lashing dead-eyes to each part, and then hauling taut by laniards.

d. A piece of rope with a knot at one end and a hook at the other, for various purposes about the deck.

Fig. 5897.



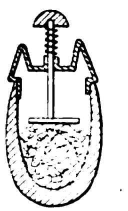
Cable-Stopper.

2. (*Railway Engineering.*) A trailing-brake formerly used on inclined planes. It was in the rear of the last wagon in ascending, and was thrown into action by the pressure of the cars, if the rope broke. It penetrated the ground and stopped the descent. Also called a *trailer* or *cow.*

3. A plug to condense tobacco in a pipe. Fig. 5898 shows a stopper attached to a spring-rod.

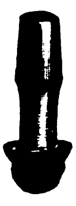
4. A cork or plug for closing a bottle. Many materials and forms have been used. See BOTTLE-STOPPER; FRUIT-JAR.

Fig. 5898.



Tobacco Stopper.

Fig. 5899.



Bottle Stopper.

Fig. 5899 is Matthews's bottle-stopper for aërated liquids. It is of glass, with a gasket of caoutchouc, and was perhaps the first gravitating stopper longer than the internal diameter of the bottle, so that it cannot tip over.

The gasket may be compressed in one direction, but not in the other, so that it may be forced in, but not blown out.

Stop'per-bolt. (*Nautical.*) A large ring-bolt driven in the deck of a ship before the main-hatch, for securing the stoppers to.

Stop'per-hole. (*Puddling.*) A hole in the door of the furnace through which the iron is stirred, and the operation observed; it is sometimes stopped with clay: hence the name.

Stop'ping. 1. (*Mining.*) *a.* A door in a drift or gallery which *stops* the passage of air at a certain point, being a part of the artificial ventilation system of a mine.

b. Cutting down mineral ground with a pick.

2. (*Dental Surgery.*) Material for filling carious teeth. The holes are cleared of carious matter by instruments called *burs, excavators, drills, chisels,* etc. Among the filling materials may be cited: —

Gold.
Silver.
Tin.
Amalgams of silver, tin, or cadmium.
Os artificial: oxychloride of zinc mixed with a liquid.
Foil: gold or tin.
Hill's stopping: india-rubber and silex.

3. (*Engraving.*) Covering with varnish such parts of an etched plate as may have been sufficiently *bitten in* with acid; the remaining portions are then again exposed to acid to deepen the lines. See ETCHING.

4. Patching incomplete work with cement, such as gaps made by the spalling of marble or stone, of veneer, etc. *Badigeon.*

5. (*Farriery.*) A pad or ball occupying the space within the inner edge of the shoe, around the *frog* and against the *sole.* Its object is to keep the parts in a moist condition, similar to that which they possess in a state of nature, where the hoof is not lifted clear of the ground by a shoe, but the *sole* and *frog* come in contact with the damp earth and verdure.

Dickenson's English patent, some 50 years since, consisted in placing a piece of stout leather over the whole bottom of the foot, and nailing the shoe thereupon. An angular plate of iron is riveted to the outer surface of the leather, over the frog, whose form it imitates. Beneath the leather is packed a quantity of sponge which absorbs and retains moisture.

A common practice with horses habitually stabled, and where great care is exercised, is to stop the feet after coming from work, a composition of cow-dung and clay being used. Several devices for *stopping* the feet of horses have been suggested, and a number patented. Pads of india-rubber, felt, sponge, cork, etc.

Stop'ping-brush. 1. (*Hat-making.*) A brush used by hat-makers when working at the *battery,* to sprinkle boiling hot water upon the napping and the hat body to assist in uniting them as they are worked, pressed, and rolled by the hand, the *glove,* and the rolling-pin.

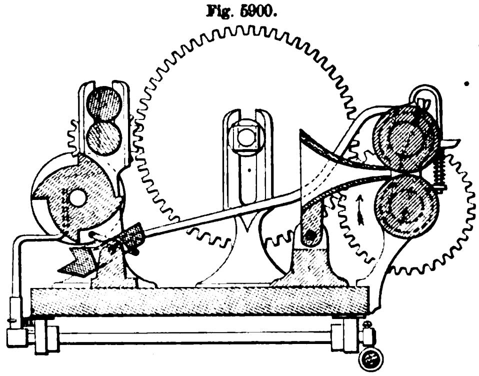
2. (*Engraving.*) A camel's-hair brush, used by engravers in *stopping* out portions of etched plates. See ETCHING.

Stop'ping-knife. The glazier's putty-knife.

Stop'ping-mech'an-ism. An automatic device in machinery by which the motion is stopped if a thread (for instance) should break. Automatic stopping-mechanisms are applied to looms to arrest the motion of the machine if the weft-yarn break or the shuttle be emptied; to spinning-machinery, if the roving or thread should break. See STOP-MOTION.

Fig. 5900 is a stop-mechanism for railway-heads of spinning-machines, designed to shift the belt and stop the machine when the sliver passing between the condensing or delivering rolls is above or below a given thickness. A rise or fall of the upper roller above or below a certain point moves a lever and raises a tripping-dog into contact with a ratchet-wheel.

Fig. 5900.



Stop-Mechanism for Spinning-Machines.

Stop'ping-off. (*Founding.*) A term applied to the filling up with sand of a portion of a mold, when the casting is desired to be smaller than the pattern from which the mold is formed. It is in opposition to cutting out, when a portion of sand is removed, so as to enlarge the mold to represent an addition to the size of the pattern.

Stop'ping-out. (*Engraving.*) Covering with varnish any portion of an etched plate which has been corroded to a sufficient extent; after the *stopping-out,* farther portions are deepened by a repetition of the process called *biting-in.* See ETCHING.

Stop'ping-up Pie'ces. (*Shipbuilding.*) Timbers placed on the middle part of the *bilge-ways,* to meet and support the bottom of the ship. They form a part of the *cradle.*

Stop-plank. (*Hydraulic Engineering.*) One of a set of planks to occupy vertical grooves in the wing wales of a lock or weir, to hold back water in case of temporary disorder of the lock-gates.

Stop'ple. A stopper, cork, or bung, for a bottle, jar, keg, or cask. See STOPPER; BOTTLE-STOPPER.

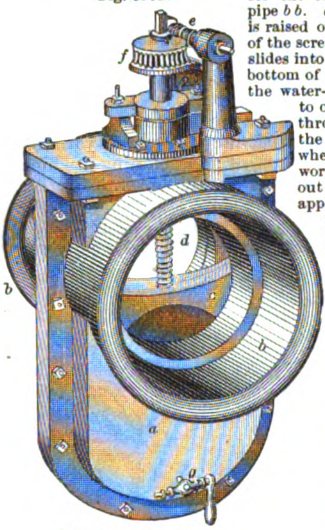
Stops. (*Nautical.*) The square projections or shoulders left on the outsides of the cheeks at the upper parts of the hounds.

Stop-valve. 1. (*Hydraulics.*) A valve which closes a pipe against the passage of fluid. The large valve used in water-mains is known by this name. It is usually a disk which occupies a chamber above the pipe when the passage-way through the latter is open, and is driven down by a screw to *stop* the aperture, its face being pressed against the seat by the contact of the rear with wedging abutments.

The smaller device, with a spigot, is called a Stop-cock (which see). See also Three-way Valve.

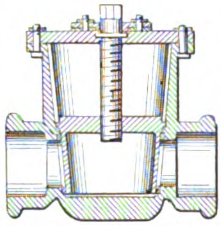
In Kearney's stop-valve for water-mains (Fig. 5901), the casing *a* has a circular opening for the ends of the supply-pipe *b b*. *c* is the valve, which is raised or lowered by means of the screw *d*. When open, it slides into the chamber at the bottom of the casing, leaving the water-way clear; in order to open it the worm *e* is thrown into gear with the worm-wheel *f*, and when it is started the worm may be thrown out of gear and power applied directly to the screw. This lessens the labor of opening and closing the valve under great pressure, and the opening being effected very gradually at first, avoids the danger of bursting the pipe by sudden pressure. *g* is a cock for drawing off or forcing out any foreign matters which may collect at the bottom of the valve-casing.

Fig. 5901.



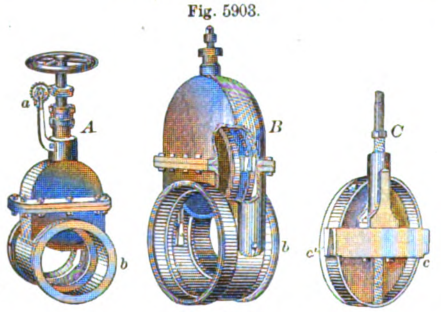
Kearney's Stop-Valve.

Fig. 5902.



McClelland's Stop-Valve.

Fig. 5903.

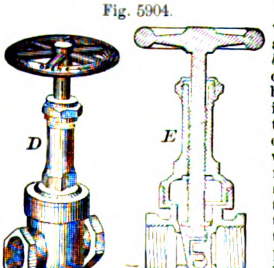


Stop-Valve.

Fig. 5902 is the McClelland valve. It is a hollow cone, the hollow being of a diameter greater than the bore of the pipes. The body of the valve is cast upon and within bronze rings, which serve for bearings.

Fig. 5903, *A*, *B*. The gate when raised is received in a box above the pipe-joint *b*. In *A*, the screw which operates the gate is turned by a hand-wheel, and an indicator *a* shows its position in the pipe. *B* has a double gate, shown at *C*, with one of the faces removed; when the gate is shut down, wedges within the casing *b* enter between the two wedges *c c'*, forcing the two faces against their proper bearing surfaces, to prevent leakage.

Fig. 5904.

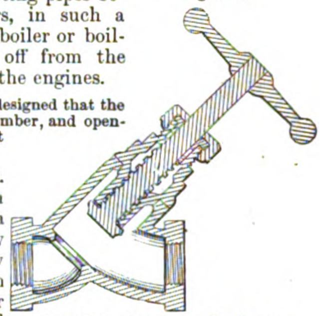


Stop-Valve.

Fig. 5904, *D*, *E*. A perspective and section of a small stop-valve having a wedge-shaped valve, whose form renders it self-packing.

2. (*Steam-engineering.*) Stop-valves, or *communication*-valves, are fitted in the steam-pipes where they leave the several boilers, and in the connecting-pipes between the boilers, in such a manner that any boiler or boilers may be shut off from the others, and from the engines.

Fig. 5905.



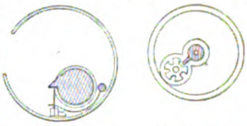
Stop-Valve for Steam-Enginery.

In Fig. 5905, it is designed that the bore of the pipe, chamber, and opening in the valve-seat shall be the same.

Stop-watch. A watch in which the works (or a part of them) may be stopped by pressing in an exterior pin. Used in timing races, etc. The most improved form is the independent-seconds watch. See Independent-seconds Watch.

Stop-work. A device attached to the barrel of a watch, musical-box, or spring-clock, to regulate the winding of the spring and prevent over-winding. The middle turns of the spring are most equably efficient, and it is better to so organize the stop that the strongest and weakest powers of the spring be rejected. This is particularly necessary in watches destitute of the *fusee*, which is a conical wheel, whose office is to regulate the action of the *spring* on the *train*.

Fig. 5906.

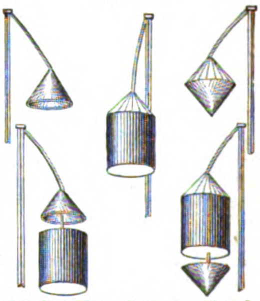


English Stop. *Swiss Stop.*

Storm-drum. A signal. *a*. A painted canvas drum, distended by hoops.

b. A semaphoric device of Admiral Fitzroy, consisting of a hollow cylinder and cone, either of which, or both simultaneously, may be suspended from a mast or staff; their positions denoting the probable direction of the wind in an approaching storm. Thus: Cone point upward, to the right of the staff, northerly gale. Cone point downward, to the left of the staff, southerly gale. Cylinder above: expect dangerous winds from both quarters successively. Upright cone above cylinder: dangerous wind expected from north. Reversed cone below cylinder: dangerous wind expected from south.

Fig. 5907.

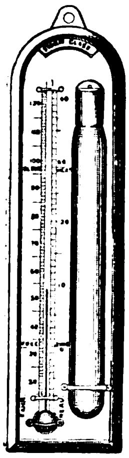


Admiral Fitzroy's Storm-Signal.

It took some time to inspire the sailors with confidence in the storm-signals of Admiral Fitzroy, but in 1864 it was found in England that fifty per cent, at least, of all the storm-warnings had proved correct, and in 1865 that seventy-three per cent had been fully verified. In France, during the years 1865, 1866, out of one hundred warnings sent, seventy-one were realized the first year, and seventy-six in the second year; and out of one hundred storms which occurred, eighty-nine were signaled during the first winter, and ninety-four during the second. The North German "Seewarte" mentions that out of thirty storm-warnings hoisted at Hamburg, ninety-four per cent were correct. The system in the United States is gaining the confidence of navigators, and is yearly growing more correct. A number

of disastrous storms have been predicted with marvelous precision from Washington, and our daily weather-forecasts very seldom fail to express the general atmospheric conditions, and usually fore-announce the changes to within an hour or two of their occurrence.

Fig. 5908.



Storm-Glass.

Storm-glass. A tube containing a liquid holding a solution which is sensible to atmospheric changes. In clear weather the substance is said to settle near the bottom of the tube, the liquid remaining comparatively clear; previous to a storm the substance rises, causing the liquid to present a turbid and flocculent appearance. It is sometimes, as in the illustration, mounted on a back and associated with a thermometer. A thin bladder is tied over the top.

The solution is: —

Camphor................2 dr.
Niter....................1½ dr.
Sal. am. ....1 dr.
Proof spirit.............2¼ fluid oz.

Storm-kite. A contrivance for sending a rope from a stranded vessel to the shore. An *anchor-ball* is frequently used from the shore to the vessel. See ANCHOR-BALL.

Storm-pane. A supplementary, framed sheet of glass, to substitute, in an emergency, for a broken pane in a lighthouse.

Storm-pave'ment. (*Hydraulic Engineering.*) The sloping stone paving which lines the sea-face of piers and breakwaters. The breakwater glacis.

Storm-sail. (*Nautical.*) A sail of reduced dimensions and extra heavy canvas, for heavy weather. Thus we speak of a *storm-jib*, *storm-trysail*, etc.

Storm-sig'nal. See STORM-DRUM.

Sto'ry. (*Architecture.*) The space between two floors of a building.

Sto'ry-post. (*Building.*) One occupied in supporting the *bress-summer* when a window occupies the whole front of the ground floor.

Sto'ry-rod. (*Building.*) A rod equal in length to the hight of the floor, and having the hights of the several steps of the stairs marked upon it.

Stove. 1. A close fireplace for warmth or cooking.

In Asia and some parts of Europe stoves are made of brick, or even of clay. In Germany they are frequently of tile, which is but a form of brick. In England and in the United States iron is preferred, though steatite (soapstone) is sometimes used. For burning hard coal, stoves are lined with fire-brick.

Stoves are made specifically for wood or for coal; they are also heated by charcoal, coal-oil lamps, or by gas, the construction being agreeable thereto. See HEATING-APPARATUS; HEATING-STOVE; FURNACE; and also under the various heads in the following list of stoves and heating appliances: —

Fig. 5910.

Roasting-Stove.

The *laconicum*, or heating-stove, used by the Romans in the fourth apartment of their Thermæ, was so called because introduced from Laconia. It sent forth a dry heat, and was of a cylindrical shape. It was placed in one of the angles of the apartment, and was heated by the flames of the *hypocaustum* beneath. It had a cupola, open at top, and the heat admitted from the *hypocaustum* was regulated by a brazen damper in the shape of a shield, according to Vitruvius, but of a globular shape in some cases, as in the baths of Titus, erected after the death of that useful compiler.

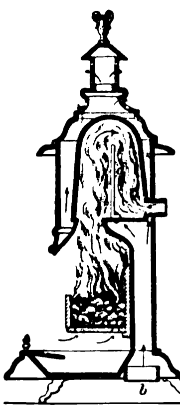
The apartment in which it was used was frequently called the *laconicum*, after the name of the stove.

The bathers here took their sweat, and then, after oiling themselves, plunged into the cold bath of the adjacent *frigidarium*. The heat of the stove modified the temperature of the adjacent *tepidarium*.

The *laconicum*, in some cases, was provided with niches, which were occupied by those requiring a dry bath. These niches were known as *sudationes*, or sweating-places.

Stoves on the Continent of Europe have a double casing which surrounds the fuel-chamber. Into the interval between the casings air is admitted from the outside of the building, and from this space the heated air is conducted to the room. The stoves are generally of earthenware, being made round or square, and are frequently constructed mainly of tiles. Some of them are like a small *hypocaustum*, in which the ceiling of the fuel-chamber is supported by earthen pipes, which conduct air to the chamber above. The fire is made around these pipes, heating their contents as well as the ceiling above it.

Fig. 5909.



Stove.

In the stove shown in section (Fig. 5909), the back and top of the fire and smoke chamber are surrounded by a metallic drum. The fire-chamber is open in front, at once radiating heat directly into the apartment and admitting the air to support combustion. The products of combustion, after passing over a bridge *a*, are deflected downward and carried away by a flue passing through the back of the drum. Air from the apartment enters the drum through an opening *b* in its bottom, and, becoming heated, is again returned through apertures in its top. The combustion-chamber should, of course, be made perfectly fire and smoke tight.

The stove, Fig. 5910, has a roasting-chamber at front, provided with doors, by opening which the meat may be exposed directly to the rays of the fire. Doors above allow the heated air from this chamber to pass into the flue.

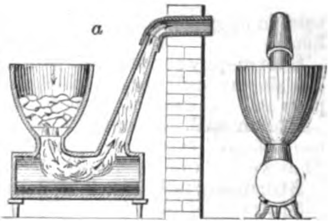
The magazine-stove has been considered under several heads. The ATHANOR (page 175) is the earliest on record, having been used by the alchemists of the Middle Ages to keep up a constant fire, the fuel in the elevated chamber settling into the fire as that in the grate was consumed. It was thus a base-burner, though its magazine was not central, like the modern. A base-burner stove (*a*) was shown in 1685 at the fair of St. Germain, in France, by M. Delasme (Fig. 5911). See pages 242 and 2225.

The first magazine and base-burning stove of modern form was that of David Riz, English patent of April 28, 1770. It is shown at *b*, Fig. 5912. The fuel-reservoir has a cover, the stove is self-feeding, the grate is arched, the bottom layer of fuel only being permitted to burn. The heated products pass up outside the fuel-chamber to the chimney. Between this up-cast space and the outside of the stove is a chamber in which air is heated. The fuel is prevented, by the grated side of the fuel-chamber, from spreading laterally.

This latter feature is shown in Walker's English stove, 1842 (*c*, Fig. 5912), and Littlefield's, 1853, 1854 (Fig. 5913).

Next to Riz may be cited the Watt patent of 1785 for a fuel-reservoir steam-boiler furnace, in which the base of the fuel only was directly exposed to combustion (Fig. 5914).

Fig. 5911.



Delasme's Base-Burner (1685).

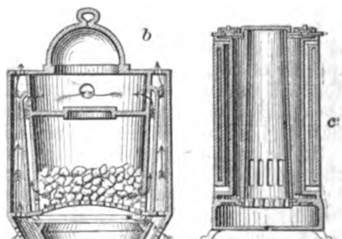
The first illuminated stove it would be difficult to determine, that is, one with mica windows, to enable the fire to shine through. The uses of mica are very ancient, the *lapis specularis* of Pliny being probably sheet-mica.

The first instance at hand occurs in the English patent of Pollok, 1807 (Fig. 5915). It is shown in two forms; one as a projecting door to an outstanding stove, and one as a fireplace-stove, with three mica windows.

Stratton, 1817 and 1822 (Fig. 5916), are other instances; the latter being much like James Watt's device.

Eliphalet Nott's stove, Schenectady, New York, in use before 1830, is shown at *i*, Fig. 5917. It was known as the *Saracenic grate*, probably in reference to the Athanor, or alchemist's stove, which has not passed entirely out of knowledge, although the writer has failed to find an illustration of it. Even the ordinary dictionaries recognize it, and it is described in Hebert's "Engineer's Cyclopædia," London, 1850, Vol. I. p. 109; Francis's "Dictionary of Arts"; Partington's Dictionary, 2 vols.; Weale's "Dictionary of Terms in Art."

Fig. 5912.



Base-Burning Stoves.
(*Riz*, 1770.) (*Walker*, 1842.)

The Nott stove was patented in England in 1830, 1831. It is a base-burning illuminated stove, without an internal fuel-chamber.

The Mott stove is shown at *j*, Fig. 5917, and had a suspended magazine, and mica doors to the fire-chamber.

The Harper and Walker stove (*k*, Fig. 5917, English) of 1839 is a magazine base-burner, with a mica door to the fire-chamber.

The Walker stove of 1842 had a tall central magazine with grated openings at its lower portion.

The Cantelo stove (English patent) of 1846 (*l*, Fig. 5918) was made for keeping a constant heat in the inventor's *incubator*. It had a central magazine with lid.

Walker's French patent of 1849 (*m*, Fig. 5918) has the central magazine and mica door.

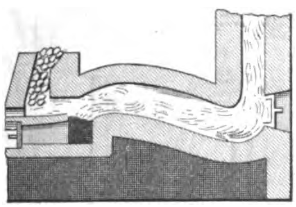
Fig. 5913.

Magazine-Stove.
(*Littlefield*, 1853.)

Grant's English patent, 1850 (Fig. 5919), has the magazine projecting into the fireplace.

Liddel in 1852 (*o*, Fig. 5920) shows a bulged combustion-chamber, a flaring fire-pot, a sheet-iron outer cylinder, and a central magazine base-burner.

Fig. 5914.



Base-Burning Furnace.
(*Watt*, 1785.)

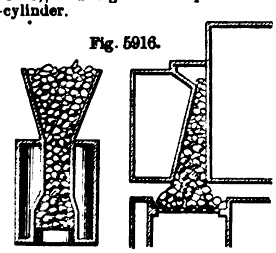
He was the first to ventilate his magazines on top by allowing the gases to escape into the chimney.

Littlefield, in 1853 (Fig 5913), had a grated fire-pot at the lower part of the magazine-cylinder.

Fig 5915.

Mica-Front Stove.
(*Pollok*, 1807.)

Fig. 5916.

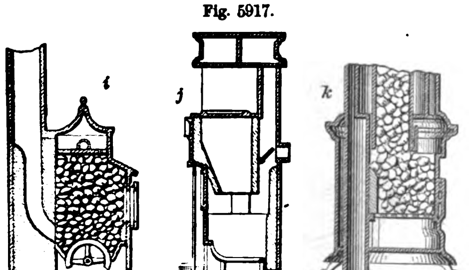


Magazine-Furnaces.
(*Stratton*, 1817 *and* 1822.)

Saxton, in 1856 (*p*, Fig. 5920), had a covered fuel-cylinder in the fire-chamber.

Cantelo's U. S. patent in 1859 (Fig. 5921) shows a petticoat fuel-cylinder projecting downward into the fire-pot.

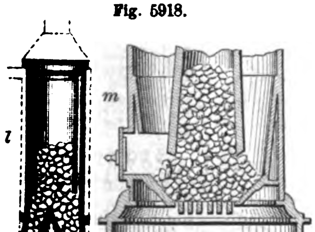
Fig. 5917.



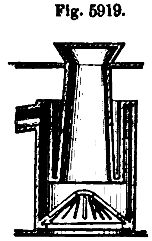
Magazine-Stoves.
(*Nott*, 1830.) (*Mott.*) (*Harper and Walker*, 1839.)

Roney, in 1861 (Fig. 5922), had a grated fire-pot of larger diameter than his magazine.

Fig. 5918. Fig. 5919.

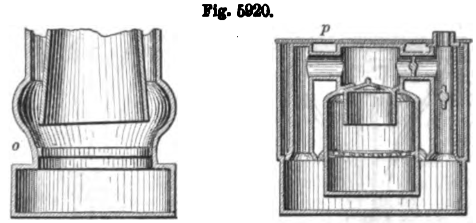


Magazine-Stoves.
(*Cantelo*, 1846.) (*Walker*, 1849.)



Base-Burner.
(*Grant*, 1850.)

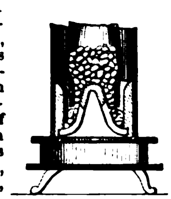
Fig. 5920.



Magazine-Stoves.
(*Liddel*, 1852.) (*Sexton*, 1856.)

There are in the United States about 350 foundries engaged in the manufacture of stoves and furnaces, using annually 500,000 tons of iron. Of stoves alone it is estimated that the 275 foundries engaged in the business in 1871 produced 2,200-200 stoves. This, of course, does not include heating-furnaces. In 1830, the estimated number of stoves made in this country was 25,000; in 1840, 100,000; in 1850, 375,000; in 1860, 1,000,000; in 1870, 2,100,000, — valued at $ 37,600,000. The value of heating-furnaces annually made in the country will amount to $ 20,000,000.

Fig. 5921.



Magazine-Stove.
(*Cantelo*, 1859.)

Fig. 5922.

Grated Fire-Pot Stove.
(*Roney*, 1861.)

2. A room artificially heated to a high degree, as, —

The room in which scoured cloths are dried before *burling* and *fulling*.

The room in which packaged starch is dried.

In many trades, articles are artificially dried by a high heat, as bent wooden stuff; figures of plastic clay; crucibles; enameled or varnished metal-work, etc.

3. (*Founding.*) The usual contraction for the *drying-stove* for cores and molds.

4. The *hot-house* of the florist. The furnace which heats the *forcing-house*.

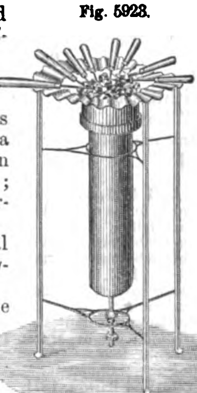
5. (*Pharmacy.*) A chamber used in drying plants, extracts, etc.

6. (*Surgical.*) A heated dry-air bath. The *laconicum* or *calidarium* of the Romans.

A vapor bath. The *tepidariam* or *vaporarium* of the Romans.

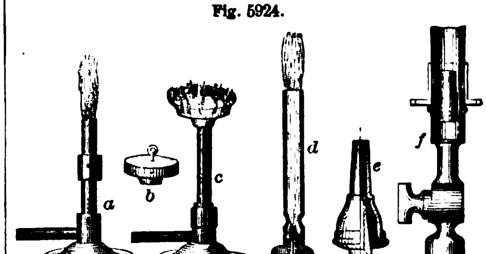
7. (*Bookbinding.*) A small gas-stove used for

Fig. 5923.



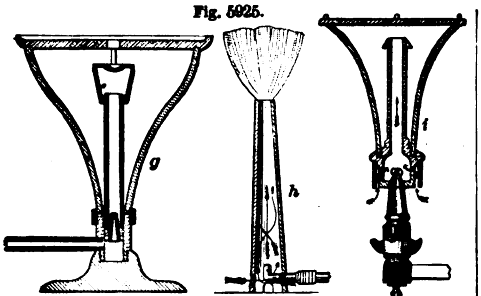
Bookbinder's Stove.

Fig. 5924.



Bunsen Burners.

Fig. 5925.

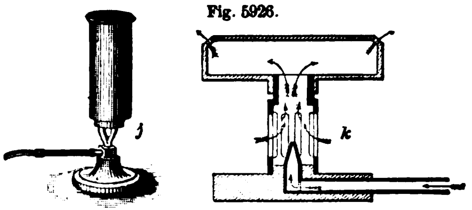


Bunsen Burners.

heating the tools with which the covers of books are lettered and ornamented (Fig. 5923).

Stove-burn'er. A gas-burner specially arranged for heating. The Bunsen burner is preferred, as it gives a blue, smokeless flame, with great heat. Its due performance depends upon the proper admixture of gas and air. If gas be in excess, the flame gives light and smoke and little heat. If air be in excess, the mixture explodes, and the gas takes

Fig. 5926.

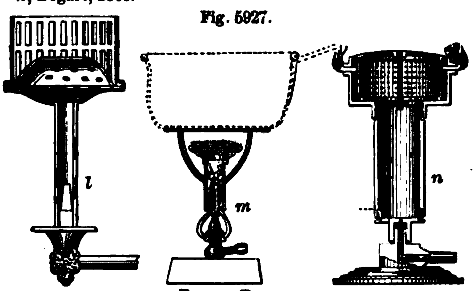


Bunsen Burners.

fire within the tube. See Griffin's "Chemical Handicraft," London, 1866, pages 96, 97. See also "Die Spectralanalyse," Schellen, Braunschweig, 1870, page 18.

Figs. 5924, 5925, 5926, 5927, show the mode of application, and several forms of the device.
a, from Griffin.
b, Rosette-burner (Griffin).
c, Rosette-burner (Griffin).
d, Bogart, 1867.
e, Allen; patent, September 7, 1869.
f, Bradley, 1865.
g, McGlensey; patent, June 19, 1860.
h, Osmond; patent, March 14, 1865.
i, Griswold, 1868.
j, Bloxam's "Chemistry."
k, Webb and Parkin, 1871.
l, Lasear and Sharp, 1868.
m, Hamilton; patent, April 26, 1870.
n, Bogart, 1866.

Fig. 5927.



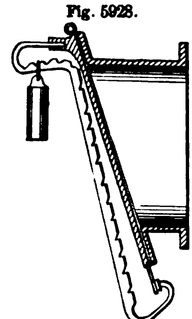
Bunsen Burners.

Stove-damp'er. A shutter or valve to regulate the size of an opening at which air is admitted to a stove, or at which smoke passes off. See DAMPER.

Fig. 5928 shows a hinged damper applied to the draft-hole of a furnace. The in-rushing air tends to close it, the gravity of the damper and the slip-weight to open it. By adjusting the position of the slip-weight, the quantity of air admitted to the fire can be regulated.

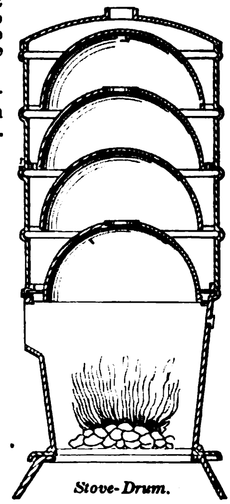
Stove-drum. A chamber above a stove in which the heated products are disseminated, in order that their heat may be more perfectly abstracted.

Fig. 5928.



Furnace-Damper.

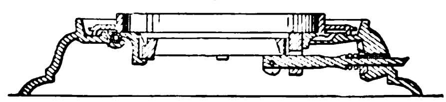
Fig. 5929.



Stove-Drum.

In Fig. 5929, the caloric current is deflected by domed plates, each alternate one having an aperture in the apex, and all having passages around their sides. The side passages of the centrally perforated deflectors are governed by an annular register-damper. See DRUM.

Fig. 5930.



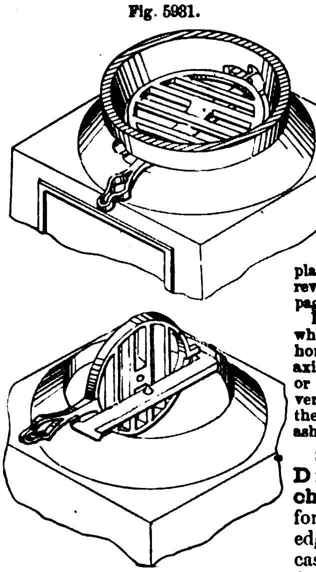
Shaking Stove-Grate.

Stove-grate. The grid or series of bars on which the fuel rests in a stove.

Fig. 5930 shows a shaking-grate in which the bed-plate rests on balls moving in slots in the base of the stove. A lug extends down on one side of the bed-plate, to which one end of the grate is pivoted, while the other is supported by an arbor in a loop on the opposite side, by which the bed-plate is rotated and grate revolved. See GRATE, page 1013.

Fig. 5931 is a grate which may be shaken horizontally about its axis to remove the ashes, or may be tilted into a vertical position to dump the spent fuel into the ash-pit.

Fig. 5931.



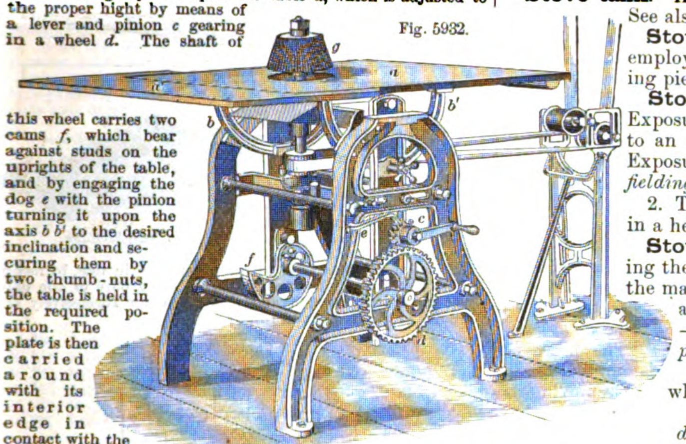
Dumping Stove-Grate.

Stove-plate Dressing-machine'. A machine for dressing off the edges of stove-plate castings, so as to form tight joints,

smoothing out the interior of the holes, etc. The operation is far neater and more rapid than filing.

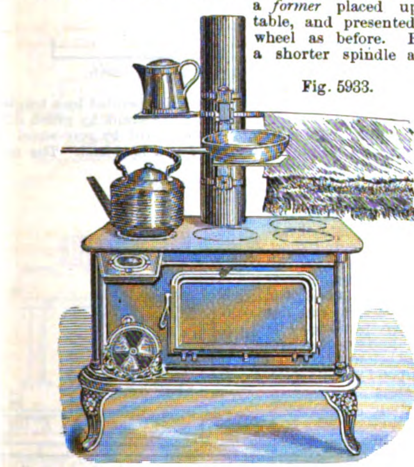
The casting is placed upon the table *a*, which is adjusted to the proper hight by means of a lever and pinion *c* gearing in a wheel *d*. The shaft of this wheel carries two cams *f*, which bear against studs on the uprights of the table, and by engaging the dog *e* with the pinion turning it upon the axis *b b′* to the desired inclination and securing them by two thumb-nuts, the table is held in the required position. The plate is then carried around with its interior edge in contact with the emery-wheel *g*, rapidly rotated by a pulley on its upright shaft, polishing this part of the plate. For dressing the outside edges, an additional table *a′* secured to the front of the main table is used. The plate is laid upon a *former* placed upon this table, and presented to the wheel as before. By using a shorter spindle and cup-shaped wheel, the machine may be employed for surface-grinding.

Fig. 5932.



Stove-Plate Dressing-Machine

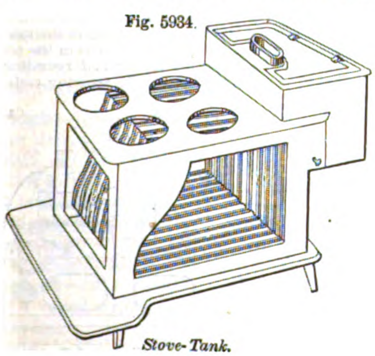
Fig. 5933.



Stove-Shelf.

Stove-shelf. An attachment to a stove to hold vessels, cloths, and what not. It has a collar encircling the stove-pipe, and is hinged, so as to project in any desired direction.

Fig. 5934.



Stove-Tank.

Stove-tank. A reservoir attached to a stove. See also Figs. 4268, 4269.

Stove-truck. (*Founding.*) A truck employed in cannon-foundries for moving pieces of ordnance.

Stov′ing. 1. (*Vinegar-making.*) Exposure of *malt-wash* (*gyle*) in casks, to an artificial heat in closed rooms. Exposure in the open air is termed *fielding*.

2. The exposure of printed fabrics in a heated room to fix the color.

Stow. A raised structure containing the furnace and set of pots used in the manufacture of tin-plate. The pots are arranged in a series of five, — *tin-pot*, *wash-pot*, *grease-pot*, *pan*, *list-pot*. See Tin-plate.

Stow′board. A place into which rubbish is put.

Stowce. (*Mining.*) *a.* The *drawing-stowce* is a small windlass.

b. Stowces. Pieces of wood of particular forms and constructions placed together, by which the possession of mines is marked; a pair of *stowces* possess a *mear* of ground.

Stow′ing. (*Mining.*) Rubbish (*attle*) put into old workings (*goafs*) to fill them up.

Stra-bis′mus-for′ceps. A straight or curved pinchers, with fine rat-tooth extremities for holding the muscles to be divided in correcting strabismus.

The operation for strabismus was first performed by Diffenbach in 1839, by dividing one of the six small muscles which rotate the eye.

Fig. 5935.

Strabismus-Forceps.

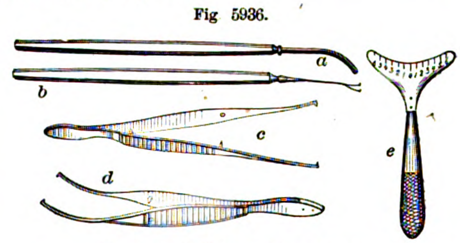
Stra-bis′mus-in′stru-ments. (*Surgical.*)

a, half-curved strabismus-hook.
b, strabismus double-hook.
c, straight strabismus-forceps.
d, curved strabismus-forceps.
e, strabometer. See also Scissors.

Stra-bis′mus-scis′sors. Scissors with straight or curved blades, for dividing the contracted muscles causing strabismus.

Stra-bom′e-ter. (*Surgical.*) An instrument for measuring the want of concordance of the optic axes. See *e*, Fig. 5936.

Fig 5936.



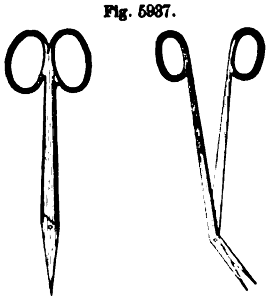
Tiemann's Strabismus-Instruments.

Stra′bo-tome. (*Surgical.*) A knife for operating for strabismus.

Strad′dle-pipe. (*Gas.*) A bridge-pipe connecting the retort with the hydraulic main. The lower figure shows one usual form, in which the eduction end of the pipe dips below the surface of the water in the hydraulic main. See Dip-pipe.

The upper figure is an improved form, in which the trap is formed in the head of the pipe without the necessity of carrying its exit aperture down into the hydraulic main.

Fig. 5937.



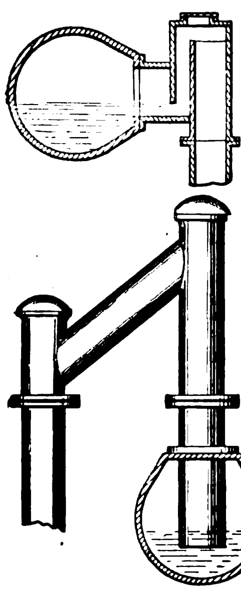
Strabismus-Scissors.

Strad'dle-plow. A plow with two triangular, parallel shares, a little distance apart, and used for running on each side of a row of dropped corn, to cover the seed.

Strad'dling. (*Vehicle.*) Applied to spokes when they are arranged alternately in two circles in the hub. Also said to be *staggered.*

Strag'gling. (*Stone-working.*) The process of working down the face of a grindstone to a regular shape, or of removing metallic particles which have become imbedded therein. The grindstone is turned as usual, while a ½-inch square piece of soft iron is applied to it as a turning-tool, a rocking or wriggling motion being imparted to the iron, which causes it to bite upon the stone. Also known as *ragging.*

Fig. 5938.



Straddle-Pipe.

Straight-arch. (*Architecture.*) A kind used for the heads of doorways and windows. It is formed of *voussoirs,* but has a level *intrados.*

Straight-arm Pul'ley. One with radial arms or spokes, like *m l n*, Fig. 3999, page 1819, and not curved like that at *v*, same figure.

The straight-armed pulley can be made with the least possible metal and the greatest possible strength for the metal. Its form is the best able to transmit the peculiar strains brought to bear upon it, and at the same time it is the most pleasing form to the eye.

Pulleys must be high on face for a belt not shifting, and straight on face for a shifting belt. A pair of fast and loose pulleys require that both pulleys should have faces high in center.

Straight-edge. A strip of metal or wood of proved rectitude, used to test the flatness of a surface or the straightness of an edge.

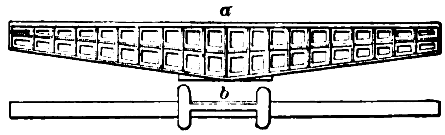
By a combination of 3 straight-edges, their absolute truth or incorrectness may be established; being tried in three binary combinations and shifted end for end and top and bottom, no fault common to them all can escape notice.

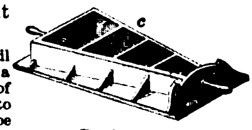
In Fig. 5939, *a b* is an elevation and top view of one of Whitworth's long straight-edges; these are from 6 to 10 feet or more in length, made of cast-iron, and ribbed at the back to prevent flexure of the fiducial edge.

c is a surface-plate, for verifying plane-surfaces. See PLANE-SURFACE, page 1726.

Straight'en-ing-ma-chine'. (*Metal-working.*) One for taking the twist or bend out of rails, shafting, bars, rods, and tubes; or the kink and bend out of hoop-iron or wire; or the buckle out of plates.

Fig. 5939.

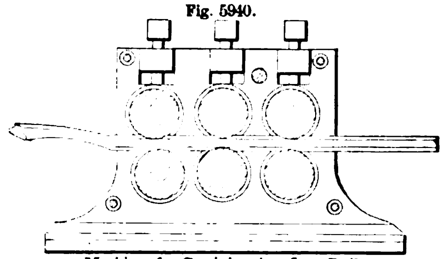




Straight-Edge.

Fig. 5940 is a railway-rail straightener. It consists of a suite of three or more pairs of rolls, each pair being grooved to correspond in size and shape with the rail to be straightened. The rolls are so arranged that the grooves of the several pairs are perfectly in line, by means of which the rail, after having entered the groove of one pair, will be drawn through and made to enter successively the grooves of the second and third pairs.

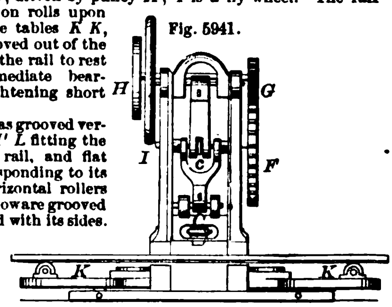
Fig. 5940.



Machine for Straightening Iron Rails.

In Fig. 5941, the sliding press-drop *C* is operated by a toggle-joint *c*, whose central pin is connected to a crank by which it is actuated. The toggle-joint crank is operated by gear-wheel *F* and pinion *G*, driven by pulley *H*; *I* is a fly-wheel. The rail is supported on rolls upon the vibratable tables *K K*, which are moved out of the way to allow the rail to rest upon intermediate bearings in straightening short bends.

Fig. 5941.



Drop-Press for Straightening Railroad-Rails.

Fig. 5942 has grooved vertical rollers *I' L* fitting the head of the rail, and flat rollers corresponding to its bottom; horizontal rollers above and below are grooved to correspond with its sides. As it passes between these its curvatures are rectified.

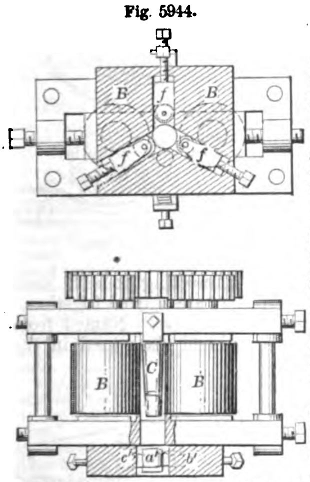
The straightening of metallic plates is performed with the hammer or by rolling. In the former case the work is the reverse of that of *raising*, in which the plate is stretched at the center and caused to assume a concave form. In straightening, each cockle or protuberance is treated as a rise, which is to be obliterated by an equal tension upon or stretching of all other parts, resulting in a plane.

Fig. 5944.



Machine for Straightening and Rounding Shafting.

In straightening by the roller, the plate is passed twice between the rollers, each side alternately upward, and is bent in each trip to the limit of its elasticity; the result, under favorable circumstances, is to reduce all outlying irregularities and reduce it to a plane. This is similar in principle to the action in wire-straightening.

The practice as to thick and thin plates differs, as it is possible, with a thick plate, to stretch the concave side of a protuberance to such an extent as to balance the tension or stretched condition of the convex side, and thus make a plane. The blows of the hammer are delivered inside the concavity.

See also WIRE-STRAIGHTENER.

Straight-joint. 1. A joint which does not curve or depart from a straight line.

2. Said of the junction line of flooring boards when the joints at the butting ends of the boards form a continuous line.

Straight-line Chuck. A peculiar chuck fitted to a rose-engine when the patterns are required to follow a straight instead of a curved direction.

Straight-of-breadth. (*Shipbuilding.*) That part of a vessel where her cross-sections are vertical at the sides.

Straight-stall. (*Mining.*) An excavation made into the thick coal, having the solid coal left on three sides of it.

Strain′er. A device partaking of the character of a *sieve* or of a *filter*. The domestic strainer is like the former; the pharmaceutical, like the latter.

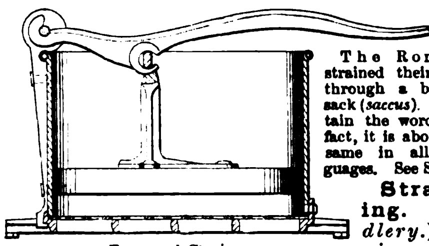
Fig. 5945 shows a domestic filter for pressing juice from fruit, water from vegetables, etc. The strainer rests upon a grating in the bottom of a casing, and articles are pressed by a follower operated by a lever. See FILTER.

Fig. 5946 is a *mushroom-strainer*, so called from its form. It screws on to the end of the suction-pipe of the pump. From the way in which the water enters, it is decanted, as it were, not disturbing the sediment on a lower level.

The *Hippocrates sieve* is a simple and very ancient form of filter. It may be made by folding diagonally a square of flannel or muslin and sewing it along the meeting edges, so as to make it of a funnel shape.

Another form is a pouch, made by uniting the opposite angles of a square piece of cloth.

Fig. 5945.



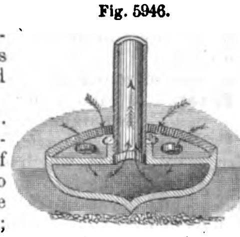
Press and Strainer.

The Romans strained their wine through a bag or sack (*saccus*). We retain the word. In fact, it is about the same in all languages. See SACK.

Strain′ing. (*Saddlery.*) A piece of canvas or leather, which, being drawn tightly over the *tree*, forms the foundation for the *seat* of the saddle.

This is covered by *cross-straining*, the *ground seat*, the *set* or *filling*, and the latter by the *top-seat*.

Fig. 5946.



Suction-Pipe Strainer.

It is called the straining, because the *stretch* is taken out of it by repeated *wettings* and *stretchings*.

Strain′ing-beam. The piece situated between the upper end of the *queens* of a frame to resist the thrust of the rafters. See ROOF; QUEEN-POST.

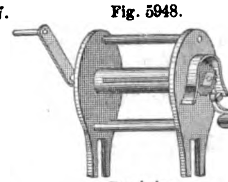
The *straining-sill* is at the feet of the queen-posts.

Strain′ing-fork. (*Saddlery.*) A tool used in straining the webbing over saddle-trees. The prongs pass through the webbing and catch against the tree, the tool being used as a lever to strain the damp webbing as tightly as possible while it is secured by tacks.

Fig. 5947.

Straining-Fork.

Fig. 5948.



Straining-Reel.

Strain′ing-leath′er. (*Saddlery.*) A kind of web forming the seat of a hussar-saddle.

Strain′ing-reel. (*Saddlery.*) A tool for *taking the stretch out* of webbing before putting it on the tree, as a foundation for the saddle-seat.

Strain′ing-sill. (*Carpentry.*) A piece of timber

on the *tie-beam*, between the feet of the *queen-posts*, to hold them against the thrust of the struts. See QUEEN-POST.

Strake. 1. (*Shipbuilding.*) A continuous line of planking or plates on a vessel's side; reaching from stem to stern.

Wales, in merchant-vessels, are strakes below the *sheer-strakes*.

Sheer-strakes are those between the main-deck ports and the *plank-sheer*, which rests on the top timbers of the frame.

Channel-wales (*in two-decked ships of war*) are the strakes between the ports of the lower and main decks. In three-deckers, they are those between the middle and main-deck ports.

Middle-wales (*in three-deckers*) are the strakes between the gun-deck ports and those of the middle deck.

The planking between the ports, fore and aft, is called *short-stuff*.

The *main-wales* are four strakes of planking, or the corresponding breadth of plating immediately below the *black*-strake.

The *black*-strake is the one next below the lower or gun-deck ports.

The *bilge*-strakes are upon the broad and flatter portion of the vessel's bottom.

The *garboard*-strake is next to the keel.

The *limber*-strakes are a part of the inner skin, and are next to the keelson, from which they are separated by spaces called the *limbers*, which are passages for bilge-water, and covered by movable boards.

The other portions of the inside skin are the *ceiling* or *foot-waling*.

The strakes immediately below the *shelf-pieces* which support each tier of deck-beams are called *clamps*.

A *binding*-strake is a longitudinal plank half notched into the beams of a ship. Sometimes called a *letting-down* strake.

A *sheer*-strake (in a boat) has its upper edge flush with the top of the gunwale, and its lower edge overlapping the *landing*-strake.

A *landing*-strake is that immediately below the gunwale.

The *binding*-strake is next below the *landing*-strake.

A *wash*-strake is above the gunwale, and is removable.

Strakes are divided by *seams*.

The *joints* formed by *planks* in a *strake* are called *butts*.

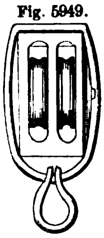
2. (*Mining.*) An inclined trough for separating ground ore according to gravity, by means of a flow of water. A *launder*. The process is known as *tying*.

3. (*Vehicle.*) A band on the fellies; in sections, and not continuous like a tire.

Strand. An assemblage of several twisted yarns wound together. Hemp is twisted into a *yarn*; and several of the latter are twisted together, or, as it is called, *laid up* into a rope. Three strands thus laid are said to be *hawser-laid*, the twist being the reverse of the individual yarns. Four strands thus twisted constitute the *shroud hawser-laid*.

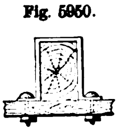
Strap. A band of leather or metal forming a fastening.

Fig. 5949.



Block-Strap.

Fig. 5950.



Strap.

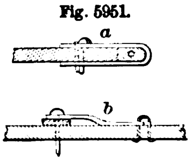
1. (*Nautical.*) *a.* One of the rudder bands, which also holds a *pintle*, which hooks into an *eye* on a *brace* bolted to the stern-post.

b. A band of rope or metal around the *shell* of a tackle-block, by which its *hook*, *eye*, or *tail* is attached thereto.

2. (*Carpentry.*) A band of iron around a beam at a scarf-joint or elsewhere. See some of the instances in Fig. 4660, SCARF.

3. (*Machinery.*) A band over the end of a rod to hold a connecting-pin or wrist. The example has a key and wedge to tighten the parts together.

Fig. 5951.



a, Rod-Strap.
b, Hammer-Strap.

4. (*Vehicle.*) *a.* A plate on the upper side of the tongue and resting upon the double-tree, to assist in holding the wagon-hammer.

b. A clip, such as that which holds the spring to the spring-bar or to the axle.

c. The stirrup-shaped piece of a clevis.

5. (*Harness.*) A leathern thong, provided with a buckle, by which separate parts of a set of harness are connected together.

6. (*Wear.*) A slip of leather or cloth to fasten a boot, a valise, or trunk; used in connection with a buckle. A girth or band around a trunk or package, such as a rolled shawl, blanket, or coat.

Fig. 5952.

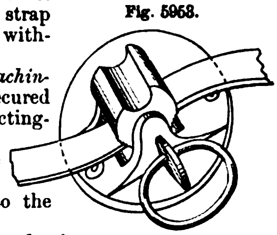
Strap-Block.

7. A piece of leather with fine emery or polishing-powder, to sharpen a razor or knife. A *strop*.

Strap-block. (*Nautical.*) A block with a strap around it, and an eye worked at the lower end for attachment to a hook upon deck for a purchase.

Strap-clamp. A device to hold a hitching-strap. The cam, being free to turn upon its pivot, bites the strap and holds it firmly when it is pulled upon in either direction. By holding the cam in its middle position, the strap may be inserted or withdrawn.

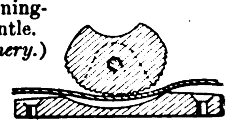
Fig. 5953.



Strap-head. (*Machinery.*) A journal-box secured by a strap to a connecting-rod. See STRAP, 3.

Strap-hinge. One with long flaps, by which it is secured to the door and post.

Fig. 5953 has strengthening-lips, and a spring on the pintle.



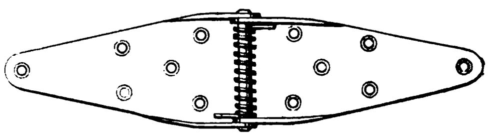
Strap-Clamp.

Strap-joint. (*Machinery.*) A connection by strap, key, and gib, as on the end of a pitman. See STRAP.

Strap'ping-plate. (*Mining.*) One of the straps or bands which bind the connecting rods to each other at the points where they are scarfed together.

Strass. 1. (*Glass.*) Fr. *Strasse.* Named from its German inventor. A pellucid glass used in the manufacture of artificial gems. It contains a large quantity of oxide and borate of lead. It is easily fused, is soft and very refractive.

Fig. 5954.



Strap-Hinge.

2. (*Silk.*) The refuse of silk in the process of working into skeins.

Stra-tom'e-ter. An instrument for determining in what manner geological strata press upon each other. *Mayne.*

Straw. 1. The stalk of wheat or other small grain; or of some descriptions of grass. The principal use of this material in the industries of this country and Europe is in *thatching*, *plaiting*, and *paper-making*.

2. (*Mining.*) A fine straw filled with powder, and used as a fuse.

Straw-board. Thick paper-board made altogether or principally from straw; usually that of wheat or rye.

The first process consists in boiling the straw with quicklime, in a wooden digester, which takes steam from a boiler. The

straw is packed in layers with lime between them, and the whole boiled for from 10 to 12 hours, according to circumstances. (See PULP-DIGESTER.) Straw is composed of a tube of woody fiber and cellular tissue, having upon its outer surface a cuticle composed of silicates of potassa and soda with some free silica. The woody fiber also contains some silica. To the silicious cuticle the straw of grain or grass owes in great part its strength. In the boiling process, the lime and the silica combine, which leaves the straw in a soft and pulpy state. The mass is now ground into pulp, and then drawn into a vat, which contains water, and kept constantly agitated by a series of revolving arms. A wire-gauze cylinder is so adjusted that it will revolve partially beneath the surface of the fluid mass. The pulp adheres to the gauze, and is carried around to another cylinder, around which an endless belt of felt runs. The latter cylinder presses upon the gauze, and by this means the pulp is made to adhere to the felt, and condensed so as to give it enough consistency to be taken up by another cylinder, called the *forming* cylinder. This is one of a pair made of polished metal, and by them the pulp is strongly compressed. The pulp is wound around the *former* until the proper thickness is reached; this is determined by an indicator. Along the forming cylinder there is a groove planed out, through which the operator now rapidly passes a wooden knife, thus severing the soft board; and at the same time he unwinds the sheet and removes it. These sheets are cut so as to form other sizes, and then dried, which completes the process. Woolen rags are sometimes ground and mixed with the straw pulp. This makes a much darker colored and heavier board, which is worth considerably more than the pure straw-board. The boards, as thus manufactured, are applicable to a great variety of useful purposes, among which book-binding, button-making, and paper-box manufacture are most prominent

Until lately, the white lining of these boards was pasted on by hand, but now the white paper is put on by a machine at the rate of 20 sheets a minute. This machine is automatic in its movements; it pastes the boards, lays on the white paper from a continuous roll, dries, presses, and calenders them, so that when the boards leave the machine they are immediately ready for the box-manufacturer.

Straw-boil'er. A vessel for macerating straw to form paper-stock. See Figs. 4008, 4009, and following cuts.

Straw-braid.

Rye-straw is commonly used for braid in this country. It should be cut when the grain is in the milk, tied up in small bundles, the heads cut off, and the straw dipped in boiling water. It is then dried in the sun, being taken in at night to avoid exposure to dew. For hats the whole straw is used. For bonnets it is split, and the part under the husk removed. The tool used for splitting straw is a piece of wood five inches long, having a series of sharp spurs near the end, and a wooden or metal spring at one side to press down the straws as they are drawn through. The straw is wetted previous to braiding to make it pliable.

A nicer method of splitting, practiced in Europe, is by means of a wire having four, six, or eight sharp edges, which is pushed up the hollow of the straw, dividing it into an equal number of parts. The varieties of braid are very numerous, depending on the size and kind of straw, whether split or whole, and the patterns formed by the different methods of interweaving.

The Leghorn, or Italian straw-braid is made from a variety of wheat cultivated for this purpose. The straw is harvested in the mountainous regions of Prato, Empoli, etc., where the vegetation is poor and stunted, the soil being light and sandy.

The fields are worked and weeded by hand. 14 bushels of seed are usually sown to the acre; two bushels being "broadcast" at each time, and each sowing made at a different angle to the first. The effect of this is to produce a very close, compact growth, and only one elongated stem rises from each seed sown.

The straw is harvested while green, and before the ear is fully developed. It is gathered into small sheaves, weighing about half a pound each, which are at first placed upright in the field to dry, one acre bearing about three thousand of them. Next day these bundles of straw are spread out over rocks and pebbles in the dry bed of water-courses, where they are submitted to the action of sun and dew. At night they are covered up to protect them from rain. The straw is then bleached by means of sulphuric-acid gas.

The ear is next taken below the first joint, the lower useless portion separated, and the straw cut into lengths of four inches. Each blade of straw usually furnishes three such lengths. It is then bleached again.

At this point the straws are sorted according to their various sizes, — an operation performed by women who acquire, through long habit, a most remarkable tact in distinguishing the smallest variation in diameters, as may be inferred from the fact that in front of each operator are placed goblets numbered from 30 to 180, each of which is the receptable for a special size of straw.

The braids are plaited with from 11 to 13 straws each. Their length is from 300 to 320 feet, their width and the quantity of straw entering into them varying according to quality. With No. 30 straw the braid is coarse and wide, and weighs two pounds and a half. It takes, however, a whole month to plait a single bonnet from such straw. With Nos. 120 to 180 it takes about one pound and a half of straw to a braid. With extra straw (No. 180) the braids are not more than 0.039 of an inch in width, and it takes six months' labor to make a sufficiency for a single bonnet for a lady.

The braids are cleaned, exposed to the sun for a short time, and then sent to the manufacturer to be sewn into shape. This last operation is performed with the very greatest care, the stitches being nearly invisible and yet strong, and not liable to unravel during the pressure to which the hats are often subjected after being sized.

The hats are "ungreased," and any bumps or protuberances on their surface are effaced by rubbing one portion of the tissue against another, or by means of friction with a dog-skin glove.

Straw-car'ri-er. 1. An endless apron in a thrashing-machine to lift the straw as it comes from the cylinder, and discharge it at the tail of the machine. The carrier being of open work, the grain and chaff are sifted out on the way. See THRASHING-MACHINE.

2. A straw-elevator at the end of the thrasher to lift the straw on to the rack.

Straw-cut'ter. *Cutting-boxes* or machines for reducing long feed, such as straw, hay, or corn-stalks, to chaff are very numerous and varied.

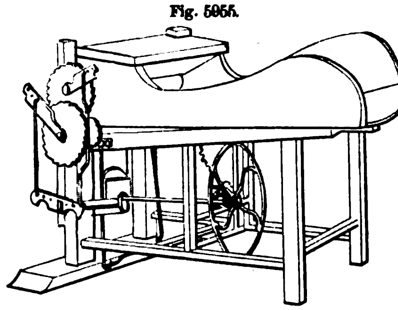
They may be classed under certain heads.

I. The guillotine-knife, operating in a straight line upon the straw which issues at a throat. *The knife reciprocates.*

II. The radial or curved knife, attached to a wheel revolving on an axis parallel to the direction of the feed, and thus cutting off the straw as it issues from the throat of the machine. *The knife revolves in the plane of its length.*

III. The cutting roller or pair of rollers with knives, between which the straw passes. *The knives are across the throat of the machine.*

Fig. 5955.

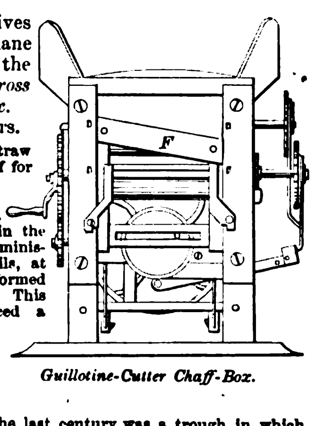


IV. Cutting knives revolving in the plane of the direction of the feed, and *cutting across the mouth of the box.*

V. Straw-grinders.

The Hebrews cut straw and grain in the sheaf for food.

Hohlfield, of Saxony, 1711-1771, invented a straw-chopper, while in the service of the Prussian minister, Count de Podenils, at Gusow. We are not informed as to its construction. This inventor also produced a thrashing-machine, an odometer, a pedometer, a loom for figured fabrics, a harpsichord, and several other ingenious machines.



Guillotine-Cutter Chaff-Box.

The chaff-cutter of the last century was a trough in which the straw or hay was pushed along by a fork, so as to be exposed at the end of the trough to a knife which was pivoted at one end, and oscillated by hand.

I. Of the guillotine knives, some make a simple straight cut, others an oblique cut, others a draw cut.

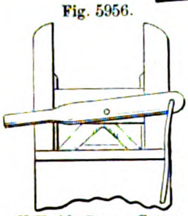
a. The straight cut is when the whole edge of the knife is brought into contact at once with the body of straw. This is so inferior in its results that it needs not to be illustrated.

b. The knife is presented obliquely so as to commence at one corner of the throat and terminate at the diagonally opposite corner.

This form is seen in the early patents of Hotchkiss, August 2, 1808, and January 18, 1817.

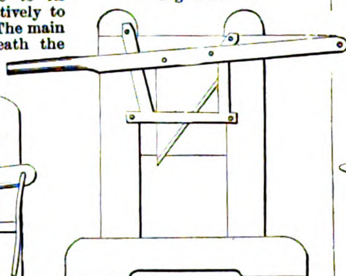
Fig. 5955 may be given as a sample. The knife *F* moves in vertical guides, the *draw* of the cut being due to its oblique position relatively to its line of motion. The main shaft is placed beneath the

Fig. 5956.



V-Knife Straw-Cutter.

Fig. 5957.



Angular-Knife Straw-Cutter.

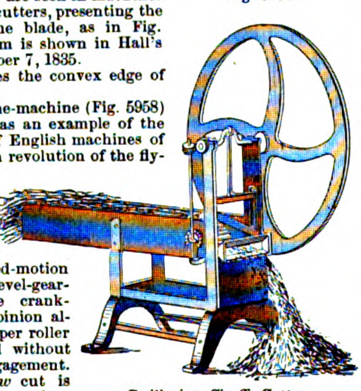
box and operates the knife-gate by a wrist-pin. A cam on the shaft also operates the lever which actuates the ratchet feed-wheels by means of connecting-rods.

Modifications are seen in machines with V-shaped cutters, presenting the concavity of the blade, as in Fig. 5956. This form is shown in Hall's patent, November 7, 1835.

Fig. 5957 uses the convex edge of the knife.

The guillotine-machine (Fig. 5958) may be taken as an example of the present state of English machines of its kind. Each revolution of the fly-wheel and crank gives an effective cut to the oblique guillotine-knife. The feed-motion is derived by bevel-gearing from the crank-shaft, a long pinion allowing the upper roller to rise or fall without risking a disengagement.

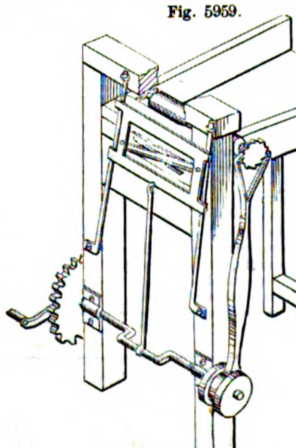
Fig. 5958.



Guillotine Chaff-Cutter.

c. The *draw* cut is when the knife receives a positive endwise motion in addition to its descending motion. The latter is the most efficient.

Fig. 5959.



Draw-Cut Straw-Cutter.

In Fig. 5959, the knife has cutting edges above and below, and is reciprocated in inclined guides, which give it a positive endwise motion.

Fig. 5960.

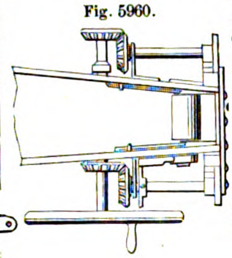


Fig. 5960 is a machine in which the knife is also double-edged. The ends of the knife are attached to separate co-acting cranks, which give a downward and lengthwise motion to the knife.

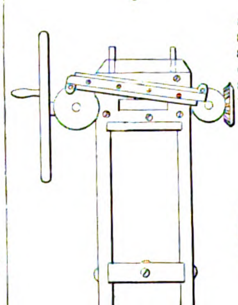
In Fig. 5961, one end of the knife is operated by a crank, while the other depends from a swinging arm.

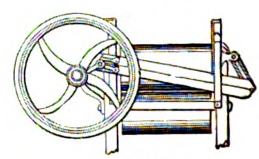
Class II. Knife cutting in a plane at right angles to the feed.

The knife is curved, so as to act diagonally across the body of straw, moving with the edge in advance. The feed is by a worm on the axis of the cutter-wheel, acting on wheels upon the axes of the feed-rollers. The feed is continuous, the straw advancing the length of the chaff between each cut.



Double-Edged Straw-Cutter.

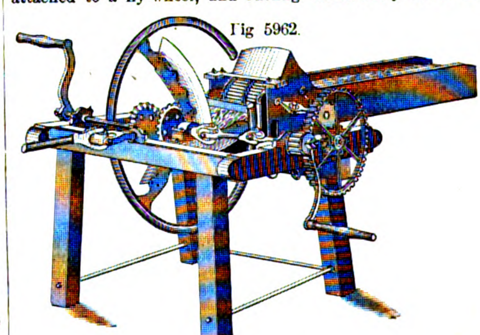
Fig. 5961.



Straw-Cutter.

Lester's machine, patented in England in 1800, had a knife attached to a fly-wheel, and cutting transversely across the throat. The earliest feed was an endless web of cloth passing over two rollers; but Heppenstall's improvement, patented in 1818, substituted a worm to turn two feeding-wheels to convey the straw to the knives attached to two arms of the fly-wheel.

Fig. 5962.



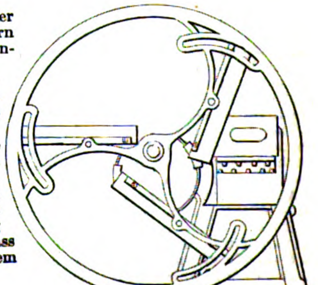
Corne's Chaff-Cutter.

Corne's straw-cutter (English) is a modern form of the same general design.

It has capacity for adjustment to cut chaff from ⅛ inch to 4 inches long.

Fig. 5963 has three knives, which are pivoted to the wheel-arms and governed by an eccentric, so as to have a rocking motion as they pass the throat, giving them a draw cut.

Fig. 5963.



Straw-Cutter.

Class III. has several varieties :

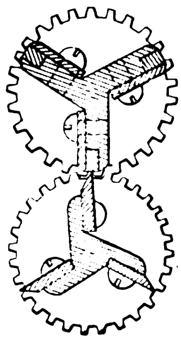
a. Radial knives mutually interlocking, as in the Sanford patent, October 12, 1843.

b. Knives cutting against a flat-faced roller, usually made of leather or raw-hide disks on a mandrel.

Fig. 5964 has spiral knives, with roller.

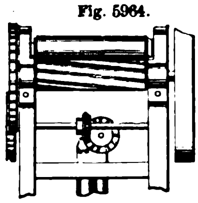
In Fig. 5965, the edges of the spiral knives cut against corresponding surfaces of comparatively soft metal which are clamped in the arms of the cylinder above.

Fig. 5965.



Straw-Cutter.

Fig. 5964.



Spiral-Knife Straw-Cutter.

c. In Fig. 5966, one roller has spiral knives and the other spiral abutment corrugations, whose intervals are entered by the knives.

The furze-cutter of England has interlocking spiral knives, like that just described. See Fig. 946, page 392.

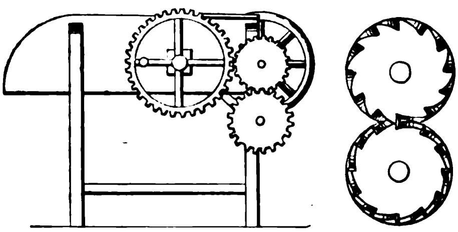
d. Rollers with spiral flanges mutually interlocking, as in the Macomber patent, November 5, 1850.

Fig. 5967 is an illustration of a machine in which the flanges make a shear-cut past each other.

IV. Cutting-knives upon a cylinder on a horizontal axis in front of the throat, and cutting toward the opening.

Salmon of Woburn, England, about 70 years since, introduced the oblique knife attached, cylinder fashion, between two

Fig. 5966.



Spiral-Knife Straw-Cutter.

wheels and cutting toward the throat of the straw-box; revolving in the same plane of motion as the straw is moved.

The feature is also seen in United States patents, Eastman, January 29, 1822; Denson, May 2, 1835.

In Fig. 5968, the cutters extend diagonally along the cylinder, being secured at their ends to the rims of the cylinder-heads. A sheet-iron band forms the periphery of the cylinder.

In Fig. 5969, the hay, after being cut, is crushed between rollers, and winnowed to expel the dust.

V. Feed-grinders.

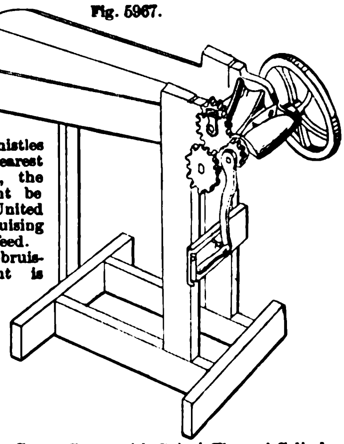
Fig. 5970 has a series of circular cutters *C* on a horizontal shaft. The knives work against an apron *J*, and the spaces between the knives are kept clear by the fingers *L*.

Fig. 5971 has a series of circular saws on two shafts. The teeth of the larger saws are designed to split or divide the stalks, and are aided by the smaller saws to crush the articles to be cut. Notched and forked plates pass between the saws, to clear them.

Supplementary to the subject of machines for cutting straw, hay, etc., into chaff for feed, may be mentioned a machine used in England for grinding the furze (*Ulex Europæus*, also called *gorse*, or *whin*). See Fig. 946. This is a thorny, evergreen, succulent plant, which covers square miles of country, making the landscape yellow with its beautiful yellow blossoms. It is cut with bill-hooks, and handled with leather mitts. It is relished by cattle when bruised so as to mash the spines with which it is so plentifully covered.

Although we have nothing like the furze to run through the machine, thistles being the nearest approximation, the machine might be useful in the United States for bruising sheaf oats for feed.

Fig. 5967.

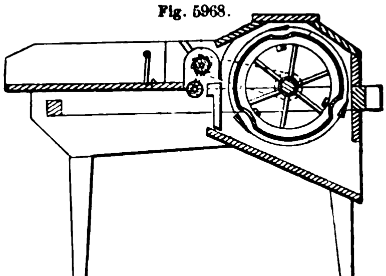


Straw-Cutter with Spiral Flanged Cylinders.

In the furze-bruiser, the plant is broken by hammers and then ground between rollers, which break and mash it. We should dispense with the hammers and be content with a mashing action which would break the kernel and scatter flour enough over the straw to make the whole mass palatable.

The peasants of Brittany use a more primitive mode of producing the same effect: a pair of pestles suspended from the

Fig. 5968.



Straw-Cutter.

ends of a bar, which is oscillated by the feet of a man standing thereon.

Straw-drain. (*Husbandry.*) A drain filled with straw.

Straw-fab'ric Loom. A loom for making goods the weft of which is of straw. Each piece of filling is laid in separately, and looms of this character are made to work with *straw*, *slats*, *splints*, *wands*, *willows*, *cane*, *rattan*, *palm-leaf*, *splints*, *whalebone*, and what not. See SLAT-WEAVING LOOM, page 2203.

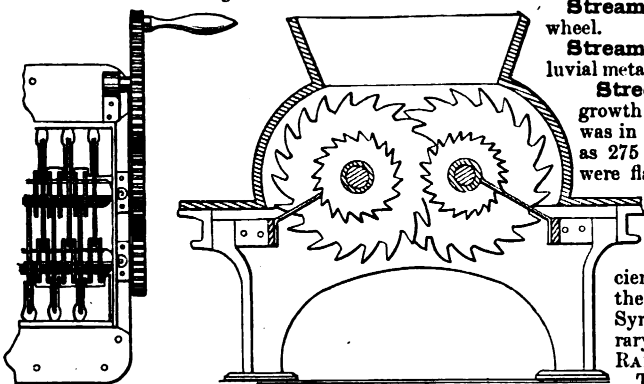
Fig. 5971.



Cutting-Machine for Hay, Straw, and Vegetables.

Straw-hat Mak'ing. Tuscan straw is prepared by pulling the wheat while the ear is in a milky state. The wheat is sown very close, so that the straw is thin and short. The straw is spread out upon the ground for three or four days in fine hot weather to dry. It is then tied up in bundles and stacked, to complete the drying. After remaining in the mow for about a month, it is removed to a meadow and spread out, that the dew, sun, and air may bleach it. During this process it is frequently turned. The first bleaching being complete, the root and lower joint are pulled off, the straw is then steamed, and afterward fumigated with sulphur to complete the process. See STRAW-BRAID.

Straw-pa'per.

Straw is cut into small pieces by a chaff-cutting machine or grinder (see Fig. 4015), and then subjected to the action of a boiling solution of hydrate of soda or potash. It is then put into a vessel with a perforated false bottom, and a pipe communicates from this to a close iron vessel containing alkaline solution, which is kept boiling by steam heat. (See PULP-DIGESTER, pages 1821-1823.) The pressure of steam in this vessel drives the alkaline solution through the pipe, and it falls in streams upon the cut straw. From 30 to 40 gallons of the solution are used to each 100 pounds of straw. The liquor is caused to circulate through the straw for 8 or 10 hours, when the liquor is drawn off, and water is run through the straw until it runs off clear. The straw is then put into a bath of hypochlorite of alumina, in order that it may be bleached and its fibers disaggregated. There it remains 12 or 13 hours, being stirred from time to time. The straw is by this time reduced to *half-stuff* of good color, when the liquor is strained off, and the pulp well washed with boiling water. It is then carried to the beating-engine, and made into paper. It is customary to use a portion of rag-pulp where a good quality of paper is desired. See Figs. 4008-4112, and pages 1821-1823.

Stray-line. (*Nautical.*) A portion of the log-line, say 10 fathoms, between the log-chip and the first knot, and left unmarked in order to allow the latter to get out of the eddy in the ship's wake before turning the glass. When the *stray-mark* is reached, the glass is turned, and counting commences. See LOG.

Streak. 1. (*Shipwrighting.*) A course of planking on a vessel's side. See STRAKE.

2. The color of a mineral, when scratched to detect the appearance of ore.

Stream-an'chor. (*Nautical.*) An anchor of a grade between the *bower*, or large anchor, and the *kedge*. Used in warping; or mooring in a place but slightly exposed.

Stream-ca'ble. (*Nautical.*) One smaller than the cable of the *bowers*, and used in mooring or riding by the stream-anchor.

Stream'er. A pennon. See FLAG.

Stream-tin. (*Mining.*) Tin ore found in lumps in diluvial formations.

Stream-wheel. An *undershot* or *current* wheel.

Stream-work. (*Mining.*) Work on alluvial metalliferous deposits; of tin, for instance.

Street-car. The street-railway was a growth from the *tram-road* system which was in use in the English collieries as much as 275 years ago. The *tramways* at first were flat boards, balks, or paving-stones, so as to allow the wheels of the *trams* (wagons) to roll more easily, and prevent the road wearing into chuck-holes. This is a very ancient device, as old as the moving of the obelisks and ashlars of Egypt and Syria upon rollers running on a temporary track of timbers. See TRAMWAY; RAILWAY.

To this succeeded *rails* of wood, which are described, in a publication of 1676, as being shaped so that the "four rollers" of the wagon "fitted" to them. They were laid on transverse sleepers and secured by wooden pegs. It may be said with truth that these tram-roads were the precursors of our street-railways, as they united the cities with the suburbs.

Wooden rails with malleable iron caps were used in 1716.
Cast-iron rails in 1767.
L-shaped rails in 1776.
Rolled rails in 1820. See RAIL, pages 1857, 1858.

The railways originated in the collieries of the North of England, and the iron district of Shropshire.

They were at first used entirely for freight. When rails were invented it was a century and a half before steam-cars were made to run upon them. On the early railways of England horses were employed for 150 years. The Milton and Quincy, Mass., Railway, 1826; the Baltimore and Ohio, 1830; the Mohawk and Hudson, N. Y., 1830, were all worked by horses at the first. See RAILWAY, page 1861. The steam-car was at first made for common roads, as the steamboat was first made for canals. The early steam-carriages were those of

Cugnot (French).........1769	Evans (American)........1787
Hornblower (English)....1769	Medhurst (English)......1800
Symington (Scotch)......1770	Bompas (English)........1828
Murdoch (English).......1784	See STEAM-CARRIAGE.

The *locomotive*, considering the term as referring to a *steam-car on rails*, originated in Wales. The list of early inventors is about as follows: —

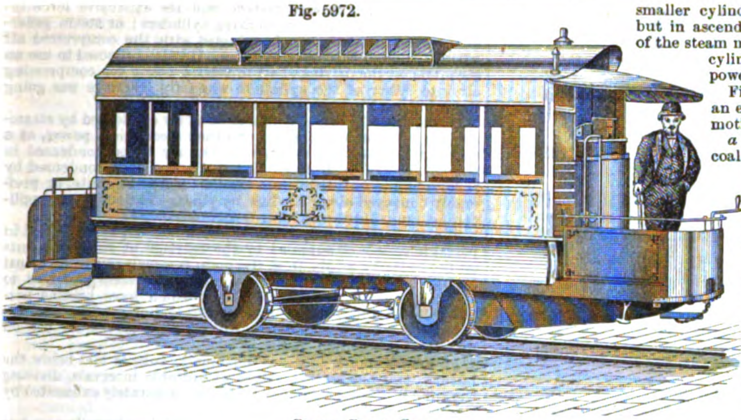
Trevethick (Wales).......1802	Stephenson (England)....1825
Blenkinsop (England)....1811	Stephenson (England)....1829
Blackett (England)......1812	Hackworth (England)....1829
Hedley (England)........1813	Braithewaite and Ericsson (England).............1829
Stephenson (England)....1815	

The three latter were contestants at the great trial on the Liverpool and Manchester Railway, in 1829. See LOCOMOTIVE, pages 1343-1347.

For other forms of steam-moved vehicles, see ROAD-ROLLER; STEAM-PLOW; PORTABLE ENGINE; TRACTION-ENGINE.

Beginning with horses, and then using stationary engines to raise or lower the wagons on grades, and to the *staiths* whence

Fig. 5972.

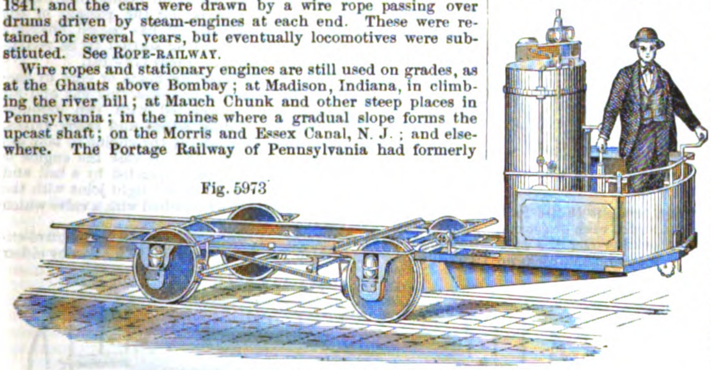


Steam Street-Car.

they discharged by chutes into the colliers, the contest for some years previous to 1829 had been between stationary and locomotive engines. Stephenson threw the weight of his influence in favor of the latter, and the trial on the Liverpool and Manchester Railway was to encourage invention on the latter plan. The London and Blackwall Railway of $6\frac{1}{2}$ miles was opened in 1841, and the cars were drawn by a wire rope passing over drums driven by steam-engines at each end. These were retained for several years, but eventually locomotives were substituted. See ROPE-RAILWAY.

Wire ropes and stationary engines are still used on grades, as at the Ghauts above Bombay; at Madison, Indiana, in climbing the river hill; at Mauch Chunk and other steep places in Pennsylvania; in the mines where a gradual slope forms the upcast shaft; on the Morris and Essex Canal, N. J.; and elsewhere. The Portage Railway of Pennsylvania had formerly

Fig. 5973



Truck and Machinery of the Baxter Steam-Car.

ten inclined planes overcoming an elevation of about 1,400 feet, going west. The western terminus of the railway is about 1,173 feet below the summit level. See INCLINED PLANE, pages 1174-1177.

Rope railways are also used in overcoming special elevations, such as the passenger elevators at Niagara, Cincinnati, and Pittsburgh; a vertical elevator for cars is used at Hoboken, N. J.

Street-railways for passenger cars were first established in the United States about 1850, and in England about ten years afterward. The Boston and Cambridge Railway, commenced in the fall of 1858, was the first in New England.

Street-cars are usually drawn by horses, but many attempts have been made to drive them by machinery. Steam-engines, known as *dummy* engines, have been used with success, but the fire and the noise of escaping steam are considered objectionable.

Fig. 5972 is a view of the Baxter steam-car; Fig 5973, the truck and machinery of the same.

The boiler is upright, and is placed on the front platform; a non-conducting partition prevents heat from entering the car.

The engine is below the platform. It is compound and double-acting. In ordinary use, the steam from the smaller cylinder exhausts into the larger; but in ascending grades, the full pressure of the steam may be made available in both cylinders, greatly increasing the power.

Fig. 5974 is the Knapp car; *B* an elevation, and *C* a plan of the motive apparatus.

a is the furnace, supplied with coal from the platform through the chute *b*; *c*, the boiler; *d d*, the cylinders. The exhaust steam is condensed by a blast of cold air from the fan-blower *f*; *g* is a smoke-pipe, terminating in a reservoir *h* containing milk of lime, to remove the carbonic acid from the smoke; this also acts as a spark and dust arrester, so that the gas, which finally issues from the pipe *i*, is invisible, and causes no inconvenience to the passengers or others.

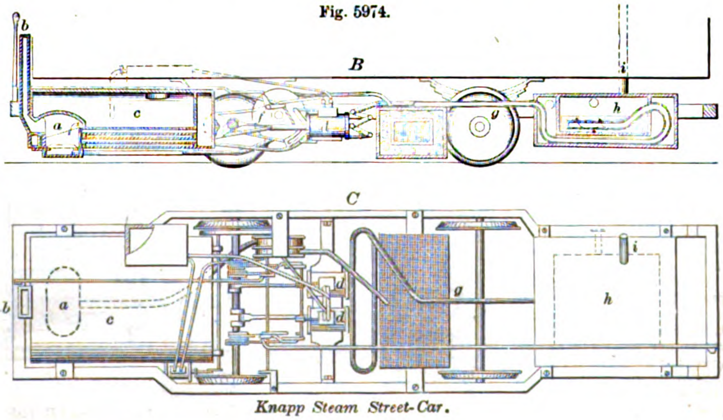
The car, Fig. 5975, has a circular cab *B*, which contains the dummy engine and boiler, and is supported on a circular platform *I* resting upon the fore truck *V*, and is provided with anti-friction rollers *h i*, upon which the front of the car body *A* rests; the shell of the cab also bears against vertical anti-friction rollers *m m*. A reach and center pin *U* connect the body and fore truck of the car, and the body is supported on a similar pivoted truck, provided with anti-friction rollers, enabling the two parts to turn independently of each other. The front and rear axles of the fore truck are coupled by connecting-rods *N*, and the rear axle *J*, which is cranked, is worked as a driver by a pair of oscillating engines. See also STEAM-CAR.

The following statement includes a number of applications of condensed air to the driving of street-cars: —

A British form of steam-locomotive, in which the engine carries no boiler, but a supply of steam sufficient for a trip, is termed the Fireless Locomotive.

Todd's combined dummy and car has a main lower frame 22 feet 6 inches long over the buffers, 7 feet wide over all, and 3 feet high from the rail to the top; and on this frame is placed the 14-feet body of an ordinary car. In the center of the frame are two receivers, each containing 30 cubic feet of water. Below the buffer-beams are screw-couplings and stop-valves with perforated pipes running right through the receivers. The wheels are 24 inches diameter, placed 4 feet 6 inches between centers. Cylinders, 9 inches diameter and 8 inches stroke, surrounded with large jackets open to the water of the receivers. At each end of the car, outside the dash-plate, is placed a brake-handle, and on either side of this a regulator and reversing handle, all arranged as shown. These latter handles fit into spring sockets,

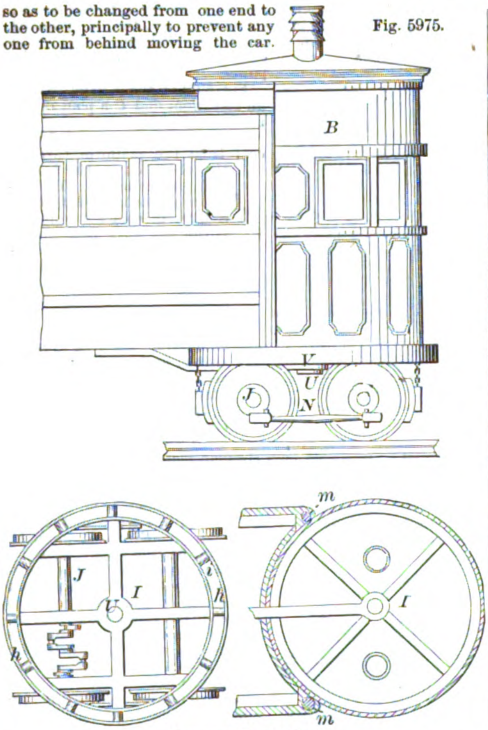
Fig. 5974.



Knapp Steam Street-Car.

so as to be changed from one end to the other, principally to prevent any one from behind moving the car.

Fig. 5975.



Dummy Street-Car.

There are four sand-boxes, with handles brought to the foot-boards. There are two exhaust-pipes, the end of each projecting slightly upward from the edges of the curtains over the foot-boards; and by a cock the waste steam is turned into whichever pipe happens for the time to be at the rear end of the car. All the working motion is quite protected from dirt by light boxes which have hinged doors at the sides. The engine is started on its journey with an initial pressure of 200 lbs. to the inch; and owing to the jacketing of the cylinders, the loss by radiation is said not to exceed 5 lbs. pressure per hour, allowing the engine to run 40 miles on level lines at one charging of the boiler.

The upper figure is a longitudinal section of the car, and the lower is an exterior elevation, also showing the stationary boiler from which the apparatus is charged.

Medhurst, English patent, August 2, 1800, proposed to propel carriages by means of compressed air carried in a reservoir, using a single-cylinder engine, or a double-cylinder engine with compound beam, according to the amount of power required.

Bompas, April 29, 1828, patented a method of propelling carriages or boats by means of air compressed by pumps in cylindrical iron vessels, with hemispherical ends placed in one or more rows underneath and behind the carriage. Fixed reservoirs to be located at appropriate stations, to replenish the air as the pressure becomes diminished in the cylinders; the compression to be from 30 to 150 pounds or upward. He preferred to use two cylinders, working expansively, if desired. The use of air or gas, condensed by being disengaged chemically from substances with which it is in combination in a confined space, is also mentioned.

Wright, April, 1828. Compressed air, contained in metallic cylinders beneath the car and charged from a stationary reservoir or by means of air-pumps, was admitted by appropriate pipes with valves to a third cylinder, where, by means of a furnace beneath, it was heated, and its expansive force increased before entering the working cylinders; or steam generated by the furnace might be mingled with the compressed air when it entered this third cylinder. He also proposed to use an eccentric on the driving-shaft to work a pump for compressing air into either of the cylinders when the carriage was going down hill, and to serve as a brake in descending.

Mann, June 1, 1829. Application of air condensed by steam-engines, wind or water mills, or other mechanical power, as a motor for vessels or carriages. The air to be condensed in portable reservoirs, to be carried on the carriages, condensed by steam-engines at the different stations along the route, or preferably conveyed along the line by pipes. Various other applications are pointed out.

Surrey, September 1, 1856. Compressed air, to be carried in portable vessels or supplied to the carriage at suitable points on the route by a tube from the main reservoir at the principal depot. In the former case, several small vessels preferred to one large one, as the air from those which have become partially depleted may be employed in descending grades, or where less power is required, and the full vessels reserved for use on up grades or for high speeds.

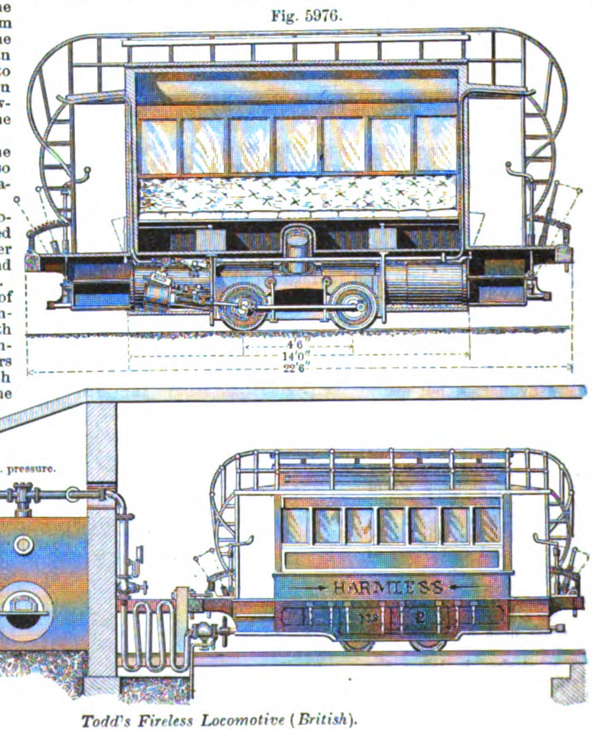
Pinkus, March 1, 1834. A pneumatic tube is laid below the railway, and has section valves at suitable intervals, dividing the tube into compartments, which are separately exhausted by engines at each of these stations.

The piston is attached to a frame or carriage traveling on two wheels, one in front, and the other behind, and having circumferential grooves fitting a continuous rib on the interior of the tubing. An arm projecting upwardly from the piston-carriage passes through a slit in the upper part of the tube, and is connected to the car, or the first of a series of cars on the railway. The slit is closed by a flexible valve arrangement, kept closed in front of the "dynamic traveler" by atmospheric pressure, but pushed aside as this advances, to admit air behind the piston. The section valves are opened to permit the passage of the traveler, and each may be closed after it has passed, enabling the work of exhaustion in the preceding section to be recommenced. See ATMOSPHERIC RAILWAY, pages 179-181.

Pinkus, August 26, 1839. Propelling boats or cars by gas-explosive engines. The engine has double-acting gas and air pumps, two piston-cylinders connected with two globular explosive chambers having igniting slides and safety-valves. Arrangements may be made for enabling the engine to take gas from the main without stopping. In this case the engine is provided with a flat pipe or tongue suspended by a ball and socket joint, and made so as to form an air-tight joint with the main or valve. The tongue is also furnished with a valve which shuts when it leaves the main or valve.

Count de Fontainemoreau, June 21, 1844. Locomotive-engines, either reciprocating or rotary, are put in motion by either

Fig. 5976.



Todd's Fireless Locomotive (British).

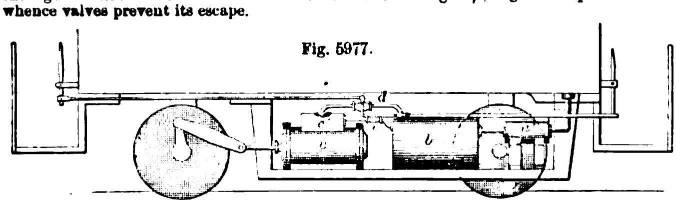
compressed or rarefied air derived from a tube along the roadway. Above the tube are fixed distributing-boxes, having a valve at bottom, and other valves at top, which are opened by a slide carried along with the locomotive and running in a groove at the top of the box, having a strip of sheet-iron on one side, and a leathern strip on the other; the valves automatically close after the slide passes over them.

Parsey, October 17, 1844. Employs a receiver and a regulating-chamber, where the density of the air is reduced, and from which it passes to the valve-box of the cylinder. After doing its work, it may be allowed to escape, or it may be forced back into the receiver by two air-pumps contained within it and communicating with the two ends of the working cylinder. See pages 603, 604, Vol. I.

Anderson, June 29, 1846. Using gun-cotton or yarn as means of propulsion. The locomotive has two cylinders, enlarged at their outer extremities, having pistons connected together by side-rods, and each furnished with a valve to allow escape of gas during the down stroke. The cotton or yarn is fed by rollers alternately in the narrow extremity of each cylinder through a small slit, and is exploded by wires from a galvanic battery.

Fell, October 7, 1847. Employs rarefied or compressed air. The latter is conveyed by a main or pipe placed centrally between the rails to reservoirs at equal distances along the line. These are located below the main, and have valved pipes passing through it, and flush with its upper surface. The main is partially embraced by a long slider attached to the engine, connected by a pipe with its air-chamber, and as the engine passes over each reservoir, levers connected with the valves of the pipes leading therefrom are struck by a bar attached to the engine opening the valves, and air passes from the reservoirs through the slider and tube into the air-chamber of the engine, whence valves prevent its escape.

Fig. 5977.



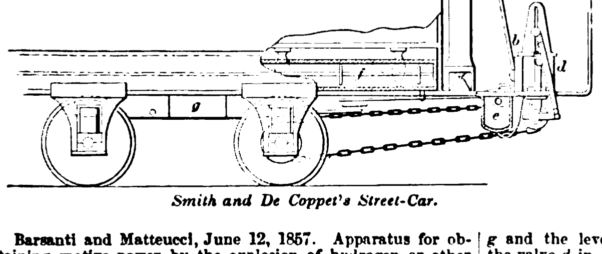
Smith's Pneumatic Engine for Street-Cars.

A different arrangement of valve is employed if rarefied air is used.

Van Rathen, November 2, 1847. High-pressure air from a reservoir is made to enter a set of expanding and warming tubes, by which its pressure is reduced from about 50 to 5 atmospheres, while retaining its heat and elasticity, and thence a moderator or chamber provided with a piston which is forced into the chamber by the action of a regulating spring or weight, and raised by the pressure of the air. From the moderator the air passes to the propelling machinery.

Johnson, June 26, 1856. Proposed to carry a small steam-engine and boiler for working two or more double-action air-pumps to compress the air into a receiver, whence it was to be delivered to the main actuating cylinders of the engine.

Fig. 5978.



Smith and De Coppet's Street-Car.

Barsanti and Matteucci, June 12, 1857. Apparatus for obtaining motive power by the explosion of hydrogen or other inflammable gas mixed with atmospheric air. In one method the vacuum produced beneath the piston by the explosion is alone availed of, two alternately acting cylinders being employed. In a second plan both the force of the explosion and the vacuum are utilized. Four cylinders are employed, one on each of two pairs of driving-wheels. The locomotive carries a reservoir of gas with regulating apparatus to give a uniform supply. The charge is exploded by a cylindrical circuit-breaker rubbing against a steel spring and rotated by band and pulley connection with the fly-wheel shaft.

Crever and Keeney, September, 1859, proposed the use of a stationary steam-engine at one of the termini, for compressing air into a large air-holder. A main connected with this reservoir leads along the track, and is provided at intervals with ascending branches having valves, which may be opened by contrivances under the control of the conductor, in order to replenish a compressed air-tank carried beneath the car.

Liquid carbonic-acid gas exerts a pressure of about 690 pounds per square inch at 42° Fah., 855 pounds at 60° Fah., and 1,200 pounds at 86° Fah. One pound of the liquid expands so as to form rather more than eight cubic feet of gas. It may be kept in tanks made of several thicknesses of sheet-steel rolled together in the form of a scroll and united by a solder of pure tin run in between the layers. (Mathews's patent.) Tanks made of a single thickness 1/16 inch of sheet-steel, lapped four inches at the edge, and soldered in this way, may be trusted to sustain a pressure of 300 pounds to the inch, the bursting pressure being 700 lbs. One of the thicker kind above mentioned, tested by hydraulic pressure at the Newport torpedo-station, withstood strains up to 3,132 lbs. per square inch before rupture.

Barbour, March 14, 1865. The car carries a supply of liquid carbonic-acid stored in a tank beneath. This is admitted in regulated quantities to the cylinder, where it expands, and after doing its work, the gas is exhausted into a reservoir over the car, having a capacity 450 times that of the tank in which it is contained in the liquid state. It is recondensed by appropriate machinery at the stations, and again used.

Smith, August 8, 1871. Compressed air, contained in a large tank on the body of the car, is admitted to a governor or regulator a', and thence passes to a small auxiliary tank b underneath; this is connected with the cylinder valve-chest c' by two pipes, one of which d is open and the other e closed while the car is in motion, but on stopping the car the latter is opened and the former closed, causing the compressed air in the cylinder c to be pumped back into the auxiliary tank, where it is stored up to assist in starting again. The illustration (Fig. 5977) shows the car-bed and lower works.

Smith and De Coppet, July 29, 1873 (Fig. 5978). Liquid ammonia, stored in a reservoir a, is withdrawn and injected by a pump b into a vaporizer c, heated by a lamp beneath. The gas is conducted to the engine d by a pipe, and is exhausted into a condenser e, where it is liquefied by a shower of spray falling through a perforated plate, the water being supplied by tanks f, one at each side of the car, and withdrawn therefrom by a pump. A third pump removes the ammonia from the condenser and forces it into a tank g beneath the car, where it is retained for farther use. Chains communicate motion from pulleys on the engine crank-shaft to pulleys on the driving-wheel shaft.

Bowen, September 2, 1873 (Fig. 5979). The car has under the seats tanks for compressed air, divided into compartments by partitions. The compartments communicate with each other by valves, which allow the air to pass from one to the other when they are charged at the end of the route, but prevent its passing in the opposite direction when the compartment first drawn on has a less pressure than that which remains intact. Each compartment has a separate pipe communicating with the working-tank d, and valves controlling these are successively opened as the pressure becomes reduced in the compartments first drawn upon.

Turnbull (Fig. 5980) employs a cut-off which automatically varies the bulk of air admitted to the working-cylinder in proportion to the degree of compression. $e\ e$ are air-holders; f, cylinder; l, slide-valve, working in chest p and operated from eccentric m by lever n and rod o secured to pivoted sleeve b, rendering the length of stroke adjustable; q is an air-chest, from which the chest p is supplied. The compressed air issues from the air-holders, which are connected by a pipe, through a valved pipe communicating with the dome t, and presses against the diaphragm f, having a stem u connected with the helical spring g and pivoted to the lever v. When, as at starting, the air in the tanks is highly compressed, the diaphragm f depresses the stem u in opposition to the spring g and the lever v, through the medium of $k\ l'\ m$, causes the valve d in chest q to cut off at short stroke; but as the pressure becomes reduced, the spring g, overcoming the resist-

ance of the diaphragm, raises the stem *u*, and allows the valve *d* to have a longer range, so as to admit a greater volume of air to the chest *p*. When the pressure in the tanks has become reduced to a certain amount, the valve *d* ceases to operate. *z* is a pipe conveying air from drum *t* to the chest *q*; *i*, connecting-rod, and *k*, crank to driving-axle *c*.

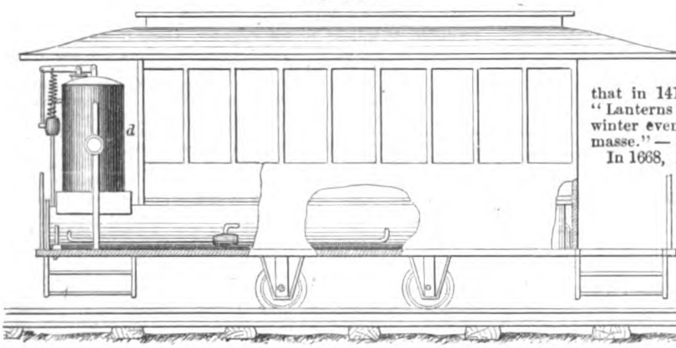
The Scott-Moncreiff system is used in Scotland.

A United States patent has been granted for a method of using the elastic force of rubber as a motor for street-cars and for other purposes. Two rubber bands, $2\frac{1}{2}$ inches in diameter and 56 feet long, are stretched to 10 times that length upon two drums, on which they are coiled. The unwinding of each coil is calculated to propel the car a distance of over two miles. When the first has been unwound, the second is brought into requisition, and while it is propelling the car, the first is to be again wound up by the devices used for stopping and controlling the car.

Still another mode of operating street-cars is by means of steel springs. This form is the subject of a French patent by M. Leveaux.

The winding-up of the spring barrels, which are carried under the car, is effected by engine power, placed at suitable intervals along the track, as may be convenient for the run. The stationary engine drives by belt the horizontal shaft, carried in bearings, inclosed in a metallic tube or casing, beneath the roadway, and extending across the track; close alongside which is a covered box, sunk in the roadway and inclosing a wheel, so shaped as to connect with the winding axle of the tramway car,

Fig. 5979.

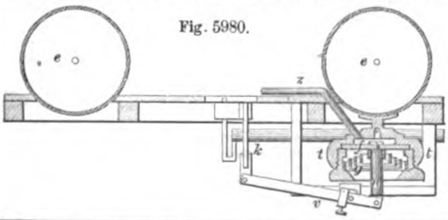


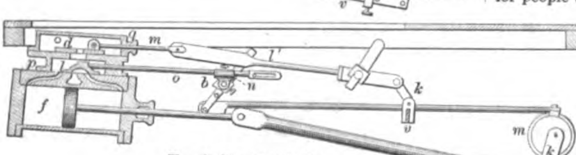
Bowen's Street-Car.

and thus give the requisite motion thereto. On the arrival of a car at any station, the spring barrels are wound up by the engine.

It has been computed that the actual tractive force, requisite to overcome the resistance of a street-car weighing gross 5 tons, is 60 pounds on the driving-wheels, corresponding to 720 pounds on the periphery of the spring barrel; 24 pounds and 288 pounds respectively correspond to a gross weight of 2 tons; and in like proportions for intermediate weights. So far as previous experience goes, a spring 6 pounds in weight, exerting a direct

Fig. 5980.





Turnbull's Street-Car.

pressure of 105 pounds, may be taken to represent the maximum in size and power of such steel springs. Steel manufacturers are now turning out springs 50 to 60 feet long, capable, when duly coiled, of exerting a pressure of 800 pounds to 900 pounds, without permanent set.

In a modification, in place of one spring, wound up at intervals along the road by means of stationary engines, a number of springs, each properly wound up, are taken on at the beginning of the route, and as fast as one expends its energy in moving the car, another is brought into play, and the trip is continued till all are exhausted, or the run is made.

Street-lamp. One publicly exposed on the street. The lighting of streets on occasions of rejoicings, processions, grand entries, and receptions has always been an accepted Oriental device for gracing such occasions. The feast of the dedication was such among the Jews. The Roman forum was lighted when night-games were celebrated. Caligula once lighted the whole city. Constantine lighted up the city of the Bosphorus on Easter eve.

The streets of Antioch and Edessa were lighted in the fourth and fifth centuries. The lights were lamps suspended by ropes.

The really comfortable lighting of some Eastern cities mentioned by Jerome, Libanius, Basilius, and others during the fourth century was far ahead of any attempts in that line in Greece or Rome, where people, venturing out after dark, were attended by lantern or torch bearers.

The public lighting of streets became large and regular service among the Saracens. In Cordova (Ar. *Korttubah*), under the Arabs, a person might walk after sunset for a distance of 10 miles in a straight line by the light of the public lamps and upon well-paved streets. *Al Makkari's* "History of the Mohammedan Dynasties in Spain." This was 500 years before any public lamp service in London or Paris.

The priority of lighting streets is contested between London and Paris. In London it appears that in 1417, Sir Henry Barton, Mayor, ordered "Lanterns with lights to be hanged out on the winter evenings, between Hallowtide and Candlemasse." — STOWE.

In 1668, householders were reminded that they should hang out lanterns duly at the accustomed time, and in 1690 this order was renewed, and these lights were required to be kept burning from dark till midnight every night between Michaelmas and Lady Day.

In 1716, farther ordinances for the better lighting of the city were made by the city authorities, but the duty still rested upon the people, and its execution was not a municipal act. The Common Council ordered that "all householders whose houses front any street, lane, or public passage shall, in every dark night, that is, every night between the second night after every full moon till the 7th night every new moon, set or hang out one or more lights, with sufficient cotton wicks, that shall continue to burn from 6 o'clock at night till 11 o'clock of the same night, under the penalty of one shilling." The rest of the night might take care of itself, and even these regulations were evaded and disregarded.

The streets were subsequently lighted by contract for 117 nights in the year. This proving unsatisfactory, an act of Parliament was passed in 1736, which authorized the corporation to establish glass lamps to be lighted from sunset to sunrise all the year round, and the number was increased to 5,000 within the bounds of the city proper; probably 15,000 within the group of municipalities known as London. In 1744, the lighting of the city was still farther regulated by act of Parliament, and at a somewhat later period Oxford Street alone was said to contain more lamps than all Paris.

Misson, the celebrated traveler, who visited England about 1680, states that in the streets of London, "instead of lanterns, they set up lamps which, by means of a very thick convex glass, throw out great rays of light which illuminate the path for people that go on foot tolerably well." These lamps were at every tenth house. They fell into disuse, and lanterns were substituted. These *bull's-eyes* were again introduced in London in 1799.

"Master Kemming" is noted as the enterprising establisher of public lamps in London. His oil lamps eventually gave way to Murdock's gas-lamps, 1798; and Winsor, 1803.

An order was issued in Paris, in the year 1524, that the inhabitants should keep lights burning, after nine in the evening, before the windows of all houses which fronted the streets; and in October, 1558, large vases filled with pitch, resin, and other combustibles were placed at the corners of the streets, or nearer together if necessary. These, in the next month of the same year, were superseded by lanterns.

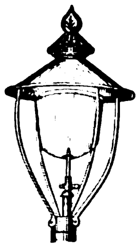
The lighting arrangements of the streets, however, still continued for many years on a very imperfect footing, and travelers still found it advisable to employ men bearing links or lanterns, when going abroad after nightfall.

In 1667 the lighting and police arrangements of Paris were improved; the project was that of the Abbé Laudati, and was legalized in 1662. In 1671 the lamps were ordered to be lighted from the 20th of October to the end of March, having previously been kept lighted only during the four winter months; at this time the lamps were kept burning on moonlight nights as well as others. Their number in 1771 was estimated at 6,232.

Amsterdam had street lanterns in 1669; The Hague, 1678; Copenhagen, 1681; Hamburg, 1675; Berlin, 1682; Vienna, 1704; Birmingham, England, 1783.

For lighting by gas, see GAS.

Fig. 5981.



Street-Lamp.

In the example, the glass is in a single piece, flaring at top, and having an opening at the bottom to receive the burner. The cover, to which it is attached, is conical in shape, is supported by four rods affixed to the top of the lamp-post, and is capped by a perforated hood.

James L. Ewin's street-lamp has a supply of naphtha or other oil sufficient to last for a week or longer, contained within a reservoir located in or beneath the pavement. Water under pressure from the street-main or a service-pipe is applied to the oil by a pipe, and the oil is conducted to the burner by another pipe, the flow being regulated by stop-cocks at the burner and in the water-pipe. The reservoir is furnished with a removable bucket inclosed by a hinged oil-tight lid, as means for discharging the water and refilling the reservoir with oil. A single padlock secures the lid and the water-supply cock. In this general form the oil-supply apparatus is used in connection with an ordinary gas-lamp post. In another form, an enlargement in the post constitutes the reservoir, and a simple cock provides for discharging the water. In some forms provision is made against the escape of the water or oil through the outlet of the other. The lamp-lighter simply turns on the oil at the burner, and the water-pressure keeps the flame supplied continuously until the flow is stopped or the oil is exhausted.

Fig. 5982.

Ewin's Street-Lamp for Coal-Oil.

Street-lo'co-mo'tive. 1. An engine (usually steam) for use on ordinary road or pavement. See ROAD-LOCOMOTIVE; TRACTION-ENGINE.

2. A small compact engine for use on board a street-car, as a substitute for horses. A dummy-engine (Fig. 5983). See STREET-CAR.

Street-rail'way. See STREET-CAR; STEAM-CARRIAGE.

Street-sprink'ler. A cask or water-box on wheels, with a rose at the rear to sprinkle water upon the street. Kinds and capacities are various. They are usually filled from the public hydrant or fire-plug, and have means by which the driver can control the issue of water.

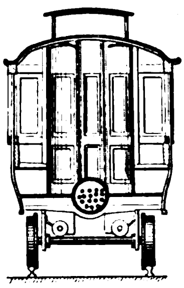
Street-sweep'ing Ma-chine'. A wagon provided with scrapers and brushes for gathering up street-dust and mud and depositing it in the wagon-bed.

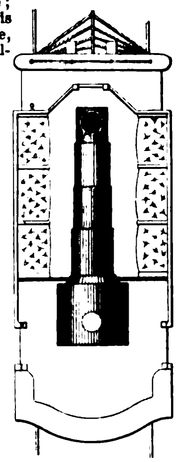
Boase's street-sweeping machine (England, 1831) had 5 rows of brushes spirally arranged on an axis which is rotated by bevel-gear from the main axle. It delivers the sweeping in a ridge at the off-side of the machine.

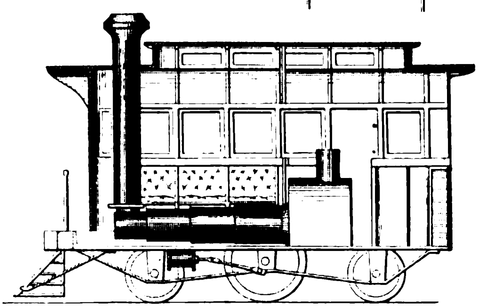
The street-sweeping machine adopted in the municipal service of Paris has a broom attached to the rear of a two-wheeled vehicle, by means of a framework, which is so hinged to the axle of the vehicle as to enable the conductor upon the box in front to raise it out of contact with the pavement, or to depress it for service at pleasure.

Upon one of the wheels of the vehicle is fixed a conical gear-wheel, which drives a pinion running on an axis inclined about 20 degrees to the axis of the vehicle; and this axis is connected with the axis of the broom by a chain working in a pair of rag-wheels. The axis of the broom itself is inclined so as to be parallel to the axis of the pinion just mentioned, and therefore oblique to the direction of movement. When the broom is applied to the pavement the rag-chain gives it a rotation opposite to that of the wheels of the vehicle; and the dust or mud of the street is swept on before it and turned aside, so as to form a continuous heap parallel with the axis of the road.

Fig. 5983.



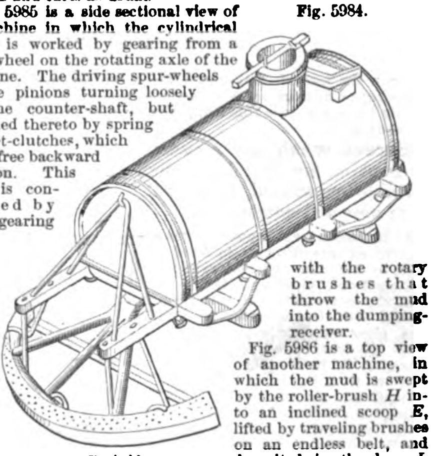




Dummy.

The broom is armed with stout splints, and is 2 feet in diameter. In length it is about 6 feet It leaves a track cleanly swept behind it of nearly this breadth. The dust is left in a ridge, or, as we should say, in wind-row, and is removed by shovels and carts as usual.

Fig. 5984.



Street-Sprinkler.

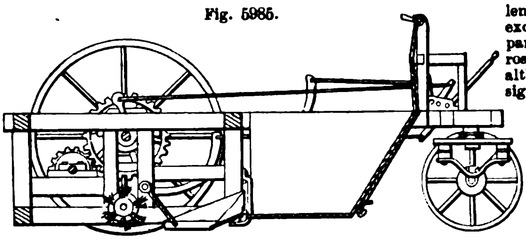
Fig. 5985 is a side sectional view of a machine in which the cylindrical brush is worked by gearing from a spur-wheel on the rotating axle of the machine. The driving spur-wheels engage pinions turning loosely on the counter-shaft, but clutched thereto by spring ratchet-clutches, which allow free backward rotation. This shaft is connected by chain gearing with the rotary brushes that throw the mud into the dumping-receiver.

Fig. 5986 is a top view of another machine, in which the mud is swept by the roller-brush *H* into an inclined scoop *E*, lifted by traveling brushes on an endless belt, and deposited in the box *I*. Erom thence it is dumped when the machine has been driven to the place of deposit.

Fig. 5987 is a machine for removing the dirt from close to the curbstone, and leaving it where an ordinary machine may reach it. The brooms and brushes are so connected by shafts and gearing with the ground-wheels as to revolve in a direction at right angles to the direction of motion of the machine.

Fig. 5988 shows, by a longitudinal section, a machine having

Fig. 5985.



Street-Sweeper.

an endless belt with brushes. The belt is moved by gear connection with the ground-wheels.

Fig. 5989 has a pair of oblique brushes to gather a wide swath of dirt into a position to be swept up by the succeeding cylindrical brush.

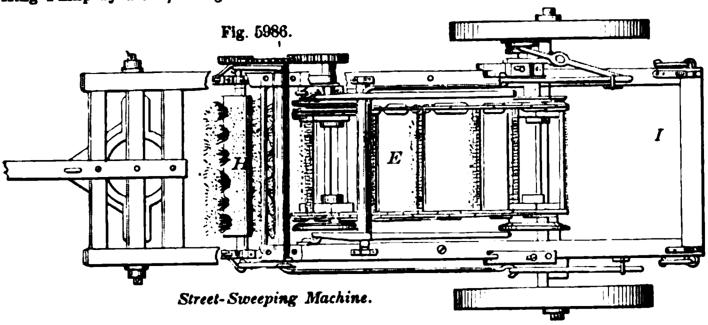
Ancient Rome had its cloacæ, and so had its beautiful colony Augsburg; but the cleaning of streets, except in exceptional cases, as in the splendid capital of the Spanish Caliphs, Cordova, was in a beastly state of inefficiency.

In Paris, in 1285, under Philip the Bold, an order was issued that each citizen should keep the street clean in front of his own house. In 1348 and 1388 stringent penalties were enacted against the remiss, and a dirt and garbage cart (*un tombereau*) was established. About the end of the fourteenth century the scavenger business became a regular trade. The government took charge of it in 1609, letting it out in contracts.

The work has changed somewhat in its character by the introduction of SEWERS (which see) and by other sanitary regulations and arrangements.

Without descending to the full particulars, we may state that every kind of filth was habitually thrown into the street until comparatively modern times. Swine were forbidden to run loose in Paris in 1131, in consequence of the death of the young King Philip by a fall, owing to one of these animals running

Fig. 5986.



Street-Sweeping Machine.

between the legs of his horse. By an ordinance of 1395 the throwing of filth into the streets was prohibited in Paris. It is only 120 years since this filthy practice was in full vogue in Edinburgh.

Street-wash'er. A name sometimes given to a hydrant or fire-plug from which the street may be sprinkled or washed, by a jet from hose and nozzle.

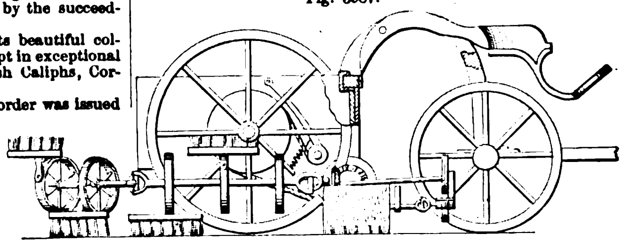
An invention for this purpose was introduced into Glasgow, in April, 1868, by Mr. Sim. On one side of the roadway, pipes were laid next the pavement, and connected with the water-main. The pipes were drilled with holes one tenth of an inch in diameter. On turning the water on from the main, it squirted across the street, completely and speedily watering, and, if required, washing the roadway.

"Engineering" describes a new process for "laying the dust" in streets, devised by a Mr. Cooper, who, amongst other contracts, undertook the watering for the parish of Marylebone, one of the largest in London, at a reduction of some fifty per cent on the other tenders. Mr. Cooper's system of watering is based upon the principle of utilizing the moisture always suspended in the atmosphere, by saturating the roads with a solution of deliquescent salts. Upwards of one million gallons of the solution have been distributed over various lengths of road with important and incidental advantages, exclusive of the enormous saving in water and labor. Apparently a sort of concrete is formed of the detritus of the road surface and the chemicals employed in the solution; for, although a road watered on this system may appear at first sight to be perfectly dry, upon closer inspection it will be seen that the dust is concreted together in masses too large to be blown about by the wind.

It is stated that the chemicals employed in the above solution have proved very destructive to the hoofs and feet of horses. *Quien sabe*

Strength of Ma-te'ri-als. The strength of materials is determined in three ways, — by their resistance to a *crushing* force, a *tensile* force, or by a *tortional* force. Of these tests, the former two possess the most general utility, as

Fig. 5987.



Street-Sweeping Machine.

compressive or tensile strains are those to which materials are most frequently subjected in structures of any kind.

The reader is referred to Barlow, "On the Strength of Materials." Consult, also, "Ordnance Manual," ed. 1861, and technical works on building, civil engineering, iron working and manufacture, etc. See TESTING-MACHINE.

Stretch'er. 1. (*Bricklaying.*) A brick whose length is laid in the direction of the length of the wall.

2. One of the extension-rods of an umbrella, attached at one end to the sleeve which slides on the handle, and at the other end to a rib of the frame.

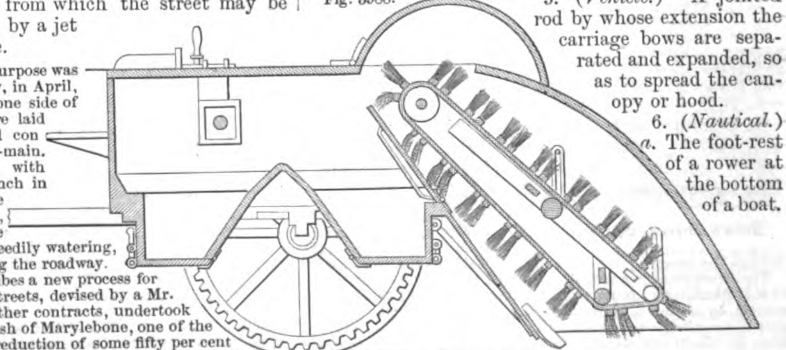
3. (*Carpentry.*) A tie-timber in a frame.

4. A round rail joining the legs of a chair. A *round.*

5. (*Vehicle.*) A jointed rod by whose extension the carriage bows are separated and expanded, so as to spread the canopy or hood.

6. (*Nautical.*) *a.* The foot-rest of a rower at the bottom of a boat.

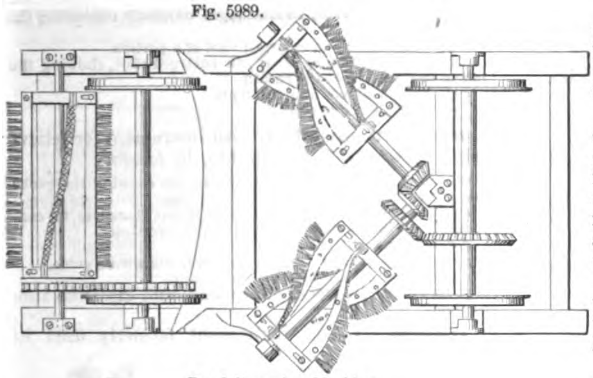
Fig. 5988.



Street-Sweeping Machine.

b. A cross-piece to keep the sides of a boat distended when slung to get on board or overboard.

Fig. 5989.



Road-Sweeping Machine.

7. A tool for expanding gloves.

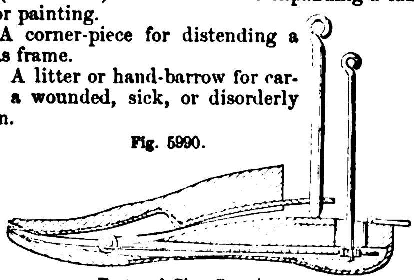
8. (*Shoemaking.*) An expanding last for distending shoes.

9. (*Fine Arts.*) *a.* A frame for expanding a canvas for painting.

b. A corner-piece for distending a canvas frame.

10. A litter or hand-barrow for carrying a wounded, sick, or disorderly person.

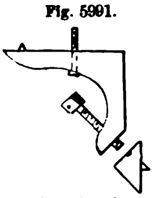
Fig. 5990.



Boot and Shoe Stretcher.

It is in great request at the front during an action, for carrying off the wounded to the rear, to a field hospital, or to ambulances for transportation farther to the rear. It is usually like a hand-barrow, with a bottom made of sacking, nailed to the frame. Some have legs, and some have none. Those with folding-legs pack more compactly for transportation.

Fig. 5991.



Stretcher for Painters' Canvas.

A number were patented during our late war. Fig. 5992 shows one which may be folded for transportation, is mounted on wheels and springs and on folding-legs, and its bed portions are adaptable to the necessities of varying cases.

Stretchers are also used for conveying dangerous persons to a place of safety; mad, drunk, or ferocious, to asylum, jail, police-station, or guard-house. See LITTER; BIER; HAND-BARROW.

Stretch'er-mule. (*Cotton-manufacture.*) A mule adapted to stretch and twist fine rovings of cotton, bringing them forward another stage in respect of attenuation and twisting. See MULE.

Stretch'ing-course. (*Masonry.*) A course of stones or bricks laid with their longest dimensions in the direction of the length of the wall. See BOND.

Stretch'ing-frame. (*Cotton-manufacture.*) *a.* A machine in which rovings are stretched in the process of converting them into yarn.

b. A long frame on which starched muslins are stretched and exposed in a warm room to dry. It is the substitute for the cylinder drying-machine, which is used upon heavier classes of goods.

To give the *patent finish*, the sides of the frame are moved backward and forward, so as to give a diagonal stretch in alternate directions to the cloth. This is continued until dry, and the effect is a soft and elastic finish, resembling clear-starching.

Stretch'ing-ir'on. (*Leather-working.*) A currier's tool, resembling a *slicker*, consisting of a flat piece of metal or stone fixed in a handle and used to scrape the surface of curried leather, to stretch it, reduce inequalities, and raise the *bloom*,— a certain powdery appearance which marks the surface of well-tanned leather.

Stretch'ing-ma-chine'. A machine for stretching textile fabrics so as to lay their warp and woof yarns in truly parallel positions.

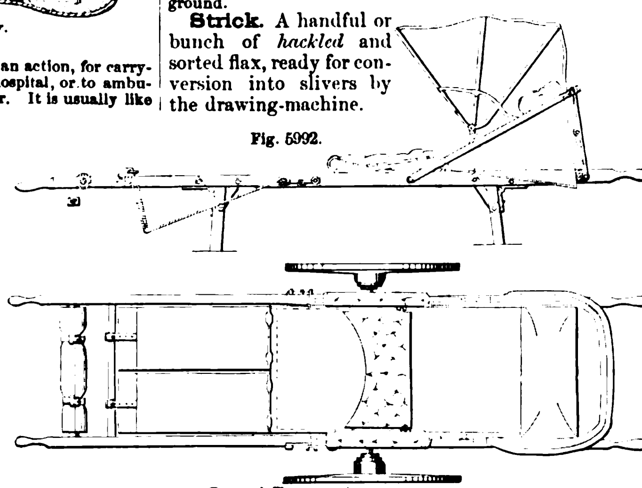
An ingenious and effective machine for this purpose, patented by Morand of Manchester, is described in Newton's "London Journal of Arts and Science" for December, 1835. See also TENTERING-MACHINE.

Striæ-de-tect'or. An instrument invented by Professor Töpler of Riga for detecting the streaks or striæ in glass-disks, caused by irregularities of density. These are sometimes of sufficient magnitude to be visible on simple inspection, but when not so, they render the glass unfit for optical purposes.

The instrument consists of a lamp before which is placed an opaque disk having apertures of various dimensions, enabling the observer to vary the size of the radiant at pleasure. The light is thrown on a large lens of short focus, and passes through the glass to be examined. Exactly at the focal point is placed an opaque disk of the exact size of the image there formed. If the lens to be tested is perfect, a complete eclipse will take place, but if irregularities exist they will cause the rays falling on them to deviate from the focal point, and will produce an image of their figure apparently more or less bright upon a dark ground.

Strick. A handful or bunch of *hackled* and sorted flax, ready for conversion into slivers by the drawing-machine.

Fig. 5992.



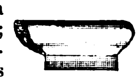
General Tompkins's Stretcher.

A cwt. (112 lbs.) of flax makes 300 to 400 *stricks.*

Strick'le. 1. (*Carpentry and Masonry.*) A pattern or templet.

2. (*Founding.*) *a.* A semicircular piece of wood used in smoothing molds of loam to form cores for curved and crooked pipes; also for spreading upon the cores a thickness of loam answering to the required thickness of the pipe. The core and its envelope form a model in the sand-flask, and are then removed; the outer thickness of loam is removed, exposing the core; this is placed in the mold, resting on

Fig. 5993.



Stretching-Iron.

prints; the mold is closed, clamped, and the metal poured.

b. A straight-edge of wood with which to remove superfluous sand from a flask after ramming up.

2. (*Cloth-shearing Machines.*) A straight-edge fed with emery and employed to grind the edges of a series of knives arranged spirally on a cylinder.

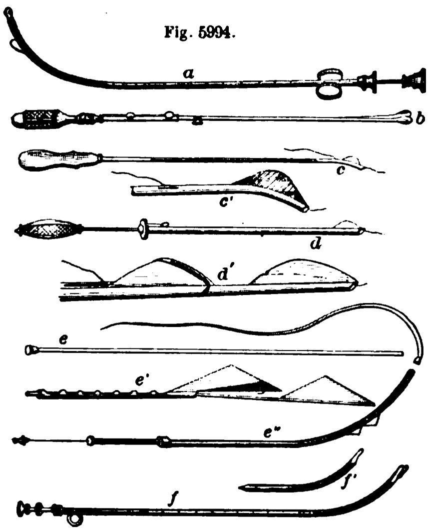
3. A straight-edge to strike grain to a level with the upper edge of the measure. A *strike.*

4. An instrument for whetting scythes. A *rifle.*

5. (*Flax.*) A *strike* or sword used in dressing flax.

Strict'ure-cut'ter. An instrument for dividing contractions of the urethra. A catheter concealing

Fig. 5994.

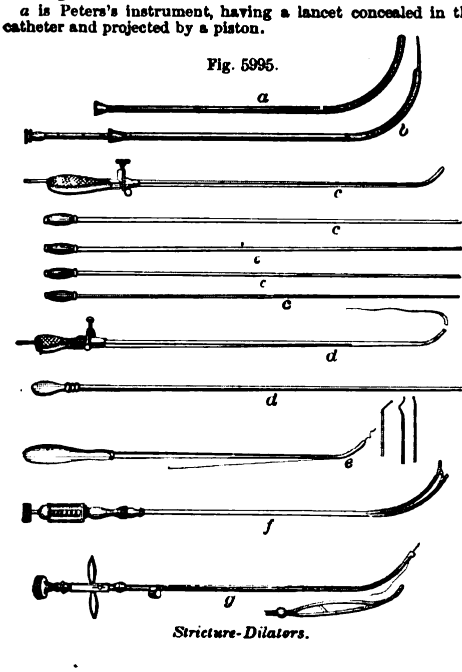


Tiemann's Stricture-Cutters.

a knife, which may be pushed out at the proper time, dividing the stricture without injuring any other part of the urethra.

a is Peters's instrument, having a lancet concealed in the catheter and projected by a piston.

Fig. 5995.



Stricture-Dilators.

b is Civialle's, having spoon-shaped terminals concealing the knife.

c is Gouley's. *c'*, an enlarged view of a portion.

d is another of Gouley's. *d'*, an enlarged view, showing the lancet projected from the sheath.

e e' e'' are Vollmier's instruments.

f f', Martin's instrument.

Strict'ure-di-lat'or. An instrument for relieving contractions in the urethra, by *tearing.*

a b are views of Miner's instrument, one showing the probe projected.

c c c c c are Holt's instruments, of different diameters, for consecutive use in expanding the walls of the urethra.

d d' is Bumstead's dilator.

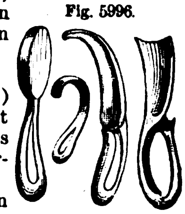
e shows dilators of varying forms, with whalebone guide.

f is an expansible bifurcated instrument.

g, Sir Henry Thompson's instrument, with expansible stem section.

Strig'il. 1. An instrument formerly used in baths for scraping off the sweat, but more specifically useful in exciting the action of the skin and tissues beneath.

Fig. 5996.



Strigils.

2. A flesh-brush.

Strike. 1. (*Brick-making.*) A small piece of wood about $1\frac{1}{2}$ in. × $\frac{1}{2}$ in., and 10 inches long, used to remove the superfluous clay from the mold.

2. A similar strip is used in measuring grain, and hence the term *struck* measure as distinguished from *heaped* measure. Customs vary in this respect, and the practice of selling by weight is superseding the old mode. See STRICKLE.

3. (*Founding.*) *a.* A hook in a foundry to hoist the metal.

b. A paddle or straight-edge. See STRICKLE.

4. (*Metal-working.*) A puddler's stirrer. A *rabble.*

5. (*Flax-working.*) A handful of flax that may be *struck* at once.

6. (*Sugar-making.*) The quantity of sirup, the contents of the last-pan, emptied at once into the coolers.

7. An iron pale or standard in a gate or fence.

8. (*Mining.*) *a.* The prolongation or extension of a stratum in a direction at right angles to the *dip.* The strike is also called the *line of bearing.* If a stratum *dip* to the N., the *strike* is E. and W.

Of the horizontal *drifts* of a mine, one set follows the strike of the vein and the other is at right angles to it. The former are for working the vein, the latter for removing the ore and draining the mine.

b. The intersection of a vein with the surface. The place where the vein *crops out.*

Strike-or-si'lent. (*Horology.*) A piece in a clock which sets the striking parts in or out of action. In the latter case, it pushes the warning piece clear of the pin in the hour-wheel, so that the latter, the prime agent in the striking, is allowed to revolve without setting in motion the train of parts which affect and regulate the striking.

In the *strike* position, the pin on the hour-wheel is effective in moving the warning-piece, so that the clock strikes the hour regulated by the *snail.*

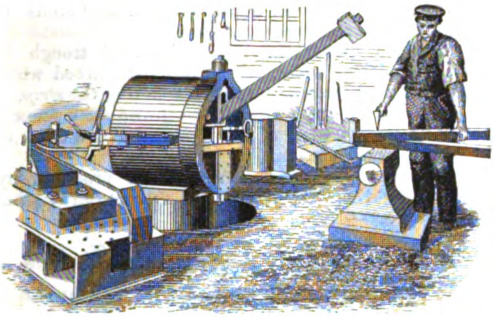
Strik'er. 1. (*Forging.*) A species of steam-hammer, striking in a manner similar to the trip-hammer, but operated directly from the engine, the cam-wheel being dispensed with. It may be adjusted to strike either vertically, or horizontally, or at any angle, and is designed as a substitute for the blacksmith's assistant, known as the *striker,* on heavy work.

Fig. 5997. Position for vertical blows.

Fig. 5998. *a* shows it in position for *upsetting*, delivering horizontal blows.

b. Position for blows at an angle of 45°, for bending angle-iron and T-stiffeners.

Fig. 5997.

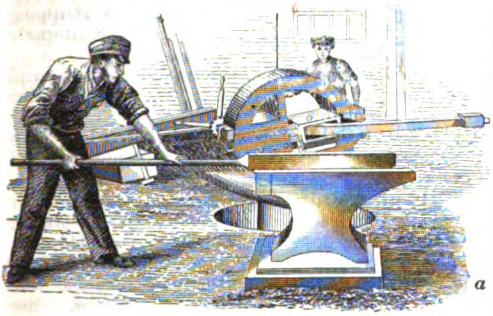


Striker.

The operator can regulate the force, direction, or rapidity of blows by actuating a foot-valve projecting through the floor, near the anvil. They can be arranged for working by compressed air or water-pressure, but are usually worked by steam.

2. A hardened mold or former upon which a softened steel block is struck, to receive a concave

Fig. 5998.



Davies's Striker.

impression from the *striker*. *Swages* are made in this way, the two portions receiving their grooves from a striker between them. See SWAGE.

3. A harpoon.

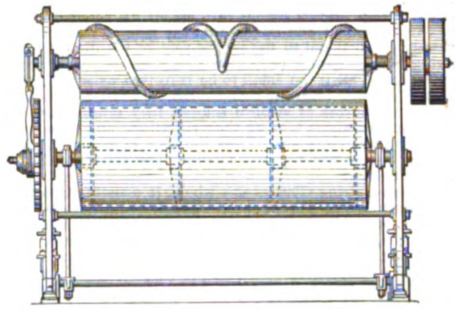
Strik'ing. 1. (*Architecture.*) The removal of a center upon which an arch has been built. It is done by striking the wedges on which the ribs rest. See CENTERING.

2. (*Joinery.*) Running a molding with a molding-plane.

Strik'ing-knife. When hides are taken from the last pit of tanning-liquor they are washed and dripped, being occasionally placed upon a long cylindrical horse and *struck* or smoothed with a triangular steel knife, which brings a bloom to the surface.

Strik'ing-ma-chine'. 1. (*Leather.*) One for

Fig. 5999.



Striking-Machine for Scraping Hides.

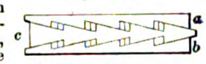
scraping hides. The hide, being laid upon the lower of two rollers, is gradually allowed to pass beneath the upper roller, which carries a sharp-edged spiral knife. The lower roller, being supported on springs, maintains a uniform but yielding pressure, and adapts itself to the varying thickness of the hide, the knife in the mean time scraping out the *bloom* on the hide.

2. (*Metal-working.*) A machine for stamping metals. See STRIKING-UP PRESS.

Strik'ing-plate. (*Carpentry.*) The device by which the wooden centering of an arch is lowered when the arch is completed.

The upper plate *a*, notched on the lower side, serves as a base for the framing of the center, and the lower plate *b*, notched on the upper side, rests on the pier or posts which support the whole. The two are separated by the compound wedge *c*, which is secured by keys. When these keys are driven out, the wedge *c* is free to slide backward, allowing the plate *a* and superposed framing to descend, leaving the voussoirs unsupported.

Fig. 6000.



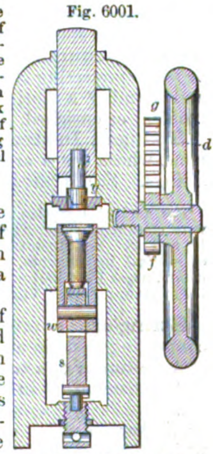
Striking Plates and Wedges.

Strik'ing-up Press. (*Sheet-metal Working.*) A press for *striking-up* or *raising* sheet-metal in making dishes, pots, pans, cups, etc. See also DROP-PRESS.

In that illustrated, the disk to be shaped is laid on the upper face of the hollow die *w*, the upward movement of which clamps it against the collar *y*, while the cameo-die a^2 descends and forms the object, which is afterward ejected from the matrix by a follower. The movements of both dies are derived from a rocking cam *s*, actuated from the fly-wheel *d* through gears *f g*.

See STAMPING-MACHINE.

Fig. 6001.



Striking-Machine for Metals.

Strik'ing-watch. One which indicates the time of day either automatically or in response to the pushing in of a knob. A REPEATER.

The watches of the time of Charles V. and Louis XI. had striking arrangements, and on two occasions mentioned in the chronicles of the times, thieves with the booty on their persons were detected by the striking of the watches.

String. 1. A cord of small diameter.

2. (*Music.*) The cord of fiber or metal whose vibrations produce the notes in instruments of the stringed class. See MUSICAL INSTRUMENTS.

"The following four laws govern the vibration of strings: The rate of vibration is inversely proportional to the length; it is inversely proportional to the diameter; it is directly propor-

tional to the square root of the stretching weight or tension; and it is inversely proportional to the square root of the density of the string. When strings of different diameters and densities are compared, the law is, that the rate of vibration is inversely proportional to the square root of the diameter of the string. The amount of motion communicated by a vibrating string to the air is too small to be perceived as sound, even at a small distance from the string. Hence, when strings are employed as sources of musical sounds, they must be associated with surfaces which take up their vibrations, and transfer them to the surrounding air. Thus the tone of a harp, a piano, a guitar, or a violin depends mainly upon the sound-board of the instrument.

"When a string vibrates as a whole, it usually divides at the same time into its aliquot parts. Smaller vibrations are superposed upon the larger, the tones corresponding to the smaller vibrations, which are known as overtones, mingling at the same time with the fundamental note of the string. It is the addition of such overtones in different proportions to fundamental tones of the same pitch, which enables the listener to distinguish the sound of a clarinet from that of a flute, and the sound of a violin from both. Could the pure fundamental tones of these instruments be detached, they would be undistinguishable from each other; but the different admixture of overtones in the different instruments renders their *timbres* diverse, and therefore distinguishable. When a stretched string is plucked aside, or agitated by a bow, all the overtones which require the point agitated for a node vanish from the clang of the string. The point struck by the hammer of a piano is from one seventh to one ninth of the length of the string from its end; by striking this point, the notes which require it as a node cannot be produced, a source of dissonance being thus avoided." — TYNDALL.

Pythagoras appears to have understood the relation of musical intervals, and is said to have stretched musical strings of equal lengths by weights having such proportion as to produce fourths, fifths, and octaves.

2. (*Mining.*) A small vein of ore, divaricating from the main vein and passing off into the rock. Still smaller veins are called threads.

3. (*Shipwrighting.*) The uppermost row of planks in a ship's ceiling, or that between the upper edge of the upper deck-ports and the gunwale.

4. A projecting course of bricks or stones in a wall. A *string-course.*

String-block. (*Music.*) A block in the wooden-frame piano-forte into which were driven the studs upon which the strings were looped.

It is now superseded by a *string-plate,* which has the same function, but has the advantage of metallic rigidity, as a consequence of which the strings remain longer in tune.

String-board. (*Carpentry.*) One of the slanting pieces of stairs into which the steps are notched.

String-course. (*Masonry.*) A course of brick or stone projecting slightly from the face of the wall and forming a horizontal line. It may be flat, molded, or enriched.

Stringed In'stru-ment. (*Music.*) An instrument whose tones are produced by the vibration of strings. See MUSICAL INSTRUMENTS.

The ancient Egyptian *harps* had 4, 6, 7, to 22 strings, and were elegantly made. Their *guitar* had 3 strings; *lyres*, 5, 7, 10, and 18. See MUSICAL INSTRUMENTS, pages 1499, 1500; list of musical instruments, page 1501; classification of instruments, pages 1500, 1501; table of compass of instruments, page 1498; HARP; PIANO; VIOLIN; etc.

String'er. 1. (*Carpentry.*) A horizontal timber connecting posts in a frame; as, —

A tie-timber of a truss bridge.

A horizontal tie in a floor framing.

2. (*Railway Engineering.*) A longitudinal balk or timber on which a railway rail is fastened, and which rests on transverse sleepers.

3. (*Shipwrighting.*) An inside strake of plank or of plates, secured to the ribs and supporting the ends of the beams. A *shelf-piece.*

String-piece. (*Carpentry.*) *a.* A horizontal connecting strip or plank of a frame.

b. The timber beneath a staircase which forms the soffit or ceiling.

c. A timber in a floor framing.

String-plate. (*Music.*) An iron bar in a piano-forte frame into which are inserted the studs to which the strings are secured.

Strip. 1. (*Mining.*) An inclined trough in which ores are separated by being disturbed while covered by a stream of water descending the *strip.*

2. (*Machinery.*) To tear the thread off a screw.

3. A narrow piece of board nailed over a crack or joint between planks.

Stripe. (*Weaving.*) A pattern produced by arranging the warp-threads in sets of alternating colors; or, —

In sets of varying fineness, of the same color; or,

By drawing bunches of warp-threads through the eyes of some of the heddles; or,

By passing several heddlesful through the same intervals of the reed.

A *weft* stripe crossing the warp stripe constitutes a *check* pattern.

Strip'per. 1. See FILE-STRIPPER.

2. (*Carding.*) A device for lifting the top flats from the carding-cylinder.

Strip'ping. 1. (*Carding.*) The operation of cleaning or removing the short fibers from between the teeth of the various cylinders and top flats.

Some machines are self-stripping; every other flat being moved in one motion of the stripping mechanism, the second motion taking the alternate flats.

2. (*File-making.*) The process of cross-filing and then draw-filing file blanks to prepare them for grinding or cutting.

3. Removing the *wings* of the tobacco leaf from the stems. The *wings* are piled and pressed, and form a *book.*

Strip'ping-knife. (*Husbandry.*) A tool for removing the blades of sorghum from the stalks, previous to grinding. See Fig. 1062, page 444.

Strob'o-scope. A toy depending for its effects upon the persistence of visual impressions, like the *thaumatrope* and *anorthoscope; zoetrope.* See PHENAKISTOSCOPE.

Strock'le. (*Glass-making.*) A shovel for frit, sand, etc. It has turned-up edges to increase its holding capacity.

Stroke. 1. The length of rectilinear motion of a piston, pump-rod, plunger, etc.

With a stationary engine, the motion of the piston-rod outward is the *front* stroke, the reverse is the *back* stroke. The *up* and *down* result from the position of the cylinder.

With a locomotive the *front* stroke is toward the *front* of the engine, and conversely.

The *stroke* of a valve is called its *travel* or *throw.*

The *throw* of a crank is the diameter of its circle of revolution; twice its radius.

The term *excursion* is applied in some cases; in others, the term *range.*

Strong-sand. (*Founding.*) That which contains a large quantity of clay, and is therefore tenacious.

Stron'ti-um. Equivalent, 44; symbol, Sr.; specific gravity, 2.54. This is a white, malleable metal, of but little importance in a mechanical point of view, but its salts are used in pyrotechnics to give a red glare.

Strop. 1. (*Rope-making.*) A rope with an eye at each end, used in twisting strands.

2. (*Nautical.*) A rope spliced into a circular wreath to seize around a block for hanging it.

3. Another name for strap, as *razor-strop.*

Stroud. (*Fabric.*) A coarse blanket-stuff, used in trading with the Indians.

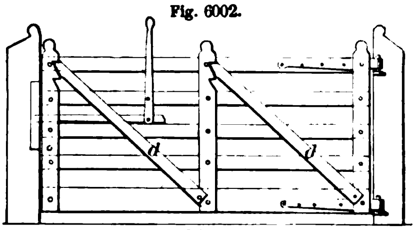
Strun'tain. (*Fabric.*) A coarse, narrow worsted braid.

Struse. (*Nautical.*) A river-craft of Russia for carrying produce and goods.

Strut. A bar in a frame having equal and opposite forces applied to its ends, acting inward and producing upon it a state of compression. A *tie* is a bar differently applied, its function being tensile. A bar applied to a strut to prevent lateral deviation is a *stay*. See TRUSS; ROOF; etc.

Specifically. *a.* A diagonal timber which acts as a post or brace to support a *principal rafter* or *purlin*. Its lower end is stepped into a *tie-beam*, or on a shoulder of a *king* or *queen post*. See KING-POST TRUSS.

Fig. 6002.



Gate with Diagonal Struts.

d d, in Fig. 6002, show struts to prevent the sagging of the gate.

b. Braces between joists. See STRUTTING.

Strut'ting. (*Carpentry.*) Diagonal braces between joists to prevent side deflection. See CHIMNEY.

When the pieces are crossed alternately, it is called *herring-bone strutting.*

Stub. 1. An old horseshoe nail. Iron formed therefrom. *Stub-iron.*

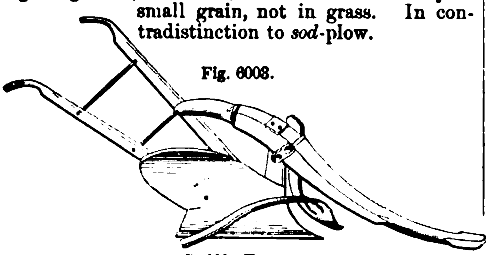
Stub-iron is used especially for gun-barrels of superior quality. The stubs are put into a tumbling-box to brighten them, removing all rust and dirt. They are then combined with from 12 to 50 per cent of steel in blocks of the same size as the *stubs*. The combined metals are puddled, hammered, heated, tilted, and rolled into ribbons, to be wound in coils around mandrels, heated to a welding heat, *jumped*, and finished by a hammer on the anvil. See GUN-BARREL; TWIST.

2. (*Locksmithing.*) A stationary stud in a lock which acts as a detent for the tumblers when their slots are in engagement therewith.

Stub-ax'le. A short axle attached on the end of a principal axle-tree. It is variously made and secured. Sometimes it is a sort of *jury* axle, made as a temporary expedient when the arm of an axle has broken off. It occurs frequently on horse hay-rakes and some other kinds of agricultural implements.

Stub'ble-plow. (*Husbandry.*) One for plowing *old* ground, so called; land which was lately in small grain, not in grass. In contradistinction to *sod*-plow.

Fig. 6003.



Stubble-Turner.

Stub'ble-rake. (*Husbandry.*) A rake for gleaning lately reaped fields of small grain; wheat, rye, oats, or barley.

Stub'ble-turn'er. An attachment to a plow to turn over stubble and trash before the principal plow reaches it. In the example, the stubble-turner is attached to the point of the coulter and curves over in front of the mold-board.

Stub-end. (*Machinery.*) The enlarged end of a connecting-rod, in which the boxes are confined by the strap.

Stub-mor'tise. (*Carpentry.*) A mortise which does not pass through the object in which it is made; not a *through* mortise.

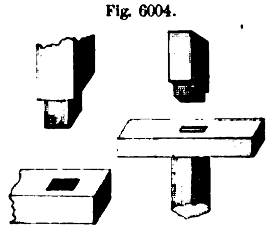
Stub-nail. A short thick nail.

Stub-short; Stub-shot. 1. The unsawed portion of a plank where it is split from the bolt or log. The saw-kerf reaches nearly to the end of the log, in *gig-back* saws; the plank is then split off the remainder of the distance: this remainder forms a short *stub*.

2. (*Turning.*) The portion by which an object to be turned is grasped or chucked. It projects beyond the ultimate surface of the object, and is cut off when the shaping is finished.

Stub-ten'on. (*Carpentry.*) A short tenon at the foot of an upright, such as the scantling or studding of a partition or a floor-bearer.

Fig. 6004.



Stub-Tenon.

Stub-twist. A gun-barrel made of a ribbon of combined iron and steel, the iron being derived from stubs (old horse-shoe nails.) See STUB.

Stuc'co. (*Plastering.*) *a.* Plaster for coating walls. It is usually made of pure lime slaked and settled, mixed with clean sand.

Stucco varies in quality and composition with the purpose for which it is intended. Gypsum and pounded marble sometimes enter into its composition, as well as gelatine or glue in solution.

One recipe gives 3 to 4 volumes of white sand, and 1 volume of fine stuff or lime putty.

b. The third coat of plastering when prepared for painting.

Troweled stucco is of the best description.
Bastard is a coarser kind.
Rough stucco is the coarsest kind prepared for painting.

Stück-fur'nace. (*Metallurgy.*)

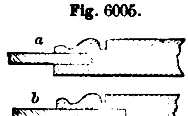
The stück furnace or Wolf's oven is a furnace for the reduction of iron, at one time common in Europe, now little employed. The interior of this furnace has the form of two cones united at their bases: it is usually from 10 to 16 feet high, 24 inches wide at bottom and top, and 5 feet at the center. There are generally two tuyeres, both on the same side. The opening called the breast is closed after the furnace is heated, after which charcoal and ore are thrown in, and the blast introduced. As soon as the ore passes the tuyere, iron is deposited at the bottom of the hearth; when this amounts to a ton, the blast is stopped, the breast-wall removed, and the metal lifted out in a solid mass, or *stuck*, *wulf*, as it is called by the Germans.

Stuck-on. (*Carpentry.*) A term indicating a molding worked on the edge of a frame; in contradistinction to one worked out of a detached strip.

a, *stuck-on.*
b, *laid-on.*

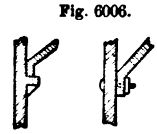
The operation of shaving down the arris is called *sticking*, *striking*, or *running* the molding.

Fig. 6005.



Stuck-On.

Fig. 6006.



Studs.

Stud. 1. (*Machinery.*) A boss or protuberance designed to hold an attached object in place.

2. (*Carpentry.*) An upright scantling.

3. (*Wear.*) A button with a shank and disk.

4. A nail with a large head.

5. (*Nautical.*) A cast-iron brace across the minor diameter of a cable link, to prevent collapse.

Stud'ding-sail. (*Nautical.*) An additional sail spread by the aid of light booms beyond the *leech* of a square sail; in order to extend the area horizontally, in light winds. They may be added on both leeches of a square sail.

The prolongation of the yard by which a *studding-sail* is extended is a *studding-sail boom*, which is supported by hoops on the yard called *quarter-irons* and *yard-arm irons*. See YARD.

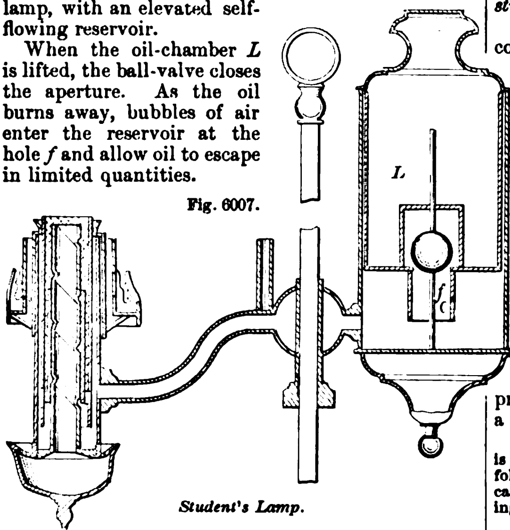
It is *rigged-out* by a *twofold purchase* called a *boom-jigger*.

Stud'ding-sail Yard. A spar rigged out from the end of a yard, to stretch a studding-sail.

Stu'dent's Lamp. A form of argand-burner lamp, with an elevated self-flowing reservoir.

When the oil-chamber *L* is lifted, the ball-valve closes the aperture. As the oil burns away, bubbles of air enter the reservoir at the hole *f* and allow oil to escape in limited quantities.

Fig. 6007.



Student's Lamp.

Stud-work. (*Building.*) Brickwork between studs. An old form of building once common in England and lately introduced into the United States by admirers of the ancient and picturesque.

Stuff. 1. (*Nautical.*) A melted mass of turpentine, tallow, etc., with which the masts, sides, and bottom of a ship are smeared.

2. (*Paper.*) Paper-stock, ground ready for use. When half ground it is known as *half-stuff*.

3. (*Fabric.*) An all-wool plain dress-goods for ladies.

4. (*Mining.*) Attle or rubbish.

5. (*Leather.*) A composition of fish-oil and tallow for filling the pores of leather. *Dubbing.*

Stuff-chest. (*Paper-making.*) The vat where the pulps from the engines are mixed and combined preparatory to molding by hand or machinery.

Stuff-en'gine. (*Paper-making.*) A pulp-grinder. See Figs. 4015 – 4020.

Stuff'er. A machine for packing or filling; as,

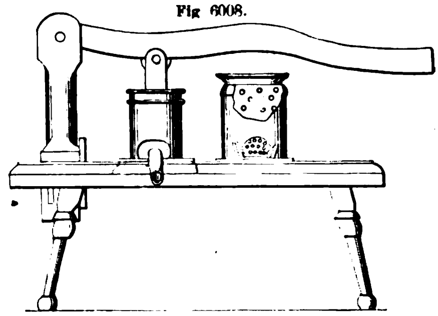
1. A machine for stuffing horse-collars.

2. A SAUSAGE-STUFFER (which see). In Fig. 6008, the sausage-reservoir is fixed to a block let into a recess of the table, so that it can be easily slipped out and the lard-vessel be substituted in its place.

3. A machine for saturating leather with *dubbing* in one part of the operation of leather-dressing.

Stuff'ing. 1. (*Leather.*) A mixture of fish-oil and tallow which is rubbed into leather after being

Fig. 6008.



Sausage-Stuffer and Lard-Press.

shaved by the currier's knife, and previous to the *boarding* or *graining*. The tool used is called a *stuffer*.

2. (*Fiber.*) Filling for cushions and mattresses, consisting of cotton, flocking, hair, wool, cork, sponge, hay, straw, tow, flax, moss, curled shreds of wood (*Excelsior*), etc.

Stuff'ing-box. (*Machinery.*) *a.* A box with an annular recess around a piston-rod, and provided with a follower and bolts, whereby the packing may be screwed down.

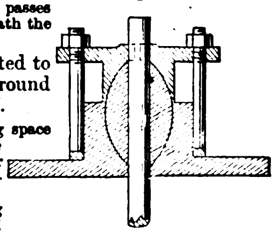
The invention of Sir Samuel Morland, an experimenter who lived in the interval between Newcomen and Watt, 1710 – 1761.

Two notable instances are: —

Around the piston-rod where it passes through the cylinder-cover; and

Around the screw-shaft of a steam-vessel where it passes through the stern beneath the water.

Fig. 6009.



Metallic Packing for Piston-Rods.

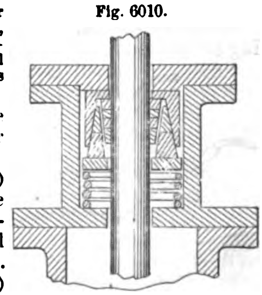
b. A sleeve adapted to press a collar of hemp around a piston-rod. A *gland*.

In Fig. 6009, the packing space is made elliptical, and the follower is perforated for casting in soft alloy as packing.

In Fig. 6010, a spring presses against the conical follower and drives the packing-rings against the piston.

The stuffing-boxes in a locomotive-engine are recesses for admitting some soft material, such as white spun-yarn, to render steam-tight any rod working through this stuffing or packing. The piston-rods, slide-valve rods, regulator-rods, and pump-plunger, all work through stuffing-boxes of this description.

Fig. 6010.



Piston-Rod Packing.

Stuff-shov'el. The paper-maker's shovel for handling materials.

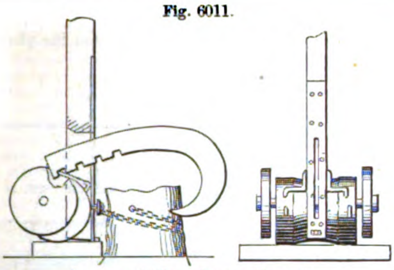
Stull. (*Mining.*) Timber placed in the back of a level and covered with boards or small poles to support rubbish.

Stump. 1. (*Locks.*) A projection, generally stationary, variously employed as a support for a dog, fence, or tumbler, as an obstruction to prevent the improper retraction of the bolt, or as a guide for any of the moving parts.

2. An artist's soft rubber, for blending or scumbling.

Stump-ex-tract'or. 1. (*Agriculture.*) A tool or machine for pulling the stumps of trees from the ground, in order to remove them from interference with cultivation.

Fig. 6011.



Lever and Claw Stump-Extractor.

There are many varieties, of which six may be mentioned as typical: —

1. The *lever and claw*. In the example of this, the lever is mounted on strong wheels, which act as a fulcrum for the lever. The claw is caught over the stump, in manner of a cant-hook, and the pulling over of the lever by a rope and team tips the stump over and lifts it free of the ground.

2. *Tackle*. This is mounted on a frame erected over the stump. The hitch is shortened or lengthened by means of the bar *c*. The team is hitched to the fall of the rope.

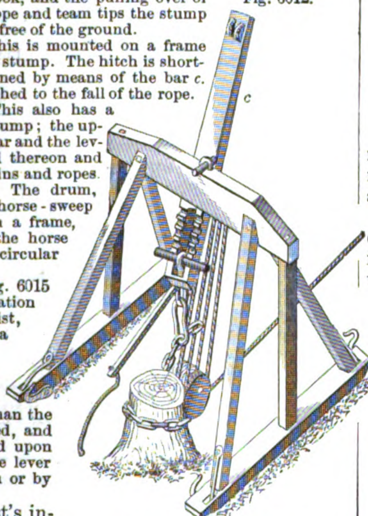
3. *Toggle*. This also has a frame over the stump; the upright hoisting-bar and the levers are arranged thereon and operated by chains and ropes.

4. *Windlass*. The drum, gearing, and horse-sweep are arranged on a frame, around which the horse walks in a circular path.

5. *Screw*. Fig. 6015 shows an application of a screw hoist, mounted on a wagon.

6. *Capstan*. The capstan is anchored to a firmer stump than the one to be pulled, and the chain wound upon the barrel as the lever revolves by team or by hand.

Fig. 6012.



Tackle Stump-Extractor.

2. A dentist's instrument for removing the stumps and roots of decayed teeth. They are of various forms.

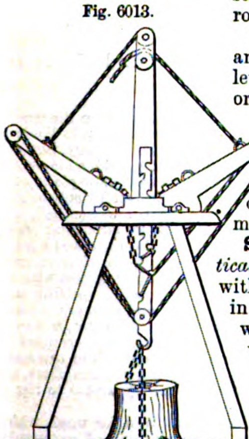
The *screw* is driven into the nerve cavity, and serves to withdraw the root.

Other tools are *gouges* and *elevators*, which act as levers to pry out the stump or root.

The *hook* is another form.

The *punch* operates, as its name indicates, by the blow of a mallet.

Fig. 6013.



Toggle Stump-Extractor.

Stump-mast. (*Nautical.*) A lower mast without tops. Common in those steam-vessels which never depend wholly upon sails.

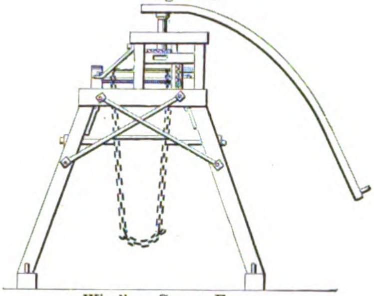
Stu'pa. (*Surgical.*) Tow used as a pledget, compress, or as a wad in fomentations.

Style. 1. (*Architecture.*) A name by which the more modern systems of architecture are known, in contradistinction to the Grecian and Roman *orders*.

2. A hard point for tracing, in manifold writing. See Pen.

3. The gnomon of a sun-dial.

Fig. 6014.



Windlass Stump-Extractor.

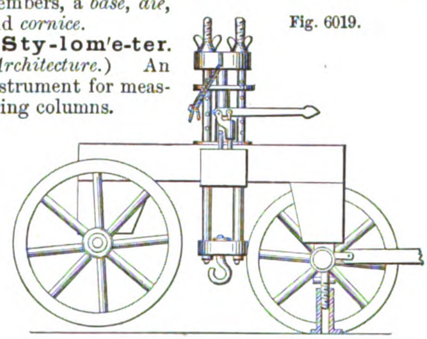
Sty'let; Sty'lus. 1. A *probe*.

2. A pencil or marker.

Sty'lo-bate. (*Architecture.*) A continuous basement beneath a row of columns or façades. It has 3 members, a *base*, *die*, and *cornice*.

Sty-lom'e-ter. (*Architecture.*) An instrument for measuring columns.

Fig. 6019.



Screw Stump-Extractor.

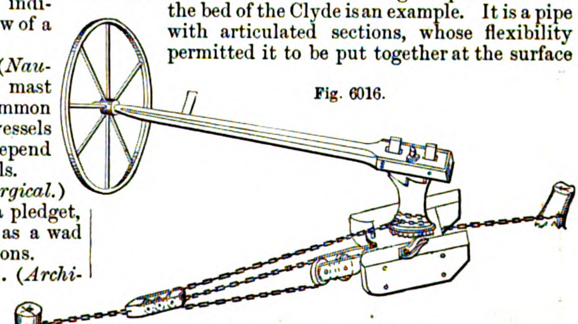
Stythe. (*Mining.*) Choke-damp, or carbonic-acid gas.

Sub. (*Well-boring.*) A short name for *substitute*. A short section of rod for connecting tools or bars of different sizes. See Well-boring Tools.

Sub-a'que-ous Hel'met. A diver's head-dress, supplied with air by pump from above. See Armor, Submarine, pages 155–157; Diving-bell, pages 713–715; Respirator, page 1923.

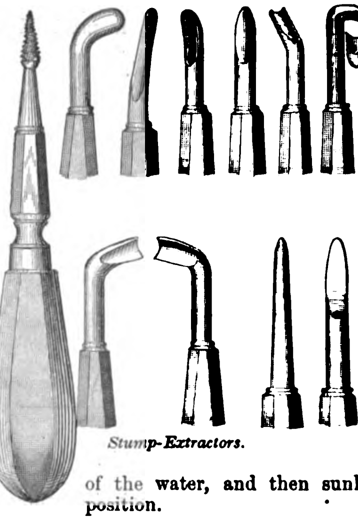
Sub-a'que-ous Tube. A pipe or tunnel (according to size) laid beneath the water as an aqueduct or viaduct. James Watt's submerged aqueduct across the bed of the Clyde is an example. It is a pipe with articulated sections, whose flexibility permitted it to be put together at the surface

Fig. 6016.



Capstan Stump-Extractor.

Fig. 6017.

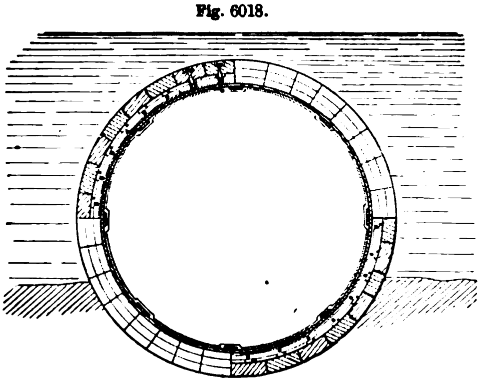


Stump-Extractors.

of the water, and then sunk into position.

Fig. 6018 shows a submerged tube whose outer casing of cement in form of blocks is attached by bolts, whose forked ends are riveted to rings of angle-iron surrounding the metallic part

Fig. 6018.



Subaqueous Tube.

of the tube. The blocks are connected together by tongues and grooves.

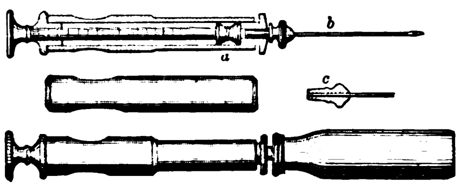
Sub-cal'i-ber Pro-jec'tile. (*Ordnance.*) A projectile for cannon or small-arms, of smaller diameter than the bore of the gun from which it is fired, but having a sabot large enough to fill the bore, allowing the usual windage; or with an expanding sabot, which is forced out so as to fill the bore when the gun is fired.

Sub'cu-ta'ne-ous Saw. A saw by which bony sections may be made without large incisions in the flesh. It may be compared to a probe, a portion of whose length, at and toward the end, is flattened and serrated, so that being driven in to the seat of its operations, it is reciprocated, so as to cut the bone without mangling the flesh to any serious extent.

Sub'cu-ta'ne-ous Syr'inge. (*Medical.*) An instrument for injecting medicinal solutions beneath the skin. It consists essentially of a tube with a piston for containing the preparation, and a perforated needle for piercing the skin, and through which the fluid is injected. Also called a *dermopathic syringe.*

Fig. 6019 is an improved form by Leiter of Vienna. In this, the lower end of the tube *a* is conically enlarged, for the more ready introduction of the lancet or needle *b* and the plug *c*, by

Fig. 6019.



Subcutaneous Syringe.

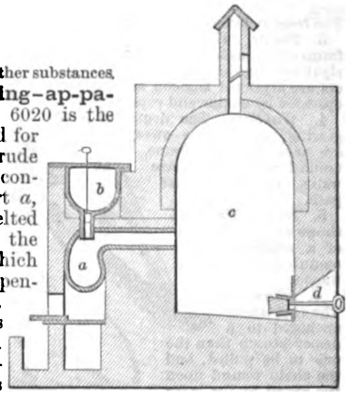
which it is secured in the tube. The piston-handle is graduated, that a definite amount of fluid may be drawn into the tube. See HYPODERMIC SYRINGE; ACUPUNCTURATOR.

Sub-li-ma'tion. A heating process by which solids are converted into vapor and again condensed, often in the crystalline form.

This process is adopted with

Mercury,
Zinc,
Arsenic,
Sulphur, and other substances.

Fig. 6020.



Sulphur-Sublimator.

Sub-lim'ing-ap-pa-ra'tus. Fig. 6020 is the apparatus used for purifying crude sulphur. This consists of a retort *a*, filled with melted sulphur from the reservoir *b*, which has a valved opening at bottom. The retort is heated by a furnace beneath, and as the sulphur is vaporized it passes over into the chamber *c*, where it condenses in the form of flowers of sulphur. After a few days' working, the walls of the chamber become sufficiently hot to fuse these as they condense, and the sulphur is then withdrawn from time to time through the plugged opening *d* and run into molds. See also ARSENIC-FURNACE, Fig. 373, page 162; CONDENSER, Fig. 1420, page 608.

Sub'ma-rine' Ap-pa-ra'tus. A device to enable persons to work under water.

The diving-bell is said to have been used among the Greeks in the time of Aristotle. It was first introduced into Western Europe near the beginning of the sixteenth century, but was not made practically available for use at considerable depths until Dr. Halley, in 1715, invented the method of displacing the water which entered the lower part of the bell by submerging casks containing air to a level a little below the bell, and discharging the air from them into it by admitting water at their bottoms by means of cocks. He also contrived a head-piece, open at the lower part, which enabled a diver to leave the bell and make explorations outside, being supplied with air through a flexible tube leading into the bell. Spalding subsequently divided the bell into an upper and a lower chamber, the former to be wholly or partially filled with water, and serving to regulate the buoyancy, while the latter was occupied by the divers. By admitting air from the barrels into the lower chamber and opening a cock connecting the two chambers, the upper could be filled with air, causing the apparatus to rise to the surface.

About 1788 Smeaton substituted cast-iron for wood, which had been previously used, made the machine of rectangular form, increased its capacity, and employed a forcing-pump for supplying it with air. See DIVING-BELL.

Submarine armor was successfully used by Klingert of Breslau, in 1798. His diving-dress consisted of a metallic cylinder with a hemispherical top for covering the head, a metallic cyl-

inder and a leathern jacket for protecting the trunk, and leathern sleeves and drawers covering the arms to the elbows and the legs to the knees. The head-piece had glazed apertures enabling the diver to see beneath the water, and pipes for breathing supplied by an air-reservoir which was sunk with him.

Tonkin's apparatus, used in Britain at the commencement of the present century, was a suit of complete metallic armor, covering the whole body except the arms, and surrounded by an exterior dress of leather. Air was supplied by an elastic tube from a compressed air-vessel at the surface.

An apparatus exhibited by the New York Submarine Company at the Paris Exposition of 1867 consists of a strong helmet of metal cushioned on the interior, and having a plate-glass window in front, and a water-proof dress entirely enveloping the person. This is weighted sufficiently to sink and enable the diver to stand firmly on the bottom. An air-reservoir is fastened upon his back, containing a supply of compressed air sufficient for several hours; this is conducted to the interior of the dress by a pipe provided with a cut-off valve under the diver's control. A cock on top of the helmet permits the discharge of the foul air from time to time. In order to prevent the dress collapsing against the person at considerable depths, is an inside protector, formed of a series of rings or ribs surrounding the person and lower extremities. See ARMOR, SUBMARINE. See also SUBMARINE BLASTING.

Secured beneath the diver's arms are a pair of water-tight sacks, which may be inflated from the reservoir at his back when he desires to rise to the surface. See also RESPIRATOR, Fig. 4272, page 1923.

Sub'ma-rine' Bat'ter-y. (*Vessel.*) A vessel capable of being submerged and maintained at a given depth below the surface of the water, and provided with means for penetrating the hull of an enemy's ship below the water line or of blowing her up, — usually a torpedo arrangement, which may be detached from the battery and attached to the bottom of the ship. The first practical development of the idea appears to be due to Bushnell during the War of the Revolution. Fulton afterward made various experiments on the subject.

Rockets of large size, guided by a tube projecting from the vessel, have been tried, but without very flattering prospects of success. See SUBMARINE BOAT; SUBMARINE GUN; TORPEDO.

Sub'ma-rine' Blast'ing. (*Hydraulic Engineering.*) A means for the removal of submerged rocks, shoals, sunken vessels, or other impediments to navigation.

The first effort in this direction was probably that of Colonel Pasley, about 1841, in blowing up the wreck of the "Royal George," sunk at Spithead, England, in 1782.

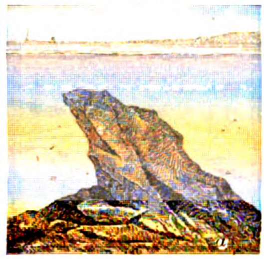
Fig. 6021 illustrates some of the operations for the removal of the submarine obstacles to navigation which formerly rendered that part of the East River known as Hellgate so dangerous to navigation in Long Island Sound. The principal of these were Pot Rock, on which the British frigate "Hussar" was wrecked at the close of the Revolutionary War, occasioning the loss of many lives and a large amount of treasure; Drake Rock; Holmes' Rock; the Frying Pan; and Way's Reef. These rocks were the cause of great injury to commerce, but though repeated surveys had been made and plans for their removal proposed, nothing was accomplished until the work was undertaken by Maillefert in 1851. Under an agreement with the New York Chamber of Commerce, this engineer undertook to remove Pot Rock, the Frying Pan, and Way's Reef for the sum of $ 15,000.

The first of these, shown in profile at *a*, was, at its highest part, but 8 feet below low-water level, and stretched across the strait, broadside to the current, for 130 feet, over which was an average depth of 10 feet water; the tide, setting through at the rate of 5 to 8 miles an hour, caused a fearful series of eddies and whirlpools among these rocks. At a short distance on either side, soundings of 50 to 75 feet are obtained. Owing to the strength and irregularities of the currents, boring was almost impossible, and the only time at which blasts could be effected was at slack water following flood or ebb tides.

M. Maillefert consequently applied his blasting charges, inclosed in water-proof cases, directly to the face of the rock, relying on the pressure of the body of water above to resist the expansion of the ignited powder sufficiently to cause it to shatter the stony stratum beneath.

The first blast was made August 19, 1851, and was perfectly successful, knocking off about 4 feet from the highest projecting pinnacle of Pot Rock. Operations were continued on this and other obstructions until March 26, 1852, when three men were killed by an explosion under the boat, owing to a misplacement of the battery connections. During this period 284 charges, containing in all 34,231 pounds of powder were exploded on Pot Rock, reducing its level to 18 feet below low-water mark; and 240 charges, containing nearly 27,926 pounds, on Way's Reef and the Frying Pan, by which they were considerably lowered. Shell Drake was increased in depth from 8 to 17 feet by the explosion of 6 charges of 125 pounds each upon it; and Bald-Headed Billy, a formidable isolated rock, dry at low water, was dislodged by a single blast, afterward drilled and split and the two parts grappled and removed. Two other small rocks were also destroyed. The total cost of these improvements was $ 13,000, a very small sum in view of the great improvements effected in the channel.

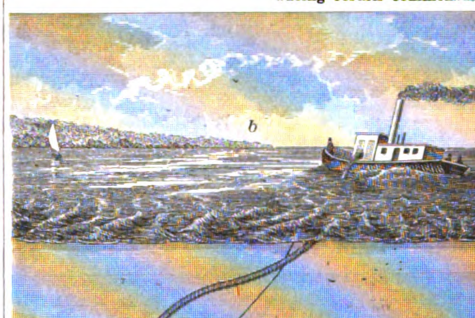
Fig. 6021.

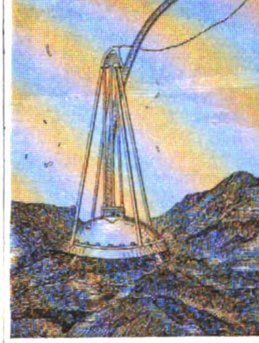


b. Mushroom-drill; a percussion drilling-apparatus, operated by steam from the tug employed as a tender.

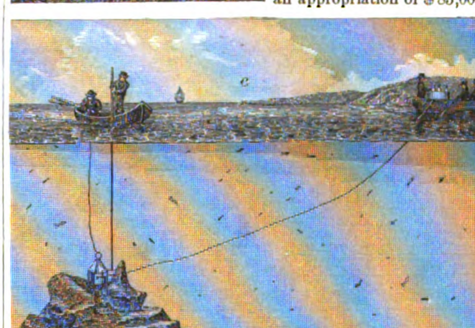
c shows the mode of applying a charge to the rock and firing it from an electro-magnetic battery at a distance.

In 1853, an appropriation of $ 20,000 was made by Congress for the improvement of the channel, which was expended without producing results commensurate with those previously attained. This, no doubt, was, in a large degree, owing to the fact that the shattering power of the charges when applied to a flat surface was far less than when employed in detaching projecting parts from a mass.



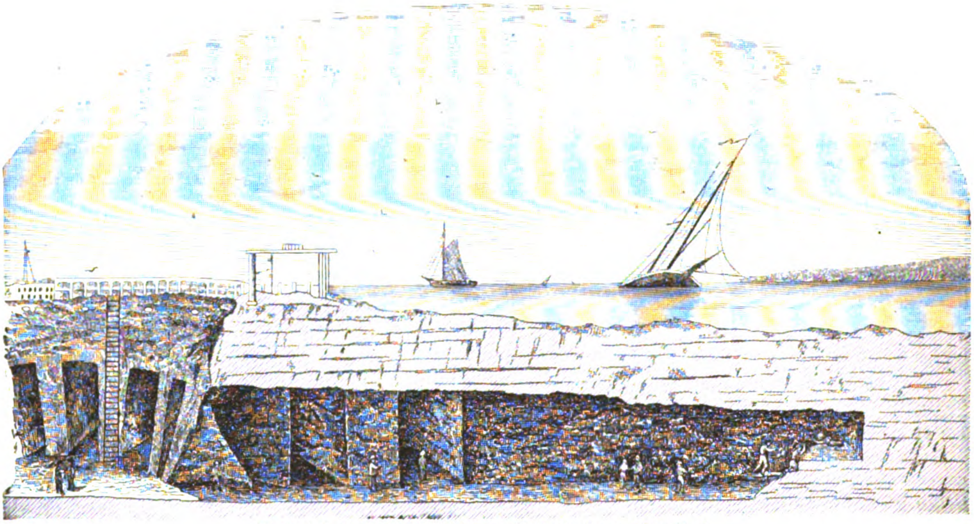


Little farther was done, notwithstanding the vast interests involved, until 1868. In the previous year, it was asserted, in a memorial to Congress, that the losses occasioned by the various obstructions in Hellgate amounted to from $1,500,000 to $2,000,000 a year. In 1868, an appropriation of $ 85,000 was made for their removal. Proposals for undertaking the work varied from $ 38,000 to $ 500,000, showing, notwithstanding the elaborate surveys previously made, that the bidders were entirely ignorant of what amount of work the requirements to be fulfilled might ultimately necessitate.



Submarine Blasting.

Fig. 6022.



Vertical Section of Excavation at Hallett's Point, New York.

Mr. S. F. Shelburne of New York, being the lowest bidder, received the contract. He employed first a small diamond-drill, rotated by a turbine; but this proving ineffectual, a larger one, the "Mushroom," of similar construction, was substituted. Drills of this construction were, however, found inadequate to do the work in such an exposed locality; and finally a powerful striking-drill was employed with fair prospects of success, but was, however, unfortunately run down by vessels and destroyed before it was practicable to test its capabilities.

Plans had been suggested by the United States Engineer De-

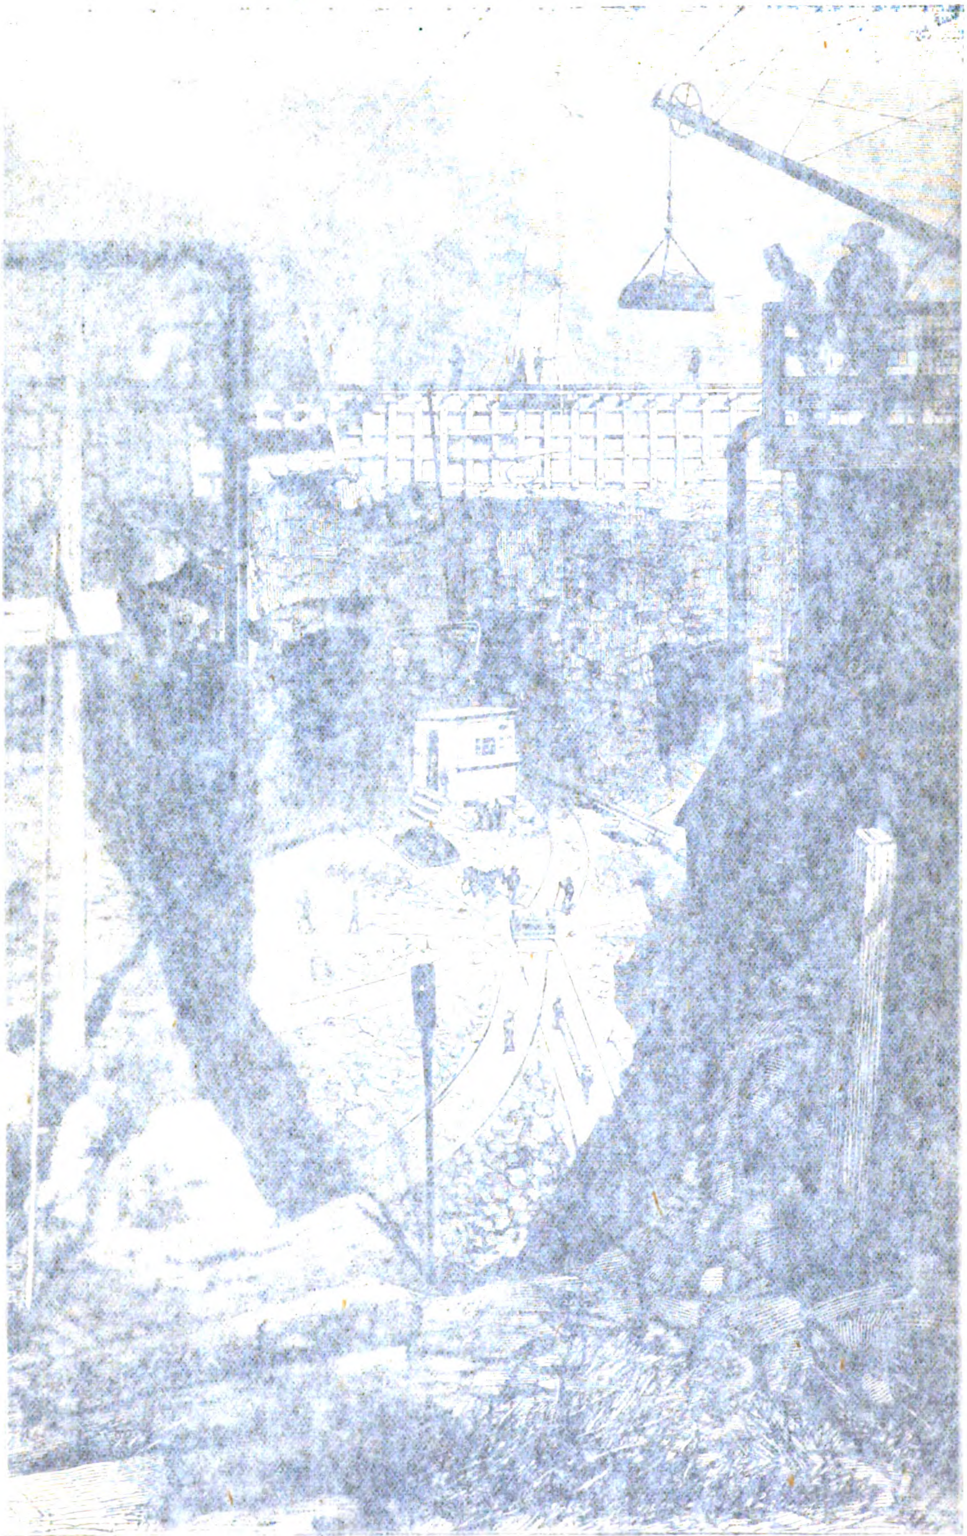

PLATE LXV

partment, involving an outlay of from $3,000,000 to $9,000,000, to entirely remove all the obstructions, and ensure a depth of 26 to 24 feet at low water. The execution of these projects would have occupied from 4 to 10 years.

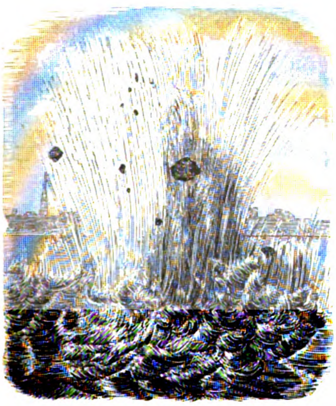
General Newton, United States Engineers, who had the general supervision of the work, in 1869, commenced operations by sinking a shaft beneath the ledge of rocks constituting Hallett's Point, which projects into the stream so as to throw the tidal current directly upon the Gridiron. For this purpose a coffer-dam 310 feet long, of heavy timbers bolted to the rock, and filled in with sand and clay, was constructed, the water pumped out, and a longitudinal shaft, having radial shafts extending from either side, excavated, the intention being to explode nitro-glycerine within the chambers, into which the displaced rock might fall and the fragments be afterward removed by grappling, if necessary.

Fig. 6021 shows a longitudinal section of "Grant" heading at Hellgate. The openings of other tunnels are seen to the left.

Fig. 6023 is a section of East River at Hallett's Point, and of one heading of the excavation, showing also the steam-drill. See also HEADING, Fig. 2463, page 1085.

The entire surface undermined measures 2½ acres, and the cuttings aggregate 7,542 feet in length, varying in hight from 8 to 22 feet, and in width from 12 to 13 feet. There is a roof 10 feet thick between the mine and the water, and the latter, at the outer edge of the excavation, is 26 feet deep at low tide. Between the headings and galleries heavy piers are left, which now sustain the immense weight of rock and water above. In each pier from ten to fifteen 2 and 3 inch holes are being drilled, and in the roof similar apertures are being made at intervals of 5 feet apart. All of these openings will be filled with nitro-glycerine, in charges of 8 and 10 pounds, and all will be connected together by gas-pipe filled with the same explosive. This will be done during the cold weather, when the danger of hauling the nitro-glycerine is greatly diminished.

Fig. 6024.



Effect of the Submarine Blast.

Previous to the explosion, the coffer-dam will be broken away and the water allowed to fill the entire excavation, so that it will serve as a tamping. Then, by means of an electric fuse, the nitro-glycerine in the gas-pipe will be fired, which will determine the blowing up of the whole affair. No fear is apprehended as to the result, since it has been determined that the explosion of half the charges will be sufficient to cave in the roof, and cause it to fall to the sunken floor, deepening the water at once to a proper depth, or necessitating but little dredging to complete the work.

The entire roof is to be blown off on the 4th of July, 1876; we cannot delay the issue of this book for the purpose of recording the success.

The Diamond reef and Coenties reef have been removed by drilling and blasting. Divers, equipped with submarine armor, descend to adjust the drills, insert the cartridges, etc.

Fig. 6025.

Diver Equipped for Descent.

The new operations at Flood Point will involve still greater cuttings than at Hallett's Point.

Fig. 6024 illustrates the effect of a submarine blast as viewed from the shore or a passing vessel; and Fig. 6025 shows a diver equipped in complete armor just about to make a descent.

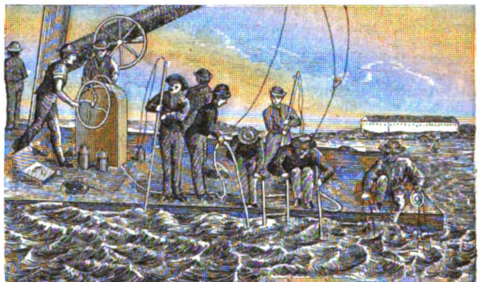
Fig. 6026 shows the diver at work.

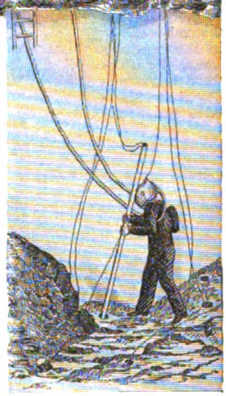
Plate LXV. shows a view of the Hallett's Point operations, looking down into the shaft. The sails of ships appear above the coffer-dam, which holds back the water.

The Blossom rock, a dangerous reef lying directly in the course which vessels are frequently compelled to take in entering or leaving San Francisco Harbor, was discovered by Captain Beechey, of H. M. S. "Blossom," in 1826. It is situated nearly midway between the islands of Alcatraz and Yerba Buena, and its top was but 5 feet below mean low water previous to the operations which resulted in its removal as an impediment to navigation in 1870. It was composed of a metamorphic sandstone of variable hardness, having a specific gravity of 2.64, and in some places containing small beds of gravel cemented together with a bluish substance resembling clay. Its greatest length was 195 feet, and its greatest width 105 feet at 24 feet below low water. The quantity of rock to be removed in order to obtain this depth was 5,000 cubic yards.

It was proposed to effect its removal by excavating longitudinal and transverse chambers in the interior of the rock to a depth of about 30 feet below low-water mark, leaving a thickness of about 6 feet between the excavation and the bottom of the bay, with pillars of stone left between these chambers, as at *A*, Fig. 6027.

Fig. 6026.





Diver at Work.

In order to sink a vertical shaft preparatory to excavating the horizontal galleries, a crib of timber, forming a coffer-dam having an interior open space 10 feet square, packed around with clay, was built and floated out to the reef, where it was sunk, and secured in position by driving steel-headed piles into the rock. On top of the crib a floor was laid, and a shed for lodging the workmen erected. The coffer-dam having been pumped dry and leakage stopped, a boiler-iron cylinder 6 feet in diameter was placed on it, and packing placed between it and the lining-walls. The sinking of the shaft was commenced December 7, 1869. At a depth of about 10 feet, the water again becoming inconvenient, a second iron cylinder of slightly less diameter was telescoped within the first; afterward a third cylinder of slightly less diameter than the second was similarly inserted.

When a depth of 30 feet was reached, drifts were run in the direction of the longer and shorter axes of the rock, and a swinging derrick constructed for hoisting the excavated matter by steam power and dumping it on the eastern slope of the rock.

The drifts were enlarged sufficiently to permit 16 men to work, who removed about 50 cubic yards of stone daily, and finally the chamber was increased to 140 feet in length, 60 in width, and 12 in hight, extreme dimensions. The crust of rock over the chambers was from 14 to 18 feet in thickness, or more than double that originally designed. This subsequently led to much labor in order to perform the conditions required.

The stone pillars were removed, with the exception of the four nearest the central shaft, and replaced by wooden props 8 to 10 inches square, each capped by a sill, between which and the surface of the rock wooden wedges were driven (*B*, Fig. 6027).

The arrangements were then made for blasting. For this purpose a nitrate of soda powder was used, being less expensive than ordinary gunpowder. Of this 43,000 pounds were used, placed in 38 ale-barrels and 7 old iron tanks, as shown at *C*, Fig. 6027. The charges were connected by tubes and wires.

An Abel cartridge was placed about midway of each iron tube and connected by two shorter wires with each of the battery circuit wires. The torpedoes were braced and fastened with timber, so that when water was admitted to the chamber, they would not rise to the surface. The charges were fired at 2 P. M., April 23, 1870, with a Beardslee battery, in a boat about 800 yards distant from the rock, raising a column of water 200

to 300 feet high, and 200 feet in diameter; around the base of this column was a simultaneous outburst of water probably about 70 feet high, which seemed to roll outwardly. The highest jet rose from the shaft.

An examination made shortly after the blast showed that there were but 14 feet water on the shoalest place over the rock. The fragments were removed into deeper water by a heavy iron drag, similar in appearance to an ordinary garden rake, and weighing $2\frac{1}{2}$ tons. This was suspended from a scow, which was towed back and forth over the rock by a steam-tug, which scraped the *débris* into deep water.

Sub′ma-rine′ Boat. A vessel constructed to navigate beneath the surface of the water.

Drebbel of Holland constructed for James I. a vessel which was manned by 12 rowers, and was tried on the Thames. The effete air was again rendered respirable by a liquor whose composition was kept secret by the inventor. The Marquis of Worcester, in his "Century of Inventions," refers to a contrivance of somewhat similar import.

Robert Fulton published his work on this subject in New York, 1810. His experiments were made at Brest in 1801. On July 3, in that year, he embarked with three companions on board his plunging-boat in the harbor of Brest, and descended in it to the depth of 25 feet, which was about as deep as the strength of his machine would bear. He remained below in darkness one hour. He afterward tried candles, but objected to them as destroying the vitality of the air. Bull's-eyes were then inserted in the top of the boat, and found satisfactory. His boat had one mast, a mainsail, and a jib, which moved her at the rate of 2 miles an hour on the surface, and were stowed in 2 minutes when preparing to dive. When submerged, the vessel was moved by the exertion of 2 men at the engine, while he governed the position of the boat by regulating the machine which kept her balanced and determined her depth below the surface.

The engine moved her about 500 yards in 7 minutes. On a subsequent occasion he took down reserves of compressed air, and descended for about 6 hours. His boat was called the "Nautilus." She did no effective service.

A large boat was projected, but the French became tired of the subject. The scheme caused great alarm in England, and Fulton was persuaded into the service of the British. He made some demonstrations with his torpedoes, but nothing effective in actual service, though some vessels exposed for the purpose were skillfully destroyed.

The Emperor Napoleon encouraged his project for a steamboat to transport the army of invasion, but afterward became tired of the subject, and forbade its being again mentioned.

A submarine boat has been employed in the pearl-fishery by the Pacific Pearl Company. It is 36 feet long, 12 feet broad, and 13 feet deep, flat-bottomed, with two hatches in the bottom, through which the oysters are gathered. It is semi-spindle shaped on top, and has a turret for the entrance of the workmen; a compressed-air chamber; a working-chamber, into which the compressed air is admitted to expel the water when the bottom is reached; and a water or ballast chamber for sinking it. When it is desired to rise, the compressed air is let into this water-chamber, gradually expelling the water as the machine rises to the surface. The air in the chamber is compressed by a 30-horse-power engine to the density of 3 or 4 atmospheres.

M. Denayrouze, whose subaqueous helmet and respirator are shown at Fig. 4272, has invented a submarine boat to move beneath the surface at 8 or 10 knots an hour, and carry a crew of divers to remove torpedoes and carry on blasting operations against submarine obstruction of even the hulls of enemies' vessels. The defense against such boats would be similar ones, and the transfer of the scene of combat from the surface to the depths would add an item of terror to what was already quite sufficiently desperate.

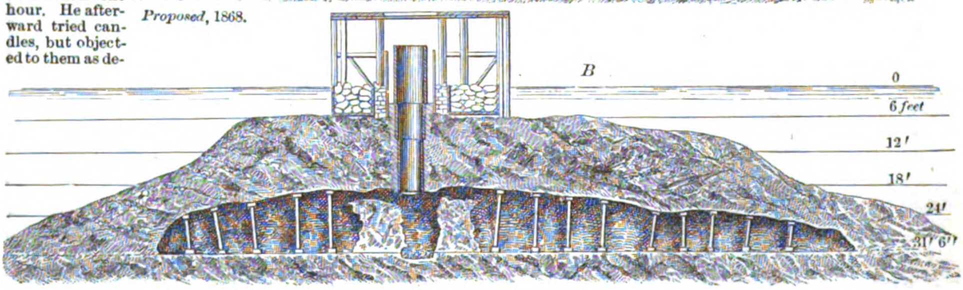
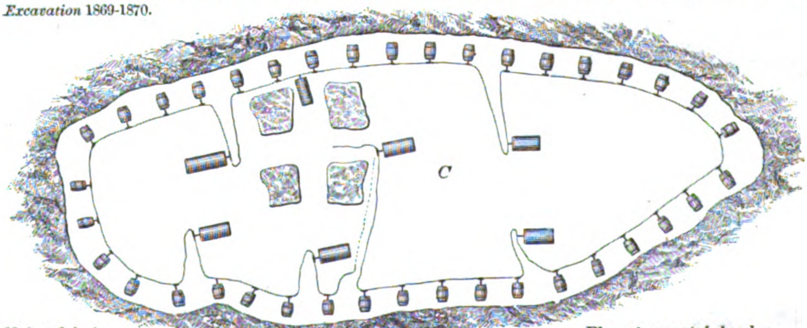
Proposed, 1868.



Excavation 1869-1870.



Scale 32 *ft. to* 1 *inch.* *Plan of excavated chamber.*

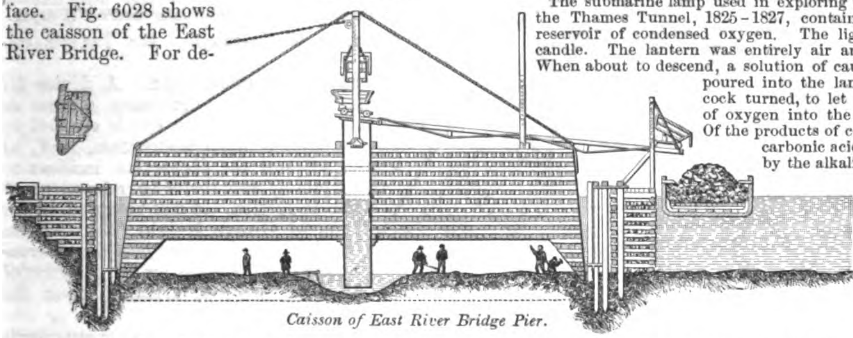
Submarine Excavation and Blasting of Blossom Rock, Harbor of San Francisco.

Sub′ma-rine′ Ca′ble. (*Telegraphy.*) A wire, or combination of wires, protected by flexible non-conducting water-proof material, designed to rest upon the bottom of a body of water and serve as a conductor for the currents transmitted by an electro-

magnetic telegraphic apparatus. See TELEGRAPH-CABLE.

Sub′ma-rine′ Ex′ca-va′tor. A device for removing earth or stone beneath the water surface. Fig. 6028 shows the caisson of the East River Bridge. For description, see the similar contrivance used in excavating for the piers of the St. Louis Bridge, page 49, and Plate II., opposite; also CAISSON, pages 420–422. See also DREDGING-MACHINE, pages 747–749; and other devices cited in the list under HYDRAULIC ENGINEERING, pages 1146–1148.

Fig. 6028.



Caisson of East River Bridge Pier.

Fig. 6029 shows an apparatus embodying a combination of conduits and mouth-pieces for excavating, dredging, and transmitting earthy and other loose matter, by means of forced currents of water, steam, or air, singly or combined. It is a form of dredge. The upper figures give details.

Sub′ma-rine′ Ex-plor′er. A diving-bell or lantern (see SUBMARINE LAMP; SUBMARINE TELESCOPE) used in examining sites beneath the surface of the water.

Storm's submarine explorer (Fig. 6030) consists of an interior and exterior shell of wrought-iron, connected by braces *N*. The interior shell is divided by a horizontal floor into two compartments, the lower of which serves as a working-chamber. These communicate by the man-hole *Q*. The lower part of the space between the two compartments constitutes a water-chamber to regulate the flotative power of the apparatus, and is divided by vertical partitions *C C′*, to prevent the water from surging from side to side when the machine is being moved. An iron ring *E* is permanently attached to the lower part, to act as a sinker; and other rings *E′*, which may be made in segments, can be added, if necessary. Light is admitted to the upper chamber through conical tubes *F*, having lenses at their inner extremities, and falls upon reflectors *V*, which diffuse it through the chamber. The upper chamber is lined with sheet-zinc *R′*, having numerous V-shaped perforations, and backed with felting, to absorb the carbonic-acid gas produced by respiration. Suitable valves are provided for admitting and exhausting air and water as required. *O* is a man-hole by which the upper chamber is entered.

Sub′ma-rine′ Gun. Submarine ordnance seems first to have been suggested by Saint Cyr in 1797, and consisted, as shown at *a*, Fig. 6031, of a mortar towed underneath a vessel by a span extending between two boats.

Fulton experimented with firing guns under water in New York Harbor in 1814, and was successful in penetrating a bulkhead representing the bottom of a first-class ship. His submarine battery of 100-pounder Colombiads is illustrated at *b*. The gun traveled on its carriage, the barrel of the piece slipping in a packed port-hole. The port was closed by a shutter, which was raised by a lanyard and dropped of its own accord when the gun recoiled.

Mr. Phillips of Indiana in 1855, and Woodbury of Boston in 1861–1864, worked at the problem. Woodbury's device is shown at Fig. 6032. An American submarine gun was shown at the French Exposition of 1867.

Fig. 6033 shows a submarine rifled projectile 5 feet long, 11 inches diameter, and with a bursting charge of 49 pounds. Total weight, 175 pounds.

Sub′ma-rine′ Lamp. A lamp adapted to burn beneath the surface of the water.

The submarine lamp used in exploring the breaches in the Thames Tunnel, 1825–1827, contained a spherical reservoir of condensed oxygen. The light was a wax-candle. The lantern was entirely air and water tight. When about to descend, a solution of caustic alkali was poured into the lamp, and a stop-cock turned, to let a small stream of oxygen into the light-chamber. Of the products of combustion, the carbonic acid was absorbed by the alkali, and the water condensed on the sides of the glass. The oxygen mixed with the nitrogen to form atmospheric air.

Oil-lamps, constantly supplied with air by means of a forcing-pump, and the electric light, have also been employed. The first was objectionable on account of the trouble it occasioned, and the latter by reason of its expense and the strong shadows cast by it.

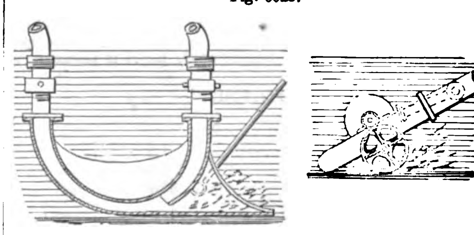
The lamp of MM. Leanté and Dénoyel is supplied with oxygen gas forced under a pressure of 10 atmospheres into a reservoir beneath, whence it is conveyed by a small tube to two annular receptacles, one inside and the other outside of the wick. Each is pierced with a number of small holes. Simple devices regulate the motion of the wick and control the supply of gas. The whole is protected by a thick glass cover, so as to be air and water tight.

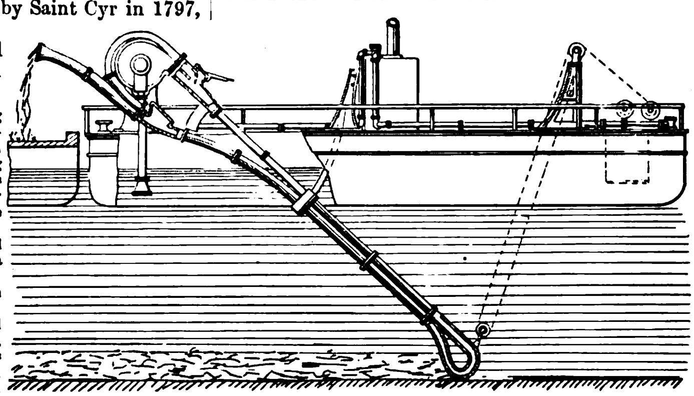
Van der Weyde's submarine lantern (Fig. 6034) has a cylindrical glass case, with the interior of which two channels communicate; one *C* connecting with a flexible pipe *D*, through which fresh air is injected, and the other *B* with the flexible pipe *E*, by which the products of combustion are carried off. *O* is the chamber, containing a hydrocarbon compound which readily vaporizes by heat, and *P* is the burner. The lantern is lowered by cords attached to the eyes *S S*. *T* is a ring by which the diver moves it from one place to another.

Sub′ma-rine′ Lan′tern. See SUBMARINE LAMP.

Sub′ma-rine′ Pho-tog′ra-phy. A photographic apparatus by Dr. Neumayer of Berlin, for ascertaining the temperature and direction of deep-sea currents.

Fig. 6029.

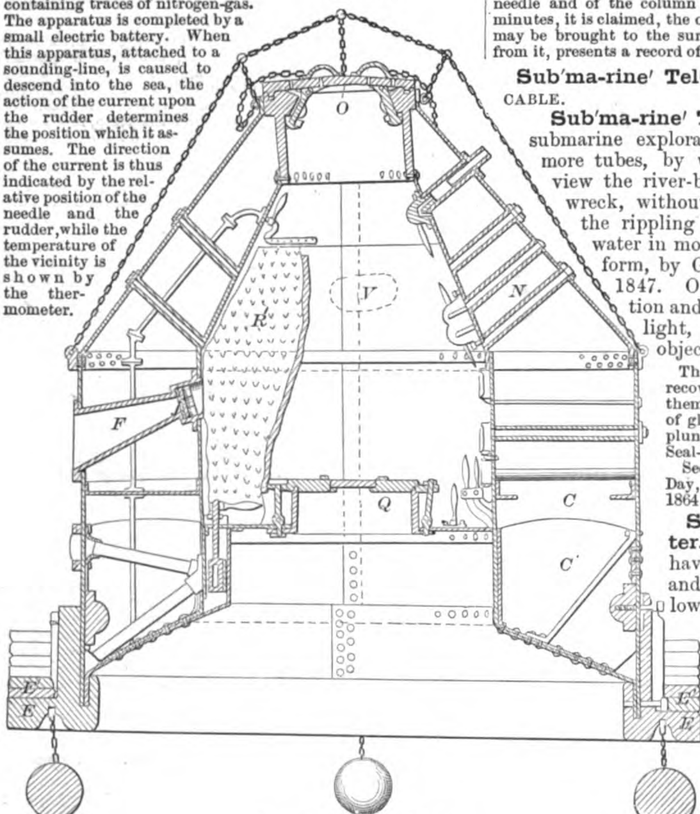




Robertson's Excavating-Machine.

It consists of a copper case hermetically closed, and furnished with an exterior appendage resembling a rudder. Within this case a thermometer and compass are inclosed, each in a glass vessel containing traces of nitrogen-gas. The apparatus is completed by a small electric battery. When this apparatus, attached to a sounding-line, is caused to descend into the sea, the action of the current upon the rudder determines the position which it assumes. The direction of the current is thus indicated by the relative position of the needle and the rudder, while the temperature of the vicinity is shown by the thermometer.

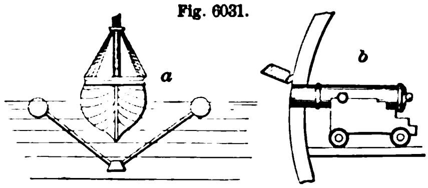
Fig. 6030.



Storm's Submarine Explorer.

But in order that these indications may be read at any desired spot in the ocean depths, it is necessary to fix them at the moment required. A leaf of photographic paper is placed in a

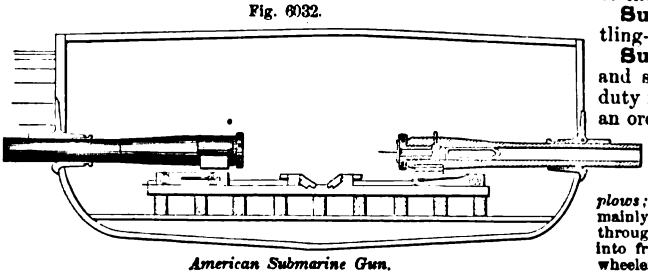
Fig. 6031.



Submarine Guns.

proper position next to the glass vessel containing the instruments. When it is desired to obtain the reading of the instruments, an electric current is sent through the nitrogen gas contained in these vessels. This produces a very intense violet light capable of acting chemically upon the photographic paper for a time sufficiently long to reproduce the shadows of the needle and of the column of mercury. At the end of three minutes, it is claimed, the operation is finished, the apparatus may be brought to the surface, and the paper, being removed from it, presents a record of the conditions observed in depth.

Fig. 6032.



American Submarine Gun.

Sub′ma-rine′ Tel′e-graph. See TELEGRAPH-CABLE.

Sub′ma-rine′ Tel′e-scope. A device for submarine explorations, consisting of one or more tubes, by which the eye is enabled to view the river-bed, an obstruction, rock, or wreck, without the distraction incident to the rippling and distorted refractions of water in motion. It was patented, in one form, by George Knight (England), in 1847. One tube was used for observation and the other for the direction of light, solar or artificial, upon the object.

The arrangement used by smugglers in recovering contraband articles sunk by them consisted of a cask having a plate of glass at the bottom. This end was plunged a few inches below the surface. Seal-hunters use the same contrivance.

See patents: Mather, April 16, 1845; Day, April 16, 1850; Mather, July 5, 1864.

Sub′ma-rine′ Ther-mom′e-ter. (*Nautical.*) A chamber having valves above and below, and inclosing a thermometer, is lowered to the required depth, the water flowing upward through the chamber as it descends. When the descent is checked, the valves close, and the chamber is hauled up, containing water from the depth reached.

A registering-thermometer is now used. See THERMOMETER.

Sub′ma-rine′ Valve. A port or valve in the side of a vessel, opening beneath the surface of the water, for the purpose of protruding a torpedo, the muzzle of a gun to be fired under water, or some other offensive weapon. See SUBMARINE GUN; TORPEDO.

In the example (Fig. 6035), the valve *D* is pivoted in a casing in the ship's side, being connected to the journal of the rock-shaft *F*, which may be operated from the engine-room or other convenient position. The movement of the valve is parallel to the side of the vessel, and covers or uncovers the exterior orifice of the blow-off pipe, a ventilator, or other opening. *i* is an index for showing the position of the valve.

Sub′ma-rine′ Ves′sel. See SUBMARINE BOAT; TORPEDO.

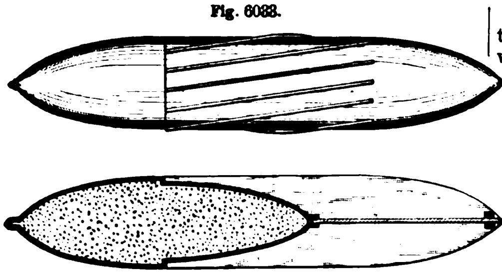
Sub-merged′ Pump. A well or cistern pump which is placed under water, the pump-rod and discharging-pipe reaching from the surface of the ground to the pump.

Sub-sid′ence-vat. A dyer's settling-vat.

Sub′soil-plow. One having a share and standard, but no mold-board. Its duty is to follow in the furrow made by an ordinary plow, and loosen the soil to an additional depth without bringing it to the surface.

In England they are called *trenching-plows;* and sometimes *horse-picks*, from their mainly consisting of a sharp share which is forced through the subsoil, lifting it and breaking it into fragments. It is drawn by 4 horses, the wheelers hitched to the clevis, and the leaders

Fig. 6033.

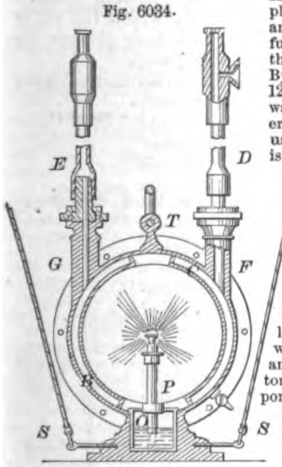


Submarine Projectile.

by a *soam*, or draft-chain, to the draft-rod of the plow, below the beam.

The first mention of subsoil-plows is in Worlidge's "Mysteries of Husbandry," 1677. He tells of an ingenious young man in Kent, England, who had two plows fastened on one stock, and the rear one plowing a furrow beneath the level of the sole of the preceding one. By this he stirred the land 12 or 14 inches deep. This was a regular subsoiling operation, though the now usual form of the implement is to stock the subsoil-plow separately and make it to follow in the wake of the ordinary plow.

Fig. 6034.



Van der Weyde's Submarine Lamp.

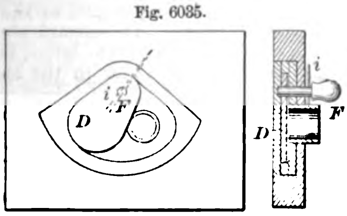
Smith of Deanston, Scotland, is credited with the invention and introduction of the modern implement. The illustration shows that it is destitute of mold-board and landside, having a share with wings adapted to raise and crumble the furrow bottom, comminuting it as a porous foundation for the mold which will be turned upon it by the ordinary plow in its next furrow.

It has a curved colter, which is designed to be self-cleaning. The draft is applied by a draft-rod, secured by a *bridle* to the beam.

It is drawn by four horses, two and two, and managed by one man. The usual mode is to make a 10×6 inch furrow with an ordinary plow, and follow with the subsoiler at an additional depth of from 5 to 7 inches.

Stracey's subsoil-plow (English) has several points in common with its predecessor, as may be readily seen by comparison. It is used with a wheel, is higher in the throat, and has the broad, flat, sharp standard, which experience has indicated is the best form of sheth for the angle-iron or winged share which cleaves the subsoil.

Fig. 6035.



Submarine Valve for Vessels.

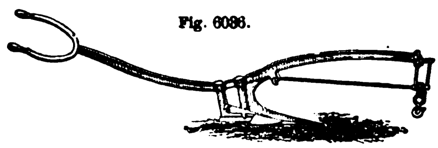
By a continued reduction of parts beneath the surface, the *subsoil-plow* becomes a *mole-plow*, in which a mere plug is attached to the *sheth* to force a way through the subsoil, leaving an arched drain, like a mole-track.

McMeekin's (Fig. 6038) has the standard *a* and brace *b* formed of a single bar of metal. The share has a flange which enters the loop thus formed, is bolted thereto, and is provided with a small landside and mold-board.

Fig. 6039 is an approved modern form of English subsoil-plow, adapted for subsoiling from 12 to 18 inches in depth. The plow-body is of wrought-iron. The small wheel serves as a furrow-marker.

Sub′sti-tute. **An optional bar or section, as the *substitute sinker-bar*, a shorter section to be used when a full-length section is not suitable.**

Fig. 6036.

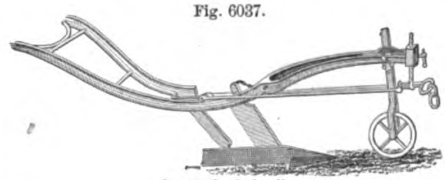


Smith's Subsoil-Plow.

Or a short section of sinker-rod having flanges to ream the hole and keep it straight. See WELL-BORING TOOLS.

Sub′ter-ra′ne-an Rail′way. A railway running its whole course beneath the level of the surface of the ground. The occasional dipping beneath the surface is a tunnel.

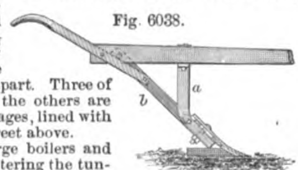
Fig. 6037.



Stracey's Subsoiler.

The subterranean railway in London, between Victoria Street, Holborn, and Paddington, was constructed 1860-1862. It is 3½ miles in length, having stations at an average distance of ⅝ of a mile apart. Three of these have glass roofs; the others are lighted by slanting passages, lined with white tiles, from the street above.

Fig. 6038.

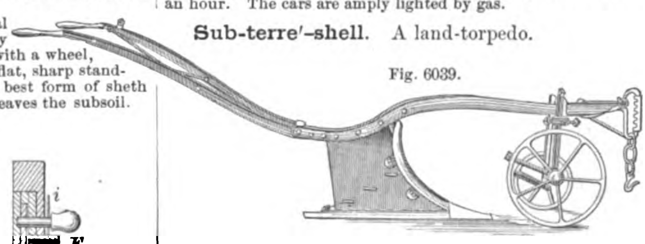


McMeekin's Subsoiler.

The engines have large boilers and cylinders, and before entering the tunnel steam is raised to 130 pounds. On entering the tunnel the exhaust is turned into a water-tank instead of up the chimney, so that the combustion of fuel is much reduced, and little smoke escapes; the steam-pressure is allowed to run down to 65 pounds, the cut-off being varied so as to maintain a uniform power sufficient to produce an average speed of 25 miles an hour. The cars are amply lighted by gas.

Sub-terre′-shell. A land-torpedo.

Fig. 6039.



English Subsoil-Plow.

Sub′way. An underground tunnel beneath the street surface in which the gas and water pipes and sewers are lodged, so that they can be examined, repaired, replaced, etc., without disturbing the pavement.

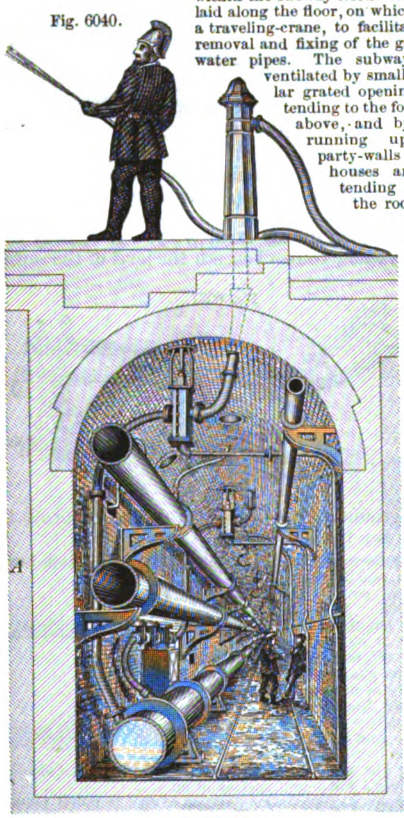
The plan was proposed by Williams in London in 1822, and has been adopted in Paris. See SEWER.

In Fig. 6040, *A* represents one of the subways on each side of the Holborn Viaduct, London. These are 7 feet wide and 11 feet 6 inches high, running between the great arches which carry the roadway and the house-vaults which support each footway. They are located immediately above the sewers, are floored with stone, and lined with brick. Along the wall nearest the fronts of the houses is a 14-inch water-main, and above this two 10-inch gas-mains supported on brackets. On the opposite side is a pipe containing the telegraph-wires.

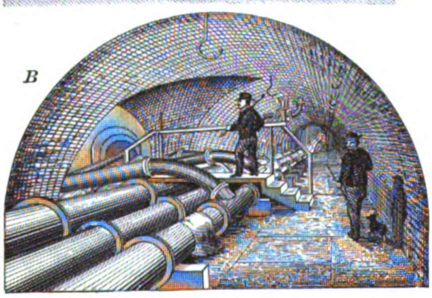
Junctions are arranged for carrying water and gas into each house along the route by pipes conducted through holes in the sides of the subways. Branch pipes are laid on to the street fire-plugs and hydrants, and gas is laid on to the street-lamps. All the usual valves, meters, and other apparatus are accessible within the subway itself. Rails are laid along the floor, on which runs a traveling-crane, to facilitate the removal and fixing of the gas and water pipes. The subways are ventilated by small circular grated openings extending to the footways above, and by flues running up the party-walls of the houses and extending above the roofs.

Fig. 6040.

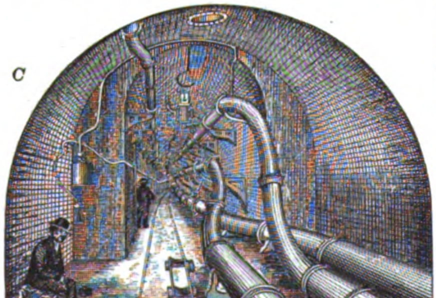
A



B



C



London Subway.

Where practicable, the entrance-doors are also constructed of open wire-work.

B, section of London subway; north side junction of Charterhouse Street.

C, section; south side at west end of viaduct.

Suc′cu-la. A plain axis or cylinder, provided with staves or handles for turning it, but having no drum.

Suck′er. 1. A pump-bucket; *embolus.*

2. The leathern flap-valve of a pump-bucket.

3. A round piece of leather having a central perforation for the attachment of a string; when rendered flexible by wetting, and applied to a smooth object, as a stone, the adhesion between the two surfaces due to atmospheric pressure enables the lifting of the stone.

Suck′er-rod. A rod connecting the brake of a pump with the bucket.

Suck′er-rod Swiv′el. A swiveled link at the top of a pump-rod. See WELL-BORING TOOLS.

Suck′ing-bot′tle. An infant's feeding-bottle.

Suck′ing-pump. A pump in which the water is raised within reach of the bucket or plunger by atmospheric pressure. A *suction-pump.*

Suck′ing-tube. Most of us are acquainted with the taste of sweet cider as sucked through a rye-straw. They are used in many parts of the world for other liquids than cider. Besides their use among us with *cobblers* and *juleps*, the Peruvian drinks his or her *mate* by means of a tube with fine holes to keep back the particles of leaf. The sucking-tube was used by the ancients as a domestic utensil, and also in the temples. The latter use has also descended to our times in the *sanguisuchello*, or blood-sucker, a golden tube by which the Pope sucks up the wine at high mass. A *chalumeau*, or tube of gold, and silver "pypes," for the same purpose, are also mentioned in old inventories of church property.

Fig. 6041.

Sanguisuchello.

Suc′tion-pipe. That pipe of a fire-engine, or other pump, which conducts water from a cistern to the cylinder of a pump.

Suc′tion-plate. (*Dental.*) A dental plate retained in position in the mouth by atmospheric pressure.

Suc′tion-pri′mer. A small force-pump worked by hand and used in charging a main-pump.

Suc′tion-pump. A pump in which the plunger or bucket is placed above the level of the water, the latter rising by atmospheric pressure, as the *sucker* (bucket) is raised. Between the upward strokes of the bucket, a *clack-valve*, below the latter, falls and prevents the reflux of the water in the ascension tube. See LIFT-PUMP.

Suc′tion-valve. 1. The valve below the plunger or bucket of a pump, and which is lifted by atmospheric pressure acting upon the water beneath it, as the plunger is raised.

2. (*Steam-engine.*) The valve through which the water is drawn from the hot-well into the feed-pump, by the rise of the plunger. See FEED-PUMP.

Sug′ar. A substance having a sweet taste, soluble in water, and capable of undergoing fermentation.

Three kinds are distinguished in chemistry: —

	Formula.
Saccharine, or cane-sugar	$C_{12} H_{11} O_{11}$
Glucose, or grape-sugar	$C_{12} H_{14} O_{14}$
Lactose, or milk-sugar	$C_{12} H_{12} O_{12}$

The first of these is derived principally from the sugar-cane (*Arundo saccharifera*), but is also obtained from beet-root, the sap of the sugar-maple, and various other plants. It is much sweeter and more readily crystallizable than either of the other kinds, and is that generally known to commerce.

The sugar-cane is a native of Asia. It is believed to have originated in China, and to have been used by the Celestials many centuries before it found its way to India and Arabia, from whence it was introduced into what is now the Christian world. In Sanscrit, sugar is *sarkara*. Our *candy* is also from the Sanscrit *kanda*. In Persian it is *schakar;* Hindostanee, *schukur;* Arabic, *sukkar*.

The references to it among ancient writers are few and indistinct. The first distinct notice of it is by Nearchus, who conducted the fleet of Alexander down the Indus. He speaks of the sugar-cane as growing in India, but does not refer to expression of the juice.

Sugar is mentioned by Dioscorides and Pliny, not from any commercial or domestic value that it possessed, but as a curious item of natural history and a presumed use as a medicine.

Galen also refers to it as a kind of honey secreted in reeds and brought from Arabia Felix and India.

It was known by the Greeks and Romans as an Oriental production, but was sometimes confounded by them with the *Tabaschir*, made from bamboo stems. (Sanscrit; *trak-kschira*, bark-mill.) Moses of Chorene, who lived in the middle of the fifth century, was the first who described circumstantially the preparation of sugar from the juice of the *Saccharum officinarum* in the province of Khorasan.

It is also mentioned by Paul Eginetta, a physician, A. D. 625.

The Arabs seem to have introduced it wherever they went, finally into Sicily and Spain. Through them it became known to the Crusaders, who liked the sweet honeyed reeds, and one of their chroniclers describes the mode of expressing and purifying the juice as practiced by the inhabitants of Acre and Tripoli.

The cane was cultivated in Cyprus, 1148, and a grant from William II. of Sicily, in 1166, includes a sugar-mill with "all its rights, members, and appurtenances." It does not, however, appear to have been generally known in Europe prior to the middle of the thirteenth century.

It is said that a Venetian merchant in 1250 visited Bengal and informed himself of the mode of culture and preparation. The art of refining sugar and making sugar loaves was also communicated by a Venetian about 1550. It is not known whether he independently originated the idea, or whether he received it from China, where it had been practiced for ages. Boiling and baking sugar was first practiced in Europe about 1420.

Bartholomew was the first Englishman who described the method of crystallizing and purifying sugar.

The plant was taken by the Portuguese to Madeira in 1420, and soon afterward, in 1506, to the Canaries, from whence it was taken to Brazil and to St. Domingo. Its culture thence gradually spread throughout the West Indies. Barbadoes was supplied from Brazil in 1641, and the culture was introduced into Louisiana by French refugees from St. Domingo toward the close of the last century.

For notice of beet-root sugar, see *infra*, also page 255.

Maple sugar was first made by the Indians, and La Salle refers to it as a kind of manna.

Sirup. The *sirup* of commerce is the residual product obtained in refining raw sugar. This is dissolved in water, filtered and decolorized, boiled, and formed into loaves.

The sirup which drains out of the loaves, called *greens*, is again purified, decolorized, and boiled down to crystallization. The crystals are separated in the centrifugal machine, and sold as a very light-colored *coffee-sugar*. The *greens* from this sugar yield, by purification, decolorization, and boiling, a light yellow sugar. The last *greens*, after three successive crystallizations of sugar, are purified and sold as *golden sirup*. This sirup still contains a considerable quantity of crystallizable sugar, which cannot be profitably extracted, together with uncrystallizable sugar, coloring matter, and the substances which give to sirup its peculiar agreeable flavor, but whose exact nature is not known.

Beet-Root Sugar. Oliver de Serres, 1605, suggested the use of beets for making sugar. Margraff first produced sugar from beets in 1747; Achard, in 1799. Bonaparte encouraged it, as his connections with the West Indies were very precarious, and were likely to become more so. 60,000 tons of beet-root sugar are now produced annually in France. Large quantities are also made in Northern and Central Europe, forming a large proportion of the amount consumed. The industry has been introduced into Illinois and California. It prospers in the latter.

Napoleon devoted 80,000 acres and 1,000,000 francs to encourage this industry,—one which has since grown to be of much importance in Europe. It is computed that beet-roots now supply nearly a fourth of all the sugar furnished to the markets of the world.

The amount of sugar contained in the beet varies from 8 to 13 per cent. As high as 40 tons of beets per acre have been raised in some parts of France. This would give, at 10 per cent, 4 tons of sugar to the acre; an average of one fourth as much is, however, considered satisfactory.

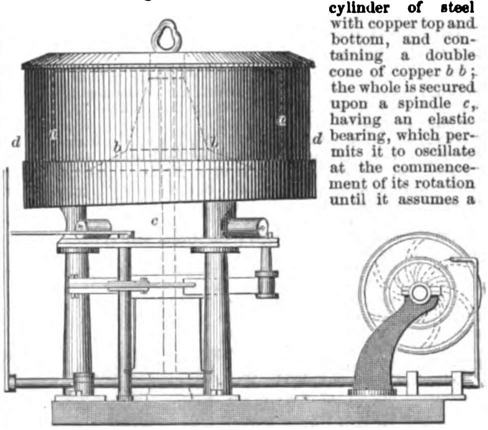
Beets for the manufacture of sugar are deprived of their tops, thoroughly washed by machinery, and then rasped into pulp or cut into thin shavings, according to the mode of manufacture practiced.

In the grating-machine the beets are fed into a hopper above and fall into two troughs beneath, where they are pushed forward, by means of two plungers operated by levers and links from a crank-shaft so as to have a quick return-motion, to a drum set with saws, which revolves at the rate of 600 to 800 revolutions per minute. The pulp is discharged into a chute.

In the slicing process a centrifugal root-cutter is employed. This consists of a stationary conical casing, within which are six grooved toothed knives. The beets fed from a hopper above are driven against the knives by two flyers on a rotary disk, and cut into slices of uniform thickness.

After the beets have been grated, the juice is expressed by a hydrostatic press, or by the centrifugal machine (Fig. 6042). The basket *a a* consists of a perforated cylinder of steel with copper top and bottom, and containing a double cone of copper *b b*; the whole is secured upon a spindle *c*, having an elastic bearing, which permits it to oscillate at the commencement of its rotation until it assumes a perpendicular position by the even distribution of the pulp in the basket.

Fig. 6042.

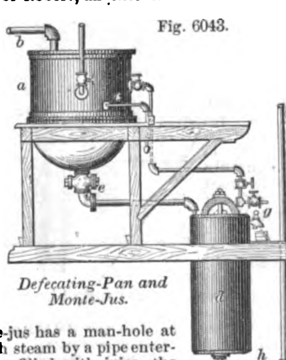


Centrifugal Machine.

The rotation of the basket by belting on the spindle assumes a great velocity, and the juice is expressed from the pulp, caught by the curb *d*, and flows to a conductor, by which it is conveyed to the defecating-pan.

The diffusion process of Robert, an extensive Austrian beet-root sugar manufacturer, is a mode of extracting the saccharine liquid from the pulp, and is described and illustrated, page 702, Fig. 1652.

Fig. 6043.



Defecating-Pan and Monte-Jus.

The defecating-pan *a* contains a steam-heated coil of copper pipe. The juice is admitted through the pipe *b*, while carbonic acid, entering through *c*, is distributed throughout the juice by a perforated pipe. The defecated juice and scums are drawn off into the *monte-jus d* through the cock *e*. The monte-jus has a man-hole at top, and is supplied with steam by a pipe entering above; as it becomes filled with juice, the air is driven out through the bibcock *g*, which also indicates when the monte-jus is full; when this takes place, the bibcock is closed and boiler-steam admitted, forcing the juice out through the pipe *h* into the receiving-tanks.

The filter-press is used for recovering the juice which runs off in the scums from the defecating-pan. Formerly the scums were put in bags and pressed in hydraulic presses. This required considerable manual labor and power, which is nearly all saved by the filter-press. This consists of a vat having cloth strainers, through which the juice is forced by steam-pressure. After this the sirup is passed through a *bone-black filter*, when it is ready for the evaporating-pans.

The sirup may be drawn off into another vacuum-pan for completion, or evaporated to the point of crystallization in the second evaporator, and then drawn off to crystallize, after which it is refined in the usual manner.

The refuse pulp from the manufacture of beet-sugar forms an excellent food for stock. Recent improvements are offered in

the treatment of the by-products of beet-root sugar-making. Hitherto they have been treated for the mineral salts they contain, and then abandoned. The residuary liquor is now concentrated, and by a process of dry distillation acetic acid, methyl, alcohol, and ammonia are obtained. The by-product is then treated for the mineral salts as before.

Glucose. Glucose, or *grape-sugar*, is a saccharine substance obtained from starch by boiling in water with one per cent of sulphuric acid. The liquid is drawn off, the acid neutralized by lime, precipitate allowed to subside, liquid decanted and evaporated.

Starch is also converted into a fermentable sugar resembling glucose, by the action of a diastase.

Ligneous fiber will also yield glucose by treatment with a stronger solution of acid than the above, the mixture being afterward diluted, boiled, neutralized by alkali, and decanted.

Glucose is also obtained from cane-sugar by boiling in diluted acid.

The term *glucose* has been made to comprise several distinct modifications of sugar, some of which are mentioned above, as well as the sugar of malt, cane sugar modified by acid; but, speaking in general terms, glucose is a non-crystallizable saccharine, which, like *dextrine*, turns the plane of polarization to the right hand, as the term *dextrine* indicates. Cane-sugar (*sucrose*), on the other hand, is crystallizable, and turns the plane of polarization to the left. See Miller's "Elements of Chemistry," Part III. pages 71, *et seq*.

Glucose is developed in the process of malting, and its infusion is the solution called *wort*, from which *beer* is made; or it makes the *wash* of the distiller.

Among the processes for the expedition or more perfect performance of the change of condition may be cited: —

Riley, March 5, 1850, converts corn meal into glucose under pressure in a boiling solution of sulphuric acid: water, 1,000 gallons; acid, 25 pounds.

Reitsch, February 3, 1852. The saccharine matter of wort evaporated to a viscid mass.

Hoffman, May 25, 1858. Meal treated with dilute sulphuric acid and steam under pressure of 350° Fah. Decant and evaporate.

Hawkes, February 3, 1863. Wort of malt boiled with decoction of hops; cane-sugar added; boiled to a thick sirup; add gelatine, and can.

Weiderfeld, April 28, 1863. Meal steeped in water impregnated with gases resulting from dry distillation of sulphuric acid; wood charcoal; crystallized soda.

Goessling, May 10, 1864. Corn soaked, bruised between rollers; soaked in repeated waters, to prevent fermentation. Knead, pass through sieve, wash; treat with caustic potash, then with acid and steam; neutralize with alkali; steam, fine, filter, and concentrate.

Thompson, June 7, 1864. Macerate grain in dilute acid.

Fleischman, July 12, 1864. Macerate grain in sulphurous-acid gas water. January 5, 1865. Add bicarbonate of soda to above, developing hyposulphurous acid.

Goessling, December 20, 1864. Attempts to crystallize a mixture of corn or starch sirup and cane-sugar.

Percy, February 28, 1865. Whey of milk and albumen boiled, and the resulting lactine treated with sulphuric acid or malt to produce glucose.

Hawks, June 27, 1865. Ground malt is macerated with corn meal and elutriated to remove saccharine, which is evaporated *in vacuo*.

Goessling, September 5, 1865. Soak corn in alkaline ley. Crush, strain, and add the starch to a boiling acid solution, defecate with charcoal, neutralize with alkali. Evaporate and crystallize (?).

Goessling, September 5, 1865. Two modifications of the last.

Watson, December 5, 1865. Kiln-dry meal, and macerate in water.

Seely, January 10, 1865. Saw-dust purified by alkali, macerated in boiling acid solution, and added to 5 times its quantity of starch, and 10 times the quantity of water. Concentrate.

Deissner, June 19, 1866. Corn boiled in water; malt, sugar, and flour added.

Hirsh, October 16, 1866. Corn soaked in dilute sulphuric-acid; heated to 170° Fah.; ground, sieved, washed; starch boiled in solution of sulphuric acid, sulphuric alumina, and charcoal. Neutralize, concentrate, evaporate, defecate with bone-black, filter, concentrate *in vacuo*.

Hoff, December 18, 1866. Soak barley in fennel water, and malt it; add various fragrant herbs. Ferment.

Pigeon, April 23, 1867. Starch and cellulose treated in acidulous water, boiled under pressure. Saccharine liquid neutralized with lime, filter, defecate with bone-black, concentrate to 20° B. Allow the lime to precipitate. Filter; neutralize with soda. Boil, crystallize (?). Mold.

Loew, June 25, 1868. Woody fiber digested in hydrochloric acid, and heat; acid distilled over. Glucose and paper-stock the results.

Wesselholft, October 6, 1868. Extract of malt for dietetic purposes.

Sim and Hutchinson, March 16, 1869. Meal treated with bisulphide of carbon to extract oil, rendering starch more easily saccharified.

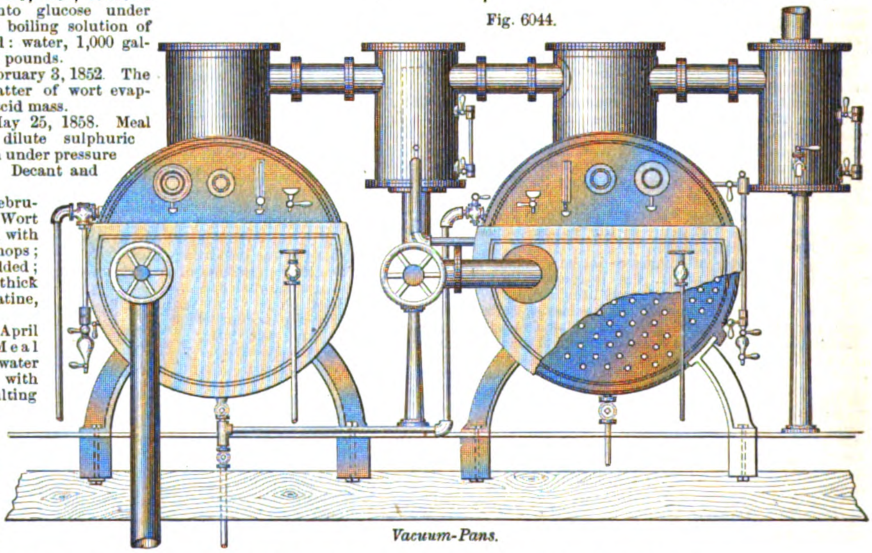
Delamarre, December 6, 1870. Sweet potatoes steamed, mashed, and mixed with malt, macerated, steamed, pulp precipitated, saccharine liquid decanted, concentrated.

Grosheintz, May 23, 1871. Hydrochloride or sulphuric acid saturated with an alkali to produce a salt which may remain in the saccharine matter.

Sug'ar-cane Mill. A mill for grinding sugar-cane. See Figs. 1059-1061, page 444. See also SUGAR-MILL.

Sug'ar-cane Plant'er. A machine for planting ratoons of cane in furrows made by the plow, to afford sprouts for the future plant.

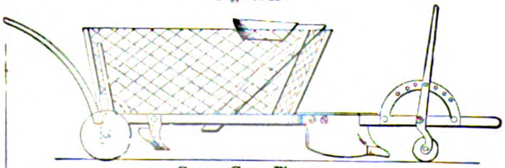
Fig. 6044.



Vacuum-Pans.

In Fig. 6045, the cane-slips are placed in the chute and delivered into the furrow made by the first plow; the two side-plows cover the cane, and the scraping-plates level the ground. The body is vertically adjustable by lever-arms carrying the wheels.

Fig. 6045.



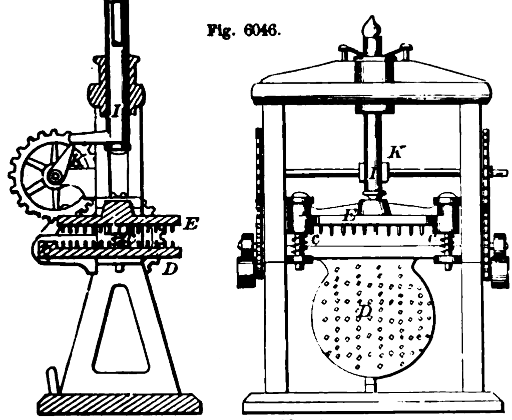
Sugar-Cane Planter.

Sug'ar-clar'i-fi'er. A filter for removing mechanical impurities or feculences from sirup. See

SUGAR-DRAINER; CENTRIFUGAL FILTER; etc. Or a DEFECATOR, see Fig. 1605, page 683; or other process by which immature, non-crystallizable, or fermenting matter is removed from sirup.

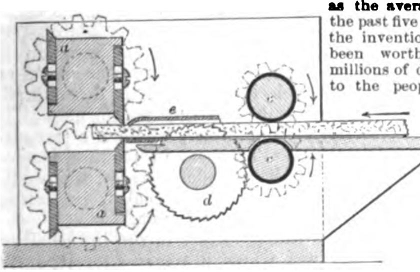
"In 1859, Richard H. Stewart patented a process of clarifying cane-juice for the manufacture of sugar, treating it with sulphurous gas. Sugar purified by this method was increased in value ½ cent per pound. The war hindered the introduction of the improvement, but since 1867 it would be difficult to find a planter who has not adopted it. In 1860, the sugar crop of Louisiana was 500,000 hogsheads. In 1867, it was only 5,000. In 1872, it had reached 80,000. If we take this figure as the average of the past five years, the invention has been worth two millions of dollars to the people of the United States during that period. Stewart received, from the fourteen years of his original patent, $44,350; or, in other words, he made from his patent in fourteen years not quite as much as the country made from it in six weeks. When the sugar production of Louisiana shall have reached its former extent, this improvement will add two millions and a half of dollars annually to the wealth produced by that State." — WHITNEY.

Fig. 6046.



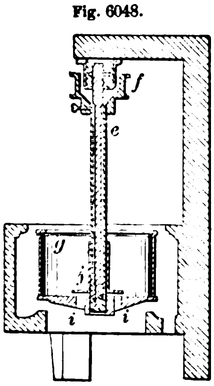
Sugar-Cutting Machine.

Fig. 6047.



Cube Sugar-Machine.

Fig. 6048.



Centrifugal Machine.

Sug'ar-cut'ting Ma-chine'. A machine for cutting up loaf or hard sugar into lumps.

In the example (Fig. 6046), the sugar in flat cakes is inserted between the hinged table *D* and the reciprocating-table *E*, both of which are studded with quadrangular pins. The table *E* is swung up and down by a cam-movement; the table *E* is struck by a hammer *I*, lifted by means of the wiper *K*, and is immediately after the impact thrown up by springs *c c*.

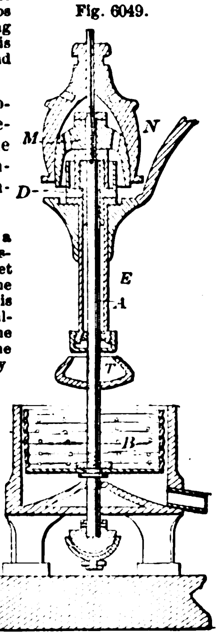
Fig. 6047 is a machine to cut loaf-sugar into cubes, operating upon slabs which are either molded in that form or sawn from the loaf.

The slab of sugar is laid upon the bench and pushed over the gang of parallel vertical saws *d* (only one of which shows in the elevation), which cut it into slips; passing onward, these slips are cut into cubes by the co-acting revolving cutters *a a*. The sugar is held by pressure-rollers *c c* and spring-clamps *e*.

Sug'ar-drain'er. An apparatus for separating the residual, non-crystallizable matter from sugar by centrifugal action. A centrifugal machine.

Weston's (Fig. 6048) has a spindle suspended from an elastic bearing or a ball-and-socket joint above. Surrounding the spindle and supported by it is a hollow shaft *e* having a pulley *f* at its upper part. The cylinder *g* is perforated at the periphery in the usual way and has openings *i i* at the bottom for discharging the sugar after the moisture is expelled. These openings are closed by a plate at the bottom of a sleeve *j*, which is lifted for the purpose of discharging. The expelled molasses flows into an annular trough in the base of the exterior casing, and access to the bottom of the cylinder is entirely unobstructed. The yielding bearing at the top of the spindle permits it to assume a truly vertical position when the cylinder is charged, and prevents any tendency to irregularity of motion when revolving.

Fig. 6049.



Sugar-Draining Machine.

In ordinary machines of this class the sugar is discharged at the top. In the English patents of Hardman, October 5, 1843, and Alliott, February 3, 1851, it was proposed to effect the discharge at the bottom. In the former, a circular plate below the cylinder was employed for closing the discharge-openings; this was lowered a certain distance for the purpose, still, however, remaining in the way. In the latter, the cylinder had to be turned, so as to bring an opening in its bottom directly over a funnel through which the discharge was effected. In both, the bearings of the shaft were under the cylinder, and obstructed the free delivery of the sugar.

Sug'ar-drain'ing Ma-chine'.

In Lafferty's centrifugal machine (Fig. 6049), the filter-box *B* is of corrugated metal, surrounded by woven wire. The shaft *A* is driven by a compound pulley composed of a drum *N*, which receives the belt, and an interior conical part *M* fitting within the former, and having perforations which cause a circulation of air around the shaft to cool it when in rapid motion. The oil from the cup *D* passing down the shaft flows down between it and the hollow exterior casing *E*, and is finally received in the drip cup *T*, which is so shaped as to prevent the oil being thrown out by centrifugal action. By lifting the barrel *N* it is disconnected from the cone *M*, and the rotation of the shaft is stopped. The appurtenances of the shaft are sustained by a hanger.

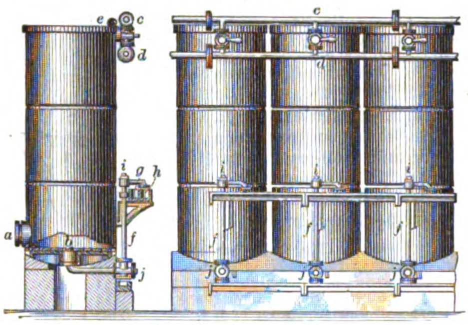
See also CENTRIFUGAL FILTER, Figs. 1213, 1214, page 514.

Sug'ar-e-vap'o-rat'or. A furnace and pan for condensing saccharine juices or solutions. See EVAPORATOR, pages 811 – 813.

Sug'ar-fil'ter. (*Sugar-making.*) The vessel employed for cleansing and decolorizing the defecated sirup by the aid of bone-black.

Those commonly employed are about 10 feet high by 4 feet in diameter, and open at the top; three are shown in the illustration. Near the bottom is a man-hole *a*, and below this an iron grating *b*, upon which a piece of filter-cloth is laid, and the vessel then filled with charcoal to within about a foot of the top. Sirup is then admitted through the pipe *c* until the charcoal has absorbed nearly all the coloring matter which it is capable of doing. The supply of sirup is then shut off, and cane-juice from the defecators is let on through the pipe *d* expelling the sirup; the power of the charcoal having been previously exhausted, its action upon the juice is simply mechanical. When this has continued to flow some time, it is shut off, and pure water is let in from the pipe *e*. This, in turn, drives out the cane-juice, and is allowed to flow until it no longer extracts

Fig. 6050.



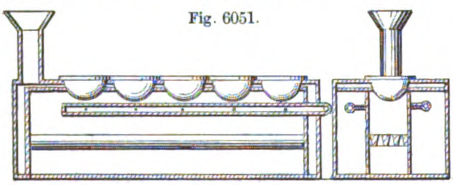
Sugar-Filtering Apparatus.

sufficient saccharine matter to pay for concentration. Several filters are employed, so that while one is filtering sirup, the second may be filtering cane-juice, and the third be cleansed by water.

The liquor and juice are drawn off by the pipe *f*, which discharges into the gutters *g h* through the swivel-joints *i*. The water is discharged through the cock *j* into the gutter below.

See also BAG-FILTER, Fig. 522; CENTRIFUGAL FILTER, Figs. 1213, 1214. See also BONE-BLACK, pages 327, 328.

Fig. 6051.



Sugar-Furnace.

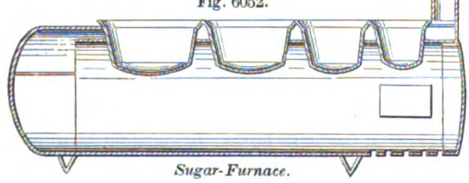
Sug′ar-fur′nace. One in which pans are set for boiling sugar-cane juice, the sap of the maple, or other saccharine solutions.

Fig. 6051 shows one in which air-jets to promote combustion are admitted below the pan.

In Fig. 6052, the kettles are set in a cylindrical metallic furnace, which may be made from a worn-out steam-boiler. The return caloric current passes through flues enveloping the upper part of the kettles.

See also EVAPORATOR, pages 811–813.

Fig. 6052.



Sugar-Furnace.

Sug′ar-gran′u-lat′or. Hersey's sugar-dryer is for granulating damp sugar.

The sugar is fed into one end through a spout, by a set of rolls placed above the machine, and by lifting shelves on the inside of the outer cylinder is carried up and dropped in a continuous shower upon the heating cylinder, and rolls off by the rotation of the machine, to be again carried up, working forward to the opposite end by the inclination of the apparatus, and is there delivered into the screen for separating into the different grades.

The steel plate heater-cylinder is put centrally within the iron conveyor-cylinder, which is 23 feet long and 6 feet in diameter, the heater-cylinder being 20 feet long and 36 inches in diameter, and makes five revolutions per minute. A striker passes off any sugar that may adhere to the cylinder when first entering the machine, and is operated by cams. The machine is rotated by means of outside gear on the conveyor-cylinder.

The current of air constantly passing through the machine carries off the moisture from the sugar through a pipe. The sugar is delivered cool from the end into which the cold air is passing, so that it does not cake, and can be immediately barreled, and will not cause the barrels to shrink.

Sug′ar-ket′tle. A kettle for boiling the sap of the sugar-maple (*Acer saccharium*), the sorghum, or the cane. A *sugar-pan*. See EVAPORATOR.

Sug′ar-ket′tle Bat′ter-y. A range of kettles in a sugar-furnace. See SUGAR-FURNACE.

Sug′ar-ma-chin′er-y. The old system of boiling in open pans is still in operation in cane-producing countries. The cane, on being passed through the rollers of the grinding-mill, is deprived of its juice, and the stalk or *bagasse* is carried on an endless belt to fall into a cart below, to be spread in the fields to dry, to form fuel for the furnaces. Meanwhile the juice runs through strainers, and is lifted by a force-pump to oblong troughs, which stand near the chimneys of the furnace. In these it is allowed to settle, and the scum rises in a few minutes to the surface, a gentle heat being applied. The juice is then drawn off into a train of copper kettles below, to be converted into sugar.

In the first of these kettles it is treated to a little milk of lime, which causes the scum to rise in a body to the surface, when it is removed by a skimmer. From this pan it is advanced to others, according to its advance toward crystallization, nearer and nearer to the mouth of the furnace, boiling furiously until it reaches at last the pan called the *teache-pan*, or *strike-pan*, over the mouth of the furnace. As the entire contents of one pan is discharged into the next, at the same time that a fresh supply of juice is introduced from those behind it, all are kept full, and the process of dipping is a very lively one, when the fires are well kept up. The feculences are principally skimmed off in the rear pan, in which the crude juice is introduced, but they are also skimmed off the boiling liquid in the other pans as they arise.

In the last pan the ultimate condensation is reached, and the sirup is subjected to the *teache* or touch test, by which its condition is determined. This is a delicate test, requiring judgment, but is preferred to the saccharometer, where the "sugar-master" is skillful. The test in making maple-sugar is different, as it is made in water, the condition of the *wax*, when rapidly cooled, indicating whether it is ready to take off or not.

From the *strike-pan* the sugar is run into shallow coolers (see COOLER), where it remains for about 24 hours, and is then transferred to cones or hogsheads to drain off the molasses. The hogsheads are set in a room called the *purgery*, resting on beams, and the molasses draining into a cistern beneath. (See PURGERY.) The cones are set into racks, and, after an interval of a couple of days, are removed to the *purgery*, the plug at the apex of the cone being removed as may be necessary to allow the non-crystallized portion to drain off. In about 20 days the loaf of sugar is found to be hard; white at the base, darker in the middle, and yellow, with molasses at the top, which, when dried, forms three grades in the Havana market. See EVAPORATOR.

The following are the processes: —

Grinding. The cane is first crushed by a powerful mill, driven by an engine of 60 horse-power, and having 3 rollers 8 feet in length and 3 feet in diameter. The cane is supplied by an endless belt moving in a channel-way of the same width as the rollers, and running almost level with the ground for 50 or 60 feet. 30 or 40 women are constantly employed in supplying this feeder with cane-stalks, which are smoothed by others. The stalks pass unceasingly between the rollers, the crushed cane falling upon another endless belt, which carries it out of the mill and drops it into light carts, which carry it to the fields to dry. This duty requires 7 carts. The cane is brought by trains of cars on a tramway from the field. See CANE-MILL.

Straining. The juice runs in a heavy stream from the mill, and passes through coarse strainers, which intercept dirt and pieces of cane. It is then pumped into cisterns in the boiling-house, from whence it is drawn in the defecators.

Defecating. These are copper kettles with steam-jackets, and

at the Yngenio San Martin there are 16 in a row. The juice being turned into one until it is nearly full, the stopcock is closed and that of the next opened. Steam is then admitted to the jacket around the first, a little slaked lime is added, and it is raised to the boiling-point. Being allowed to simmer a few minutes, a thick scum rises, and the consistence of the latter determines the time to draw off. The defecator discharges by a pipe beneath it, the clear juice running into a trough; as soon as it begins to run dirty with the broken scum, the stream is turned into another trough, leading it to a receptacle whence it is withdrawn to be purified again. A jet of cold water cleans the defecator, and it is again ready for duty. The same is true of each defecator, and when properly proportioned in size and number to the other machinery, they are worked in a regular succession, the first being again ready for duty as the last is charged, and the juice from the mill being kept constantly running. In the San Martin the circuit is completed in about an hour.

Filtering. The hot stream of defecated juice is poured into charcoal filters, 10 feet high, 23 of which stand in a row, dividing the defecators from the bulk of the machinery; and behind them is another rank of 20 filters, as many feet in hight, in which the juice is finally purified. The filters are charged with animal charcoal, and hold an amount valued at $ 2,000. A charge lasts about 7 days, and is then replaced by fresh bone-black, the sticky and lusterless coal from the filters being taken to the washing-machines, and thence to the furnaces to be reburnt. This is repeated until the coal becomes too fine for use, the loss being about 10 per cent at each use. See page 328.

It may be mentioned at this point that processes for defecating by the use of sulphurous gas have been used, and apparatus for this purpose patented. The object is to bring the juice in contact with the gas, which removes the tendency to fermentation, and thus prevents the disorganization of the sugar, by which it is turned to grape-sugar, increasing the yield of molasses and decreasing that of crystallizable sugar.

Condensing. After passing through the smaller filters, the juice is carried to the condensers, which perform the double duty of condensing the vapors rising in the vacuum-pan, and of evaporating the cane-juice which flows over them. These condensers constitute the distinguishing feature of the Degrand (Derosne) train, and are largely employed on some estates. A condenser is formed of horizontal pipes about 6 inches in diameter, arranged in a tall rack and formed by a convolution of the pipe, so that while the vapor from the vacuum-pan passes back and forth downwardly on the inside, the juice from the filters drips on to the upper fold of the pipe, and from thence to the next below, so as to keep the outside of the whole series wet, parting with a portion of its moisture, which rises in clouds of steam to the roof of the building.

Objections have arisen to the use of the Degrand condenser from the difficulty of keeping the pipes covered with an even film of juice, and the presence of clouds of steam which become condensed again in the building and interfere with other operations; the crystallization of the sugar, for instance. In some establishments the Degrand condenser is merely used to obtain the vacuum in the pan, water being dripped upon it instead of sirup. See CONDENSER, Fig. 1421.

Boiling. After passing the condensers, the sirup passes to the first vacuum-pans. In them the sirup is farther condensed, but not to the stage of granulation, it being subjected to a farther clarifying process before the final boiling. The vacuum-pan consists of a closed vessel with means for withdrawing the vapor as it is generated, and lowering the pressure of the atmosphere upon the sirup, so that the latter will boil at a lower temperature. This is favorable to the color of the sugar, as it is not subjected to a burning heat, and is also protected from the action of the atmosphere. It should have been mentioned that all the heating operations, in the defecators and in the vacuum-pans, are by means of steam under pressure. The vacuum-pans differ in some respects in their construction, though possessing the peculiar characteristic cited. They are spheroidal or nearly so, or cylindrical; are generally heated by jacket and internal coil, and are furnished with pipes and stopcocks, by which the sirup and steam are supplied to their respective places, the water of condensation removed, the condensed sirup discharged, etc. See VACUUM-PAN.

The usual form of Derosne's vacuum-train is what is called the double effect; that is, two pans stand side by side, one of which is boiled by the steam rising from the sirup in the other, the sirup also being drawn at intervals from the first to the second. In the San Martin they possess two trains of three pans each, the middle pan being slightly the largest and discharging its steam into both the others. In some places a treble effect has been tried, the vapor from the first pan boiling the sirup in the second, and that from the second boiling the contents of the third, but the plan does not seem to have been practically successful. The proof of the condition of the sugar is by *teache*, or touch, or by saccharometer, as in the case of the open-pan boiling, the sirup being withdrawn from the pan by a proof-stick for this purpose. See SACCHAROMETER.

Second Defecation. When the panful is brought to a density ranging from 26° to 28° B., where it is about half sugar, it is discharged into caldrons for farther defecation. The heat is kept up in the defecators by means of steam-coils, into which the steam is admitted at will. The liquor is brought to a froth, raising a scum, which is removed; the steam is turned off, and the action repeated each time it comes to a froth, the heat being damped and the scum removed.

Second Filtering. The sirup is now turned into the high filters, which are 20 feet high, and charged with bone-black; from them it issues a clear, bright, yellow liquid, ready for the final boiling, which is accomplished in the great vacuum-pan, called the *strike-pan*, where it is concentrated finally, being brought to the stage of crystallization.

Second Boiling. It is here boiled at a temperature of 180° Fah., but gradually, as the sirup thickens, the temperature is lowered, until, when the crystals have begun to form, the heat is not greater than 160° Fah. It is now thick with crystals of sugar floating in sirup, and the trial by *teache* is repeated frequently. The engineer peers anxiously through the glass windows at the boiling sirup, and finally makes preparations to discharge the contents of the pan into the heaters below. The sirup falls from the bottom of the strike-pan of a rich auburn color. The great vacuum-pan of the Yngenio San Martin is a magnificent piece of workmanship, costing $ 70,000, and capable of boiling in a day from 1,100 to 1,500 *panes* or cones of sugar, containing 100 pounds each of green sugar.

The heaters which receive the sirup from the vacuum-pan are kept hot by steam-jackets; their contents are stirred freely, to encourage granulation, and are then removed to the sugar-cones, which stand for a day in the high temperature of the boiling-house, and are then removed to the purgery, where they undergo the claying-process and are deprived of their molasses. The San Martin purgery is 150 × 400 feet, and affords room for 22,220 cones. One floor is pierced for the cones, and the floor below is used for a packing and drying house.

Drying. The lower room has double rows of cars, one above another, placed on tracks, and so arranged as to be run out into the sunshine with their loads of moist sugar to dry. The cones are broken into three pieces, according to quality, the base being whiter, the middle a second grade, and the tip being moistened and passed through the centrifugal machine to remove the molasses.

The molasses that drips from the cones in the purgery is reboiled in the vacuum-pan and then granulated in tanks. It is dried by the centrifugal machines, which consist of a wire cage or cylinder revolving rapidly in a case, and expelling the molasses through the meshes of the cylinder. (See CENTRIFUGAL MACHINE.) Steam is sometimes added in the centrifugal dryer to assist in expelling the molasses, thereby whitening the sugar.

The modes of packing do not need description.

Fig. 6053 shows a more modern plan.

Sugar-House.

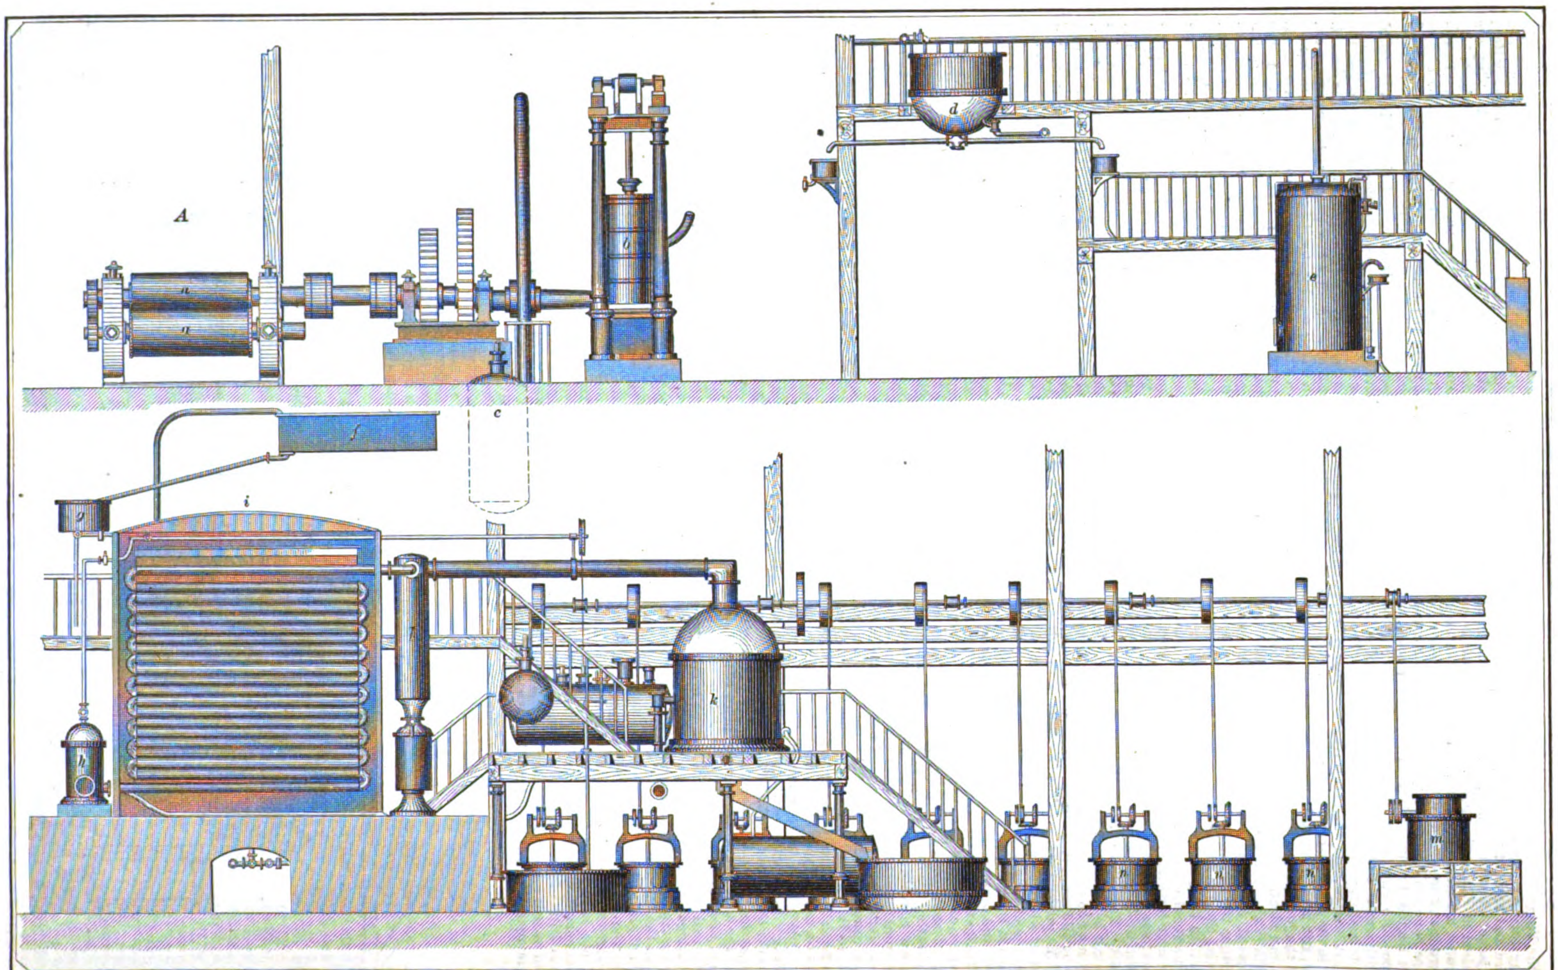

PLATE LXVI. VACUUM-PAN AND SUGAR MACHINERY OF A CUBAN PLANTATION.

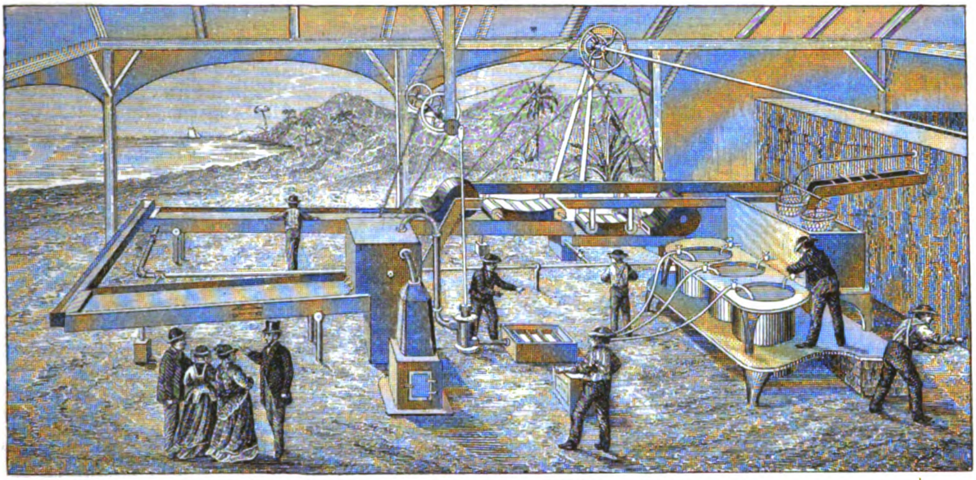
See page 2450.

Fig. 6054.



Aschenbrenner's Sugar-Apparatus.

Plate LXVI. represents a complete system of sugar-machinery built by M. M. Cail & Co., of Paris, for a Cuban plantation. *A* is the grinding machinery; the rollers *a a* are driven by intermediate gearing from the engine *b*. The expressed cane-juice flows into a tank, whence it is conducted into the filter *c*. When this is sufficiently full, the supply is cut off, and steam admitted through a pipe, forcing the juice up into the purifiers *d*, six in number. These are heated by coils with steam under a pressure of 60 pounds to the inch, and are provided with proper supply and discharge pipes. About three per cent of lime is added to the juice, part being thrown in previous to its withdrawal from the tank.

After being purified by boiling, the juice is filtered through animal charcoal in cylinders *e*, to each of which a three-branched pipe leads for the admission of juice, sirup, and steam as required. Each filter has a perforated false bottom, from whence the juice flows into a tank *e*, and is lifted by steam pressure into a vessel *f*; it thence flows into the vessel *g*, which regulates the supply to the evaporating-condensers *h*, in which a vacuum is maintained, and thence passes through the tubular steam-heated condensers *i*, after which it is pumped into the vacuum-vessel *k*, in which the processes of evaporation and condensation are completed. Separators *l* receive any water or juice that may pass out with the vapor.

The juice, now concentrated to sirup, is clarified by blood in the usual way, and again filtered and concentrated and placed in molds, where it drains and crystallizes. In order to remove any remaining molasses and thoroughly dry the crude sugar formed by this last process, the loaves are ground in crushing-machines *m*, and the pulverized sugar is then placed in the centrifugal machines *n*, driven at the rate of more than 1,200 revolutions per minute, by which the remaining moisture is expelled.

The above machinery is capable of treating 100 tons of cane daily, producing 8 tons of sugar, and cost $ 160,000.

It is claimed that in the ordinary processes of manufacture, less than one half of the saccharine matter in the juice of the cane is extracted as crystallizable sugar.

The apparatus of Dr. Aschenbrenner, shown in Fig. 6054, is designed to produce the sugar in crystalline form, no molasses being formed, unless it is so desired.

The juice from the crushing is delivered through the trough seen to the right; in this are placed two filters of different degrees of fineness, which separate mechanical impurities; the juice then passes through a flannel strainer, of which several are provided, so that one may be removed, washed, and replaced by another, as required, and is then received in a tank, from which it is drawn off into three open kettles having double bottoms and heated by steam, in which it is purified by lime and magnesia, the sediment being drawn off at the bottom. The purified juice then passes through siphons to another filter, which separates any remaining impurities held in suspension. From the filter the juice is pumped into a case, where it is agitated by a paddle-wheel and subjected to the action of sulphurous fumes from a furnace, by which it is bleached, and thence flows into a steam-heated metallic trough, from whence it is conducted to a second and third similar trough successively; at the lower end of the third trough it is subjected to the action of a fan, which cools it and promotes the evaporation of the vapor. It has now become so thick as to require the use of a scraper, which consists of an endless band moving around pulleys and carrying a series of blades; this conveys the sugar to another incline, where it is acted on by a second fan. It is now entirely crystallized, and is removed by hand into a receiver. When desired to produce molasses, a small proportion may be obtained by making the incline of the troughs steeper and dispensing with the use of the fans.

Other plans of treating the cane have been suggested, and in some cases adopted. The following may be mentioned: —

De Manöel and Brafen, of Martinique, obtained U. S. patent, February 22, 1848, for a process of drying and pulverizing sugar-cane, and then washing the saccharine matters therefrom to be manufactured into sugar by evaporation in the ordinary way. The cane is chopped into small pieces by a cane-cutter, is dried in a kiln and ground in a mill. The meal is then placed in tubs, which are tightly closed, and water passed in succession through them till the sugar is all extracted. The filter and boiling-pan conclude the operation. See also DIFFUSION-PROCESS, Fig. 1652.

See under the following heads: —

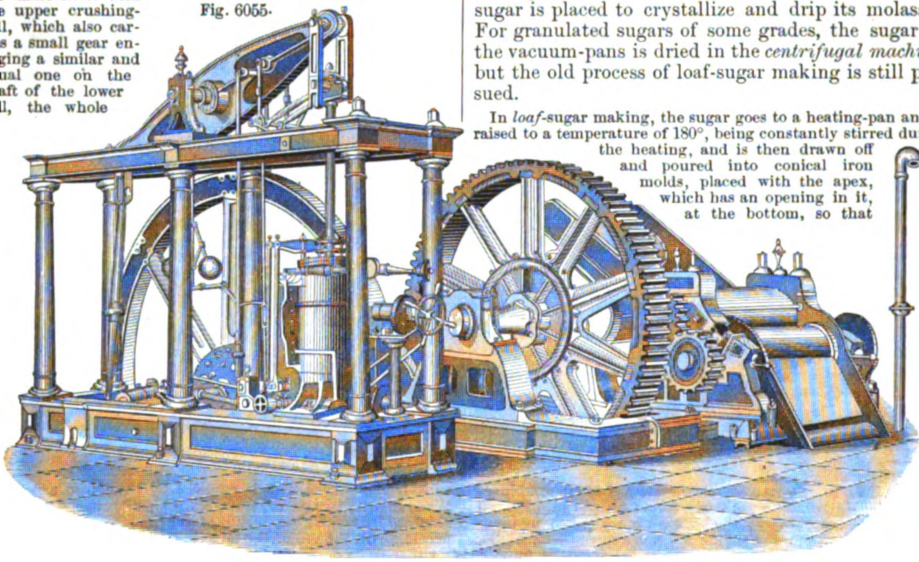
Sug'ar-mill. A mill for expressing the juice from sugar-canes. It has usually three rollers; two in the same horizontal plane, and the third over and between these. The canes are fed in between the upper and first horizontal rollers, where they receive their first squeeze, the juice running down into a trough at the base of the mill; they then travel onward, receiving a second squeeze between the top roller and the second horizontal roller, which extracts the remaining juice. The residual woody fiber, termed bagasse, when dried, is used as fuel for the furnace-boiler. Fig. 6055 illustrates an approved form of sugar-mill, with the beam-engine for driving it.

In the mill (Fig. 6056), the crushing-rolls are operated directly from the fly-wheel shaft of the steam-engine through three pairs of interposed gear-wheels and pinions; the last gear-wheel is on the same shaft with the upper crushing-roll, which also carries a small gear engaging a similar and equal one on the shaft of the lower roll, the whole forming a very compact and simple arrangement. See also CANE-MILL.

Sug'ar-mold. A conical iron mold in which sugar is placed to crystallize and drip its molasses. For granulated sugars of some grades, the sugar for the vacuum-pans is dried in the *centrifugal machine*, but the old process of loaf-sugar making is still pursued.

In *loaf*-sugar making, the sugar goes to a heating-pan and is raised to a temperature of 180°, being constantly stirred during the heating, and is then drawn off and poured into conical iron molds, placed with the apex, which has an opening in it, at the bottom, so that

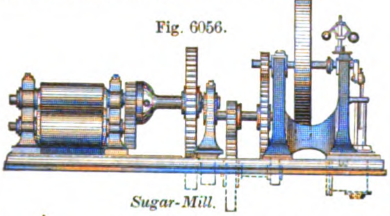
Fig. 6055.



Sugar-Mill

whatever liquor has remained may drain off through the opening. After several hours, the *loaves* left in the molds are *liquored* by pouring in at the top a clear solution of pure sugar, which removes the remaining coloring-matter. The

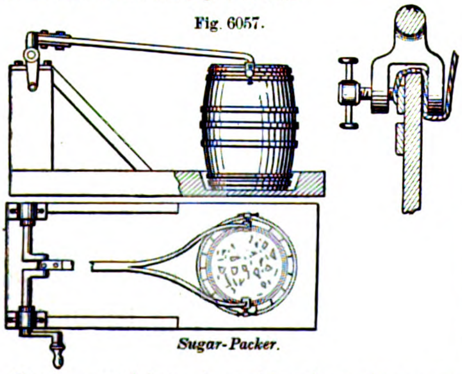
Fig. 6056.



Sugar-Mill.

liquoring-process is sometimes repeated several times, until the loaves become perfectly blanched. Then they are left two or three days in a drying-room heated by steam, are trimmed, if necessary, in a lathe, and are finally papered for market. The trimmings, the draining from the molds, etc., are saved for the manufacture of inferior grades of sugar. The old method of employing molds takes a longer time and is more expensive than the centrifugal process, and is gradually being superseded by the latter as the taste for loaf-sugars declines.

Fig. 6057.



Sugar-Packer.

Sug'ar-pack'er. A machine for packing sugar in barrels.

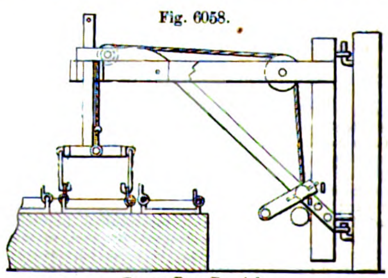
In the example, the barrel to contain the sugar rests in a cavity in the platform, and by means of a forked bar with a screw clamp on each fork end, the upper rim of the barrel, with the filling bag, is tightly clamped, while the single opposite end of the forked bar is fitted to a crank, from which it receives and imparts to the barrel a reciprocating motion.

Sug'ar-pan. See EVAPORATOR; SUGAR-FURNACE; SUGAR-MACHINERY; VACUUM-PAN.

Sug'ar-pan Lift'er. A crane rigged in a sugar-house to lift flat pans from the furnace. It is only seen in a certain arrangement of devices, where flat pans travel along the walls of the furnace as the boiling proceeds, being lifted at the rear end as the boiling is completed, and the pan set aside that the contents may granulate.

The hoisting-cord is attached to a frame from whose four corners depend hooks for engagement with the rings at the corners

Fig. 6058.



Sugar-Pan Derrick.

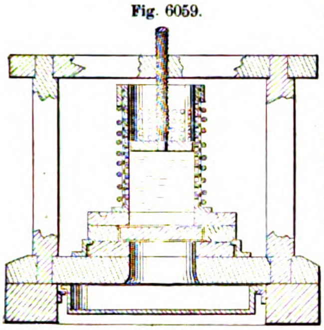
of the pan. From the center of the frame arises a sliding upright which passes through the derrick to steady the frame.

Sug'ar-press. A machine for expediting the drainage of the molasses from the sugar.

The box has perforated sides, so that the molasses expressed from the crude sugar may escape and be collected outside. After the pressure has been carried to a sufficient extent, a wedge in the platform, upon which the press-box stands, directly beneath the box, is withdrawn, and the dry sugar falls through the opening into a box below.

Sug′ar-re-fin′ing. The process of purification or discolorization of raw or brown sugar.

Fig. 6059.



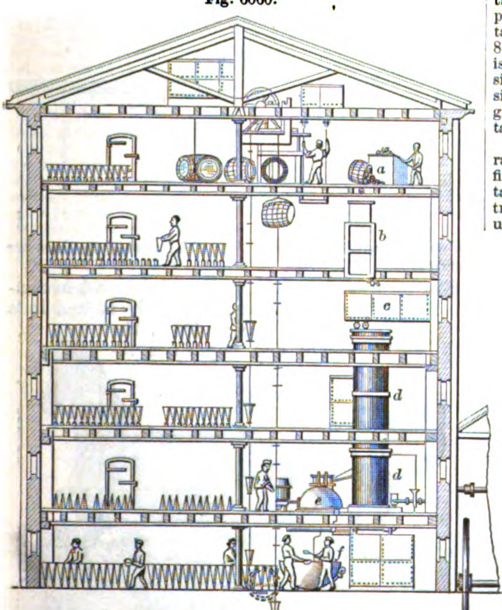
Sugar-Press.

The sugar is, —

1. *Dissolved* in water, a little blood and lime-water being added.
2. *Filtered* in bags, to remove feculences.
3. *Filtered* through animal charcoal, to remove color.
4. *Boiled* in a vacuum-pan, to concentrate it.
5. Crystallized in molds.

Fig. 6060 is a transverse section of a sugar-refinery. The packages are hoisted to the top floor of the building, emptied, and transferred to the dissolving-pan *a*, where the sugar is mixed with water and agitated by a mechanical stirrer. A temperature of about 165° Fah. is maintained in the pan by means of a steam-coil, and the solution, having been brought to the specific gravity of about 1.25, or 29° Beaumé, is transferred to bag-filters within cases *b* (see BAG-FILTER). The sirup passing through these is drawn off into a vat *c* on the floor below, and thence conducted to the bone-black filters *d*; the decolorated liquid, after passing the filters, is drawn into vacuum-pans *e* and evaporated at a heat of 170° to 180° Fah. at the beginning of the process, reduced to about 145° when crystallization is sufficiently advanced. While yet sufficiently fluid, it is let down through a valve in the bottom of the pan to the heater *f*, where its temperature is raised to 180°, and stirred until crystallization is complete. The moist crystalline mass is then drawn off into ladles and transferred to conical molds, for making loaf-sugar. After standing several hours to drain and solidify, the molds and their contained loaves are conveyed to an apartment above, kept at a temperature of about 100°, where they are still farther drained, and a clear saturated solution of sugar poured upon them which percolates through and whitens them; this is repeated several times. When the proper color is produced, they are transferred to a stove heated to 130° or 140°, where they are kept two or three days, till they are baked thoroughly dry.

Fig. 6060.



Transverse Section of a Sugar-Refinery.

The drainage from the molds is again concentrated by boiling, to form a lower grade of sugar; the uncrystallizable portion remaining after this operation constitutes treacle or sirup.

For producing granulated sugar, the processes, previous to boiling, are conducted as before. Large vacuum-pans, having extra heating-coils are employed, and the boiling is continued until crystals begin to appear, when more liquor is added, and the concentration continued. This process is repeated several times, to cause the formation of large crystals. When sufficiently concentrated, one half the liquor is removed to the heater, the remainder being left to assist in the formation of crystals in the next charge. After being thoroughly crystallized in the heater, the moist mass is transferred to the centrifugal machine, the rapid rotation of which soon expels the moisture. In order to cleanse the crystals, a small quantity of liquor is sprinkled upon them while in the machine. The percentage of sugar obtained in this and at each subsequent crystallization is considerably less than that obtained in making loaf-sugar, though the total product does not vary materially. The drainage is diluted, filtered through animal charcoal, boiled, and again passed through the centrifugal machines, forming a second quality of sugar having smaller crystals. A third, and sometimes a fourth quality of sugar is produced by similarly treating the resulting drainings.

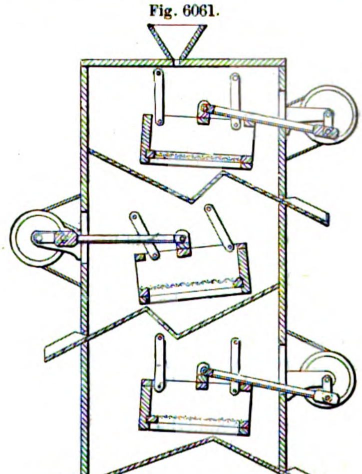
M. Van Goethem, a Belgian sugar-refiner, has a machine in which fifty sugar-loaves are ranged radially in a kind of horizontal wheel, and then the whole is made to revolve with the speed of 800 revolutions in a minute The proper liquid is applied by a beautiful contrivance; and in about twenty minutes the fifty loaves of sugar are found to be not only freed from molasses, but rendered almost completely dry. Many days would be required to effect this by the old method.

Boivin and Loiseau's process is founded upon the use of the sucrate of the hydrocarbonate of lime, for the purification of raw sugar instead of blood, bone-black, etc. For the preparation of this compound, milk of lime is made from the waste sweet liquors of the refinery, and enough sirup added to give the mixture 20° Baumé. This is well agitated, and run through a cooler until the temperature sinks to 68° Fah. From the agitators the liquid flows into vats, where it is partially saturated with carbonic acid: the gas is passed through until the desired precipitate of sugar, lime, and carbonate of lime settles as a gelatinous mass. After the purifying agent has been thus prepared, it is applied in the following manner: —

The raw sugar is dissolved in a cylindrical pan, similar to a vacuum-pan, under diminished pressure. Revolving buckets carry it into receivers over the boilers, and from these it is permitted to flow into the boilers, where it comes in contact with the sucro-carbonate of lime previously introduced, in a quantity proportional to the percentage of raw sugar. They generally take about 650 gallons of the gelatinous sucro-carbonate to 8,000 pounds of sugar. Water is added if necessary; the whole is boiled, and in this way the solution and clarification are simultaneously accomplished. One advantage is that when sirup is boiled in presence of lime, ammonia is evolved, all glucose is decomposed, and anything likely to produce fermentation is destroyed.

The sirup from the boilers is filtered, the excess of lime separated by carbonic acid, and it is farther concentrated and finished in the usual manner. The slimy residues and precipitates are squeezed out in filter-presses until they contain no trace of sugar, and can be thrown away. The wash-water is used in the preparation of new material.

Fig. 6061.

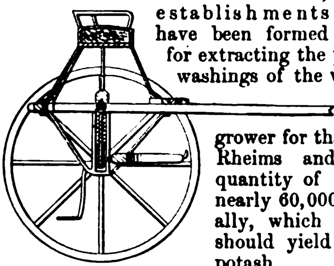


Sugar-Sifter.

Sug'ar-sift'er. A machine for sorting grades of crushed or ground sugar according to fineness of grain. The reciprocating sieves are arranged in a frame, one below the other. One end of each sieve is left open, to allow the sugar to fall on the discharge-spouts, which are arranged alternately on opposite sides of the frame. The sugar passes alternately through the sieves and conducting-troughs and is discharged below.

Su'int. The natural grease of wool. It consists of insoluble saponaceous matter together with a soluble salt containing from 15 to 33 per cent of potash. In the great wool-growing districts of France, establishments have been formed for extracting the potash from the washings of the wool, which are purchased from the wool-grower for that purpose. At Rheims and Elbœuf, the quantity of wool washed is nearly 60,000,000 lbs. annually, which it is estimated should yield 3,000,000 lbs. potash.

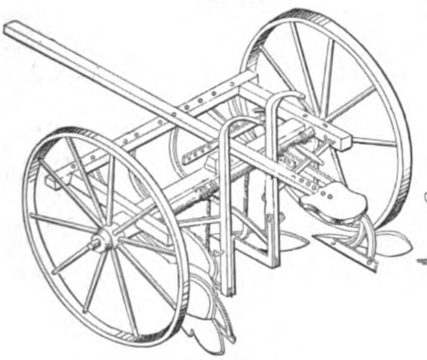
Fig. 6062.



Sulky.

Sul'ky. A light two-wheeled vehicle, having a seat for a single occupant, used as a pleasure-carriage and for trials of speed between trotting-horses.

Fig. 6063.



Sulky-Cultivator.

In the example, the usual elliptical spring is associated with a spiral spring near each wheel. Braced guide-rods from the frame embrace the axle.

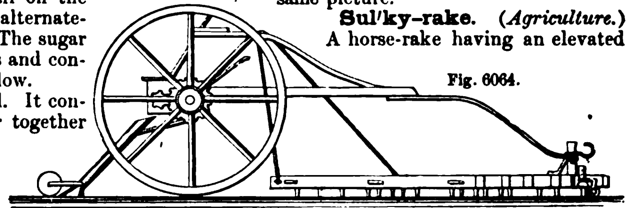
Sul'ky-cul'ti-va'tor. One having a seat for the rider, who manages the plows, moving them to the right or left as the plants in the rows may require.

Sul'ky-har'row. One having a wheeled carriage and seat for the rider. The fore part of the harrow rests upon an adjustable caster, and is connected to the front end of a flexible bar attached to the sulky-hounds. The draft-hook is at this point.

Sul'ky-plow. One having a seat for the plower. In the example, a portion of the seat is just apparent beyond the pulley *G*, on which the plow-supporting chain winds. The Bayeux tapestry, which represents the invasion of England by William I., and the death of Harold at Hastings, shows a plow having a pair of wheels, on which a man rides and drives a horse. A square harrow and a man sowing from a basket are in the same picture.

Sul'ky-rake. (*Agriculture.*) A horse-rake having an elevated seat for the driver. Levers easily accessible to the hand or foot are provided for lifting the rake when it has accumulated sufficient hay to form a windrow, and for holding it clear of the ground altogether when required. The former operation is sometimes performed by means of automatic devices. See HORSE HAY-RAKE.

Fig. 6064.



Sulky-Harrow.

Sul'lage. 1. (*Founding.*) The scoria which rises to the surface of the molten metal in the *ladle*, and which is held back when pouring to prevent porous and rough casting.

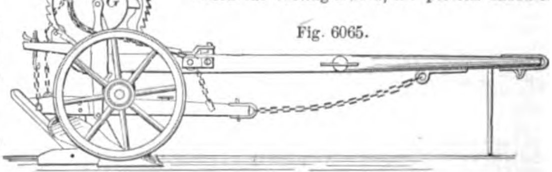
2. (*Hydraulic Engineering.*) Silt and mud deposited by water.

Sul'lage-piece. (*Founding.*) A *dead-head*, or *feeding-head.* A piece of metal on a casting which occupies the ingate at which the metal entered the mold.

When it is desired that a heavy casting (such as a gun of several tons) should be especially solid, it is always poured on end, and, in addition to the length required, a continuation of the mold upward is made. In this piece the sullage rises, hence its name.

When the casting is cold, the portion added is cut off, and, with it, the impurities which floated up there are removed.

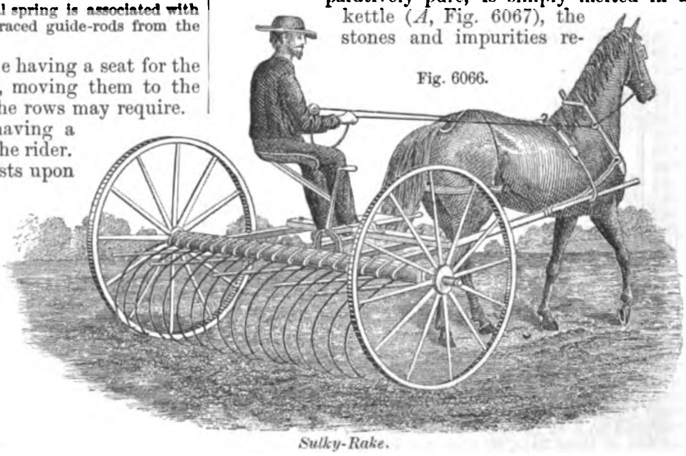
Fig. 6065.



Sulky-Plow.

Sul'phur-fur'nace. Native sulphur, when comparatively pure, is simply melted in a kettle (*A*, Fig. 6067), the stones and impurities re-

Fig. 6066.

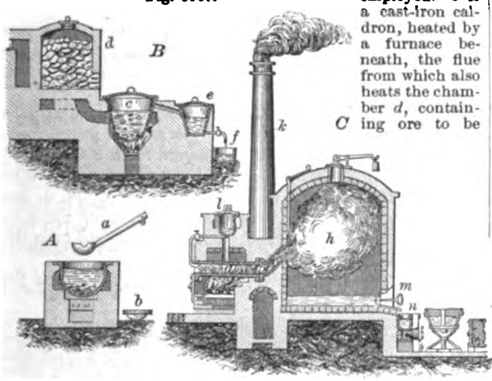


Sulky-Rake.

moved by a *ladle a*, and the mass cast in a mold *b* previously moistened with water, to prevent adhesion.

The stones and gangue containing the sulphur are sometimes roasted in a tall furnace, the fluid sulphur being drawn off at the bottom: distillation is, however, preferable. For this the apparatus *B* is employed. *c* is a cast-iron caldron, heated by a furnace beneath, the flue from which also heats the chamber *d*, containing ore to be

Fig. 6067.



Sulphur-Furnace.

transferred to the caldron. The distillate is condensed in the vessel *e*, and in the fluid state is drawn off into *f*.

***C* represents Michel's apparatus as improved by Lamy for refining crude sulphur. It comprises two cast-iron cylinders, one shown at *g*, used as retorts, and a condensing-room *h*. The retorts are heated by a furnace *i*, the smoke of which is carried off by the chimney *k*. The crude sulphur is placed in the vessel *l*, where it is melted and partially refined, passing into the retort *g*, where it is sublimed, condensing in the chamber *h*, whence it is withdrawn through the tap-hole *m*, fitted with a conical plug, being received in the vessel *n* and then cast into rolls.**

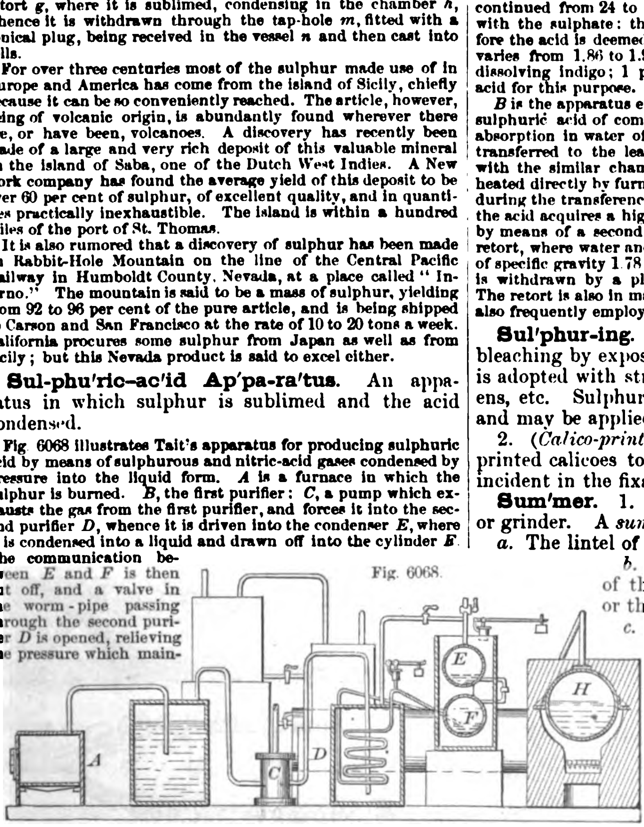
For over three centuries most of the sulphur made use of in Europe and America has come from the island of Sicily, chiefly because it can be so conveniently reached. The article, however, being of volcanic origin, is abundantly found wherever there are, or have been, volcanoes. A discovery has recently been made of a large and very rich deposit of this valuable mineral on the island of Saba, one of the Dutch West Indies. A New York company has found the average yield of this deposit to be over 60 per cent of sulphur, of excellent quality, and in quantities practically inexhaustible. The island is within a hundred miles of the port of St. Thomas.

It is also rumored that a discovery of sulphur has been made on Rabbit-Hole Mountain on the line of the Central Pacific Railway in Humboldt County, Nevada, at a place called "Inferno." The mountain is said to be a mass of sulphur, yielding from 92 to 96 per cent of the pure article, and is being shipped to Carson and San Francisco at the rate of 10 to 20 tons a week. California procures some sulphur from Japan as well as from Sicily; but this Nevada product is said to excel either.

Sul-phu'ric-ac'id Ap'pa-ra'tus. An apparatus in which sulphur is sublimed and the acid condensed.

Fig. 6068 illustrates Tait's apparatus for producing sulphuric acid by means of sulphurous and nitric-acid gases condensed by pressure into the liquid form. *A* is a furnace in which the sulphur is burned. *B*, the first purifier; *C*, a pump which exhausts the gas from the first purifier, and forces it into the second purifier *D*, whence it is driven into the condenser *E*, where it is condensed into a liquid and drawn off into the cylinder *F*. The communication between *E* and *F* is then cut off, and a valve in the worm-pipe passing through the second purifier *D* is opened, relieving the pressure which maintains the sulphurous acid in liquid form, and permitting it to assume the gaseous condition. It flows through this pipe into a receiver, where the nitric-acid gas, oxygen, and steam from the boiler *H* are admitted, and is then submitted to a pressure sufficient to liquefy both it and the nitric acid. The reactions between the oxygen and the nitric and sulphurous acids result in the production of sulphuric acid.

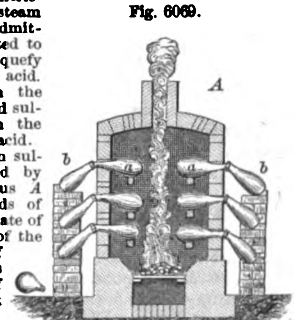
Fig. 6068.

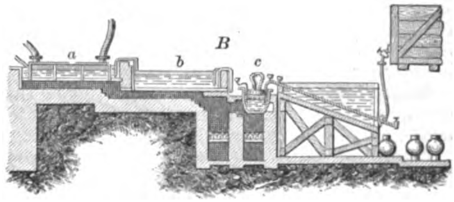


Sulphuric-Acid Apparatus.

Fuming or Nordhausen sulphuric acid is prepared by means of the apparatus *A* (Fig. 6069). 2¼ pounds of vitriol stone (dried sulphate of iron) are placed in each of the flasks *a a*, etc., made of fire-clay, whose necks pass through the walls of the furnace; on the first application of heat only sulphurous acid and weak

Fig. 6069.





Sulphuric-Acid Apparatus.

hydrated sulphuric acid pass over, which are usually allowed to escape. When white vapors of anhydrous sulphuric acid appear, the necks of the flasks are luted to the receivers *b b*, each of which contains 30 grammes water, and the distillation continued from 24 to 36 hours, when the flasks are again filled with the sulphate: this operation is repeated four times, before the acid is deemed sufficiently strong. Its specific gravity varies from 1.86 to 1.92. This variety is principally used for dissolving indigo; 1 part being mixed with 2 of the common acid for this purpose.

***B* is the apparatus employed for concentrating the ordinary sulphuric acid of commerce. The weak acid, prepared by the absorption in water of the gas evolved by calcining pyrites, is transferred to the leaden chamber *a*, connected by a siphon with the similar chamber *b*; the latter and the retort *c* are heated directly by furnaces, and the former by a flue therefrom; during the transference from the first to the second chamber the acid acquires a higher degree of concentration, and is then, by means of a second siphon, conveyed from thence into the retort, where water and weak acid are driven off, strong acid, of specific gravity 1.78 to 1.8 remaining in the retort, whence it is withdrawn by a platinum siphon of peculiar construction. The retort is also in many cases made of platinum, but glass is also frequently employed.**

Sul'phur-ing. 1. (*Bleaching.*) A process of bleaching by exposure to the fumes of sulphur. It is adopted with straw-braid, straw hats, silks, woolens, etc. Sulphurous acid is the bleaching agent, and may be applied by means of a watery solution.

2. (*Calico-printing.*) The process of exposing printed calicoes to sulphurous-acid fumes. It is an incident in the fixation of *steam-colors.*

Sum'mer. 1. (*Carpentry.*) A horizontal beam or grinder. A *summer-tree.*

a. The lintel of a doorway.

b. A floor timber receiving the ends of the joists and supporting the floor or the ceiling, as the case may be.

c. A beam resting on pillars, as in the case of a shop front, and supporting the superincumbent wall with which its front face is flush. Called a *breast-summer.*

2. (*Masonry.*) The first stone or beam laid over a column or beam. A *lintel.*

Sum'mer-tree. A *breast-summer* or *summer.* A horizontal beam brought even with the face

(breast) of a wall, to support a wall above a gap or opening, as a store front, for instance.

Sum'mit. The highest elevation of a railway or canal.

Sum'mit-lev'el. A comparatively level place of a railway, with inclined planes on either side of the mountain. The level *pond* of a canal with lockage at either end, for descent.

Sump. 1. (*Mining.*) *a.* A pit or well in the floor of a mine at the bottom of an engine-shaft, to collect the water, which is pumped from thence.

b. A catch-water drain.

c. The part of a judd of coal first brought down.

2. (*Metallurgy.*) A pit of stone at a furnace to collect the metal at its first fusion.

3. (*Salt.*) A pond of water for salt-works.

Sump-fuse. A thick kind of fuse used for blasting under water. The fuse composition is inclosed in a hempen cord, which is twisted, overlaid with another cord, and varnished. The end is placed in the water-proof cartridge and tied; the end of the fuse is then dipped in pitch, and the protected fuse is ready for duty.

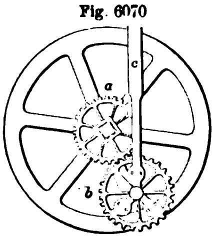
Sump'ing. (*Mining.*) A small square shaft, generally made in the air-headings, when crossing faults, etc., or to try the thickness of the seam.

Sump'ing-shot. (*Mining.*) A charge of powder for bringing down the sump, or for blowing the stone to pieces in a sinking pit.

Sum'pit. The arrow of the *sumpitan*, or blow-tube of Borneo. See ARROW; AIR-GUN, page 48.

Sump-plank. (*Mining.*) Strong balks of timber bolted together, forming a temporary bottom or scaffolding for the shaft.

Fig. 6070



Sun-and-Planet Motion.

Sump-shaft. (*Mining.*) The engine-shaft.

Sun-and-Plan'et Mo'-tion. Invented by James Watt as a substitute for the crank. Watt had applied the crank to the use of his "fire-engine," as he called it, — what was eventually termed a steam-engine. A spying fellow saw the value of the application, and, rushing to London, obtained a patent. See CRANK.

The central gear *a* is called the *sun-gear*, and the outer one *b* the planet-gear. In the form shown in the illustration, the revolution of the planet-wheel rotates the sun-wheel, together with its shaft and the fly-wheel. For this purpose the planet-wheel *b* is fast to the pitman *c*, and its axis is caused to revolve around the wheel without the rotation of the planet-wheel on its own axis. See PLANET-WHEEL and EPICYCLOIDAL WHEEL.

Sun-burn'er. A large reflecting cluster of burners placed beneath an opening in the ceiling, for lighting and ventilating a public building.

Sun-case. (*Pyrotechny.*) A strong paper case filled with a composition which does not burn so fast as rocket-composition. They are driven similarly to rockets, but solid, and are attached, at short intervals apart, to wooden frames, usually circular, to produce what are called stationary and revolving *suns* and other similar effects in pyrotechny, giving out a steady and brilliant stream of light while burning.

Sun-di'al. A time-measurer, in which a gnomon casts a shadow upon a graduated plate.

Said by Pliny to have been invented by Anaximander of Miletus, 550 or 562 B. C. The dial of Ahaz, referred to by Hezekiah, was near two centuries precedent to that of the Grecian. It probably originated with the Chaldees or with the race of Asiatic descent known to us as Egyptians, who were the dwellers in the valley of the Nile at the period of Abraham, and long previous. See DIAL.

Sunk Coak. (*Carpentry.*) A mortise or recess in the scarfed face of a timber, and designed to receive the counterpart *coak* or tenon of the other timber. See SCARF.

Sunk'en Bat'ter-y. (*Fortification.*) In a sunken battery all the earth from the parapet is taken from the interior space, which is lowered from 2 feet to 3½ feet, according to the hight of the gun-carriages to be used. This kind of battery can be constructed in less time than an elevated battery, the mass of earth in the parapet being smaller, but its command over the surrounding country is of course less.

Sunk'en Ves'sels, Rais'ing. Apparatus for lifting foundered vessels.

Sowesbutt's apparatus for raising sunken vessels consists of a number of cases, made just sufficiently heavy to sink when filled with water; each contains a metallic receiver filled with compressed air. They are lowered from the wrecking vessel and attached along the sides of the ship by divers; when the arrangements are complete, valves in the receivers are opened, either by the divers or by self-acting mechanism, and the compressed air thus liberated expels the water from the pontons, which buoy up the vessel. See also Figs 1617, 4148.

Sunk Fence. A ditch with a retaining-wall on one side.

No portion projects above the general level of the ground, and it is not visible at any great distance. For this reason it is also known as a *ha-ha* fence. It is used upon the edge of a garden bordering upon a park, so as to give an apparently greater extent to the home grounds.

Sunk Mo'tions. (*Gearing.*) The driving-gear of a rolling-mill, etc., which is below the level of the floor. The iron floor which covers it is called the *standing*. The sunk motions of the Corliss engine-shafting, Machinery Hall, Centennial grounds, weigh 200 tons.

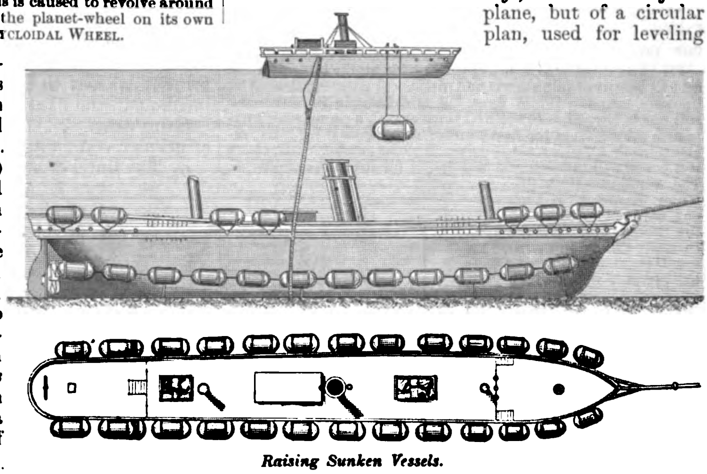
Sunk-pan'el Ceil'ing. One divided off into recessed compartments, with roses in the middle and bolection moldings around them.

Sunn. An East Indian fiber, used in place of hemp.

Sun-pic'ture. A name applicable to all kinds of pictures produced by the action of light upon sensitized surfaces. A *photograph*, or *heliograph*.

Sun-plane. (*Coopering.*) A tool like a jack-plane, but of a circular plan, used for leveling

Fig. 6071.



Raising Sunken Vessels.

down the ends of the staves of a cask or barrel. The groove for the head is then made by the *croze*, and the chamfer of the *chime* is made by the *howel*.

Fig. 6072.

Sunk Fence.

Sun-shade. 1. A parasol.

2. An awning or canopy.

Su-per-fine′ File. A dead-smooth file.

Su-pe′ri-or. (*Printing.*) A character which stands above the general line of the lower-case letters; commonly employed for notes and references.

Fig. 6073.

Sun-Plane.

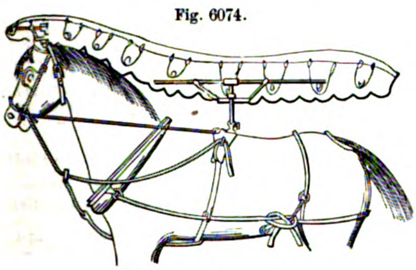
Superior letters............B^a C^b D^m

Superior figures...........A^4 H^{10} L^2

Su-pe′ri-or Slope. (*Fortification.*) A slope extending from the *crest* of the parapet to the summit of the *exterior slope*, with which it forms an obtuse angle. See PARAPET.

Su-per-roy′al. (*Paper.*) A size of drawing and writing paper measuring $27\frac{1}{2} \times 19\frac{1}{4}$ inches, and weighing according to quality and thickness.

Fig. 6074.



Sun-Shade for Horses.

Sup′ple-ment′a-ry En′gine. An auxiliary steam-engine, for feeding the boiler when the main engine is at rest; for working the pumps, cargo-winch, etc.

Sup-ply′-roll′er. (*Printing.*) An intermediate working-roller.

Sup-port′. A term of very general import. A stand, frame, or bed for an engine, machine, apparatus, implement, tool.

(*Chemistry.*) A stand for a blow-pipe lamp, crucible, retort. (See Fig. 4279.) A rack for test-tubes.

Sup-port′er. 1. (*Surgical.*) These are of various kinds, as indicated by their names. Most of them are considered under the following heads:—

Abdominal supporter.	**Pessary.**
Body-supporter.	**Pile-supporter.**
Catamenial supporter.	**Shoulder-brace.**
Fracture-supporter.	**Spinal supporter.**
Hernia-supporter.	**Testes-supporter.**
Menstrual supporter.	**Uterine supporter.**
Obstetric supporter.	**Vaginal supporter.**

2. (*Shipbuilding.*) A knee-piece of timber bolted firmly beneath the cathead, to reinforce it when sustaining the weight of the anchor.

b. A piece bolted to the hounds of a mast for supporting the trestle-tree. See BIBB.

Sup-pos′i-to-ry. (*Surgical.*) *a.* A plug to hold back hemorrhoidal protrusions.

b. A medicinal ball introduced *per ano.*

Sur′base. 1. (*Architecture.*) A cornice or series of moldings at the top of a pedestal, podium, etc.

2. (*Joinery.*) A board running round a room on a level with the top of the chair-backs.

Sur′based Arch. (*Architecture.*) An arch whose rise is less than half the span.

Sur′cin-gle. (*Saddlery.*) A belt or girth to be passed around a saddle, pad, or blanket, to fasten it to the horse's back.

Sur′face-chuck. (*Lathe.*) A face-plate chuck to which a flat object is dogged for turning.

The backs of stereotype-plates may be thus turned off.

The magnetic chuck will grasp iron disks without clasp or dog.

Sur′face-con-dens′er. 1. (*Steam-engine.*) A chamber or congeries of pipes in which steam from the cylinder is condensed. Invented by Napier.

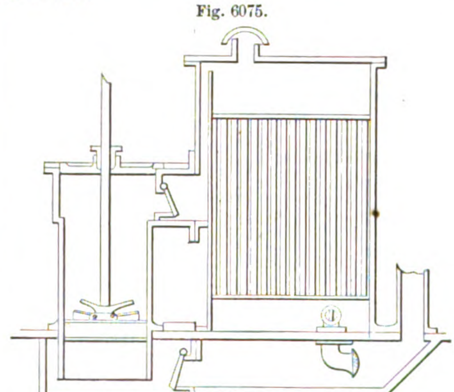
It generally consists of a large number of brass tubes about $\frac{1}{2}$ inch in diameter, united at their ends by means of a pair of flat, steam-tight vessels, or of two sets of radiating tubes. This set of tubes is inclosed in a casing through which a sufficient quantity of cold water is driven. The steam, being led by the exhaust-pipe to one end of the set of tubes, is condensed as it passes through them, and arrives in a condensed state at the other end of the apparatus, whence it is pumped away by the air-pump.

The *surface-condenser* was designed especially for marine engines, to avoid the mixing of the cold salt-water with the water of the condensed steam, which takes place by the use of the injection-condenser, usual in land engines. With marine engines, the cold-water cistern is supplied from the sea, and the constant addition of salt-water in the form of injection, which eventually passes from the hot-well to the boiler, causes the accumulation of salt in the boiler, which is got rid of by occasional *blowing-out* or by a pump. See BRINE-PUMP.

Brunel's surface-condenser was patented in England in 1822, and consists of clusters of pipes communicating with steam-mains and surrounded by the water of the cold-water cistern.

Napier's condenser was a casing around the engine-room, around which the sea-water flowed, entering before and passing out abaft.

Fig. 6075.



Church's Condenser.

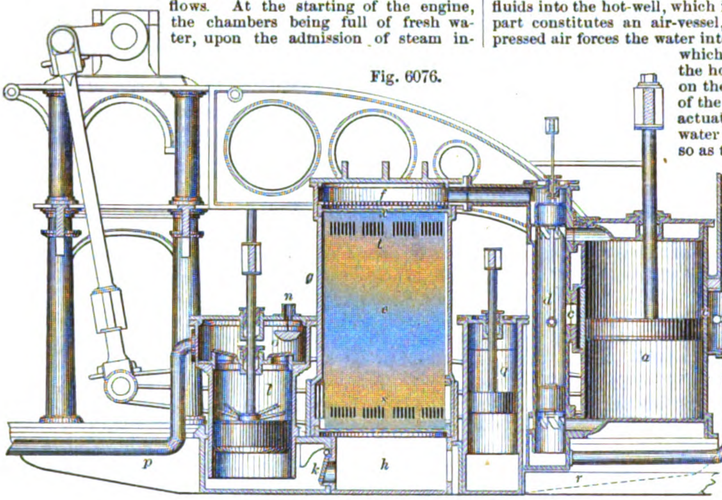
Fig. 6075 is an instance of a surface-condenser for the injection-water of a condensing steam-engine, and may be termed a combined *injection* and *surface* condenser, the surface-refrigeration being applied to the fresh water, which is injected into the condenser to condense the steam.

As has been stated, the cold-water cistern is the usual source of supply for the jet of cold water which is injected as a spray into the condenser. This cistern is supplied from the sources at hand on land, and on our rivers and lakes it is furnished with fresh water, and at sea its contents are salt water.

When the latter is used as injection-water, salt gradually accumulates in the boiler, and on reaching a certain degree of saturation must be removed by "blowing out." (See SALINOMETER.) This condenser aims to keep the contents of the boiler fresh by returning the condensed fresh water to the boiler unmixed with salt water; the latter only being used to cool the condensed water, so that it may be used for the purpose of an injection-spray.

The *refrigeratory* consists of three compartments, the upper one being connected with the lower one by means of a number of small pipes which traverse a cistern, through which a stream of cold sea-water constantly flows. At the starting of the engine, the chambers being full of fresh water, upon the admission of steam in-

Fig. 6076.



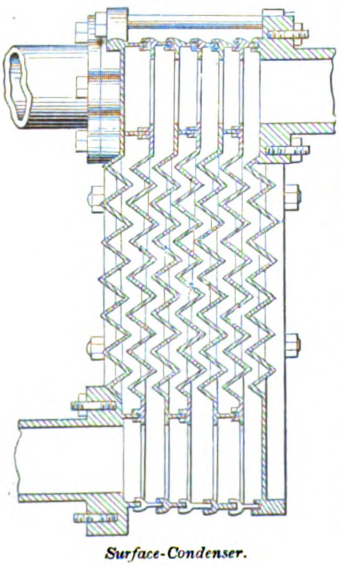
Hall's Condenser.

to the condenser by the pipe, the injection-cock is opened, and the injection-water is distributed in a shower amidst the steam by the rose; the condensed and injection pass together through the foot valve-way into the chamber beneath the air-pump, by whose bucket they are lifted and discharged by another valve-way into the upper chamber, to be again cooled in descending through the pipes which are surrounded by the cold sea-water in the cistern. Here the temperature is again reduced, so that the water becomes again effective in an injection-spray.

Hall's condenser (English) consists of a cast-iron vessel *f g h* divided into three compartments by two horizontal tube-plates. Into these plates are secured the ends of a vast number of copper tubes *e* of small diameter, which form a communication between the upper chamber *f* and the lower chamber *h*. Through the middle compartment *g* a stream of cold sea-water is maintained by means of a cold-water pump *q* and the passages *r s t*, of which the former is the cold-water induction-pipe, and the other two are respectively the induction and eduction ports by which the water enters and leaves the compartment *g*, from whence it is discharged into the sea.

The upper chamber *f* communicates with the eduction steam passage from the cylinder *a* and valve-chamber *d*; and the lower chamber *h* communicates by the foot valve-way *k* with the well of the air-pump *l*.

Fig. 6077.



Surface-Condenser.

The steam from the eduction-pipe, entering the upper chamber *f*, is instantly dispersed through the condensing-tubes *e*, which are surrounded by cold sea-water, and is thereby brought into a liquid condition, and falls in a shower into the lower compartment *h*, from whence it is drawn, together with the air and uncondensed vapor, by the air-pump *l*, which delivers the said fluids into the hot-well, which is closed at top, so that the upper part constitutes an air-vessel, and the elasticity of the compressed air forces the water into the boiler through the pipe *p*, which proceeds from the lower part of the hot-well to the feed-valves or cocks on the face of the boiler. On the top of the hot-well is placed a *snift*-valve *n*, actuated by a float *o* to maintain the water in the hot-well at a certain hight, so as to prevent air from entering the boiler along with the water. If the air accumulate at the upper part of the hot-well and the water sink below a certain level, the float descends and opens the valve, when a portion of air escapes and restores the desired condition.

The whole of the steam is condensed and the water returned to the boiler, but, to compensate for loss at the safety-valve and leakage, a still is inserted in the top of the boiler, and connected by a pipe and cock with the upper chamber *f* of the condenser. This still is charged with sea-water, and when the water in the boiler is too low, the cock is opened, and, a communication being thus established with the condenser, a partial vacuum is formed in the still. This causes the water to boil rapidly at a much lower temperature than it would otherwise, and the steam, rushing into the condenser, is condensed along with the steam from the cylinder. The additional water thus obtained is delivered to the boiler by the action of the air-pump. See STILL.

a is the steam-cylinder.

b, the steam-pipe from the boiler.

c, a belt or channel surrounding the cylinder and conveying the steam to the slide-valve chest *d*.

e, the tubes of the middle chamber *g* of the condenser.

f, the upper chamber of the condenser communicating with eduction steam-port.

g, the middle chamber, containing cold sea-water and traversed by the tubes *e*.

h, the lower chamber of the condenser, collecting the water dropping from the tubes.

k, the foot-valve.

l, the air-pump.

m, the hot-well.

n, the snift-valve.

o, the float operating the snift-valve.

p, the feed-pipe leading to the boiler.

q, the cold-water pipe, placed between the valve-chest and the condenser.

r, the cold sea-water supply-pipe.

s, the apertures in the wall of the chamber *g* by which the cold water enters.

t, outlet passages by which the water in chamber *g* is returned to the sea.

u, the throttle-valve.

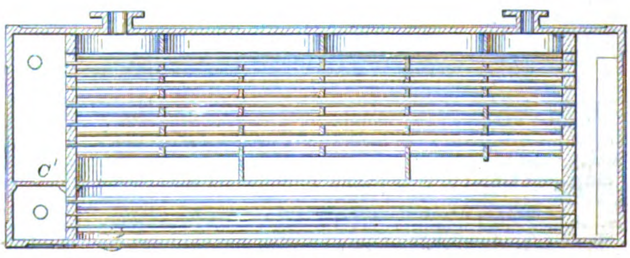
w, the blow-through valve.

x, a distributing plate in the upper chamber of the condenser.

Fig 6077 shows a form in which the steam and the water follow sinuous courses flowing in opposite directions.

In Fig. 6078, a partition C' is placed in the chamber in which the cooling water is received, for the purpose of compelling

Fig. 6078.



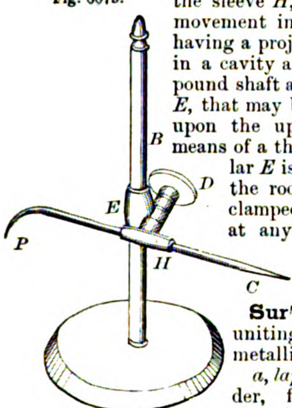
Condenser.

water to pass the tubes of the lower or cooling section of the condenser, and return it through the upper or condensing series of tubes; the object being to more thoroughly cool the condensed water than could be done if the cooling water entered both the condensing and cooling tubes at the same time. The induction and eduction nozzle for the steam and water and the division plates are arranged at the same end of the condenser, whereby the steam and water are each made to traverse the entire length of the instrument in opposite directions before being discharged therefrom.

2. A steam-heated apparatus consisting of pipes or chambers over which a solution is conducted in order that its watery particles may be driven off. Such is the Degrand (Derosne) condenser. (See CONDENSER.) Such also is the EVAPORATING CONE of Belgium. (See EVAPORATOR.) Useful hints on construction may be gathered from LIQUID-COOLER, BEER-COOLER; apparatuses which differ from these surface-condensers merely in the fact that a refrigerating liquid instead of steam occupies the hollow trunk.

Sur'face-gage. An implement for testing the accuracy of plane surfaces. In that illustrated (Fig. 6079), the pointer *P C* slides in the sleeve *H*, which is capable of movement in a vertical plane by having a projection loosely fitting in a cavity at the end of a compound shaft attached to the collar *E*, that may be raised or lowered upon the upright rod *B*. By means of a thumbscrew *D* the collar *E* is tightly held against the rod *B*, and the pointer clamped in the sleeve *H*, at any positions to which they may have been previously adjusted.

Fig. 6079.



Surface-Gage.

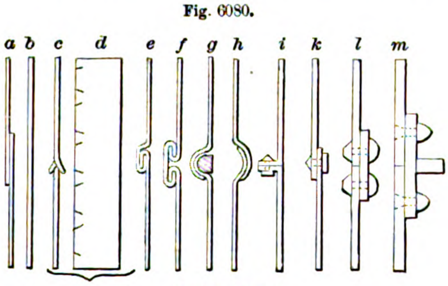
Sur'face-joint. A joint uniting the ends or edges of metallic sheets or plates.

a, *lap*-joint, with solder, for tin plates, sheet-lead, etc.

b, *butt*-joint, for sheet-metal plates and tubes.

c d, *cramp*-joint, for thin works requiring strength. The edges are thinned with the hammer, one being left plain and the other notched, forming the cramps; these are bent alternately up and down, and the plain

Fig. 6080.



Surface-Joints.

edge of the other sheet inserted, after which they are hammered down and brazed, when the joint may be made smooth with the hammer and file.

e, *lap*-joint, without solder, used for works not requiring to be steam or water tight.

f, sometimes called the *patent strip overlap*, avoids the double bend of the preceding joint; used for zinc, etc.

g, *roll*-joint, for lead roofs; the metal is folded over a wooden rib, and is not soldered; a somewhat similar joint, though the two plates do not extend over the roll, is employed for zinc, in which case the top is protected by a strip nailed to the wood.

h is a hollow crease used in vessels for making sulphuric acid; the crease is filled with lead, which is united to the edges of the sheets by means of a red-hot iron.

i is a flange-joint for pipes; the flanges are secured to each other by bolts.

k is a lapped and bolted joint employed in boilers and tubes.

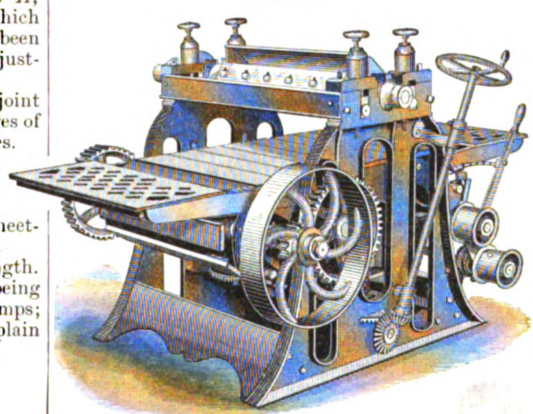
l, with rivets, is the common mode of uniting the marine boilers and other works required to be flush externally.

m is a similar mode, employed in the construction of large iron steamships; the outer skin-plates *m* form a butt-joint, and are bolted to the T-shaped iron rib, which has been bent to the proper curve.

Sur'face-plane. (*Wood-working.*) A form of planing-machine for truing and smoothing the surface of an object run beneath the rotary cutter on the bed of the planer.

The illustration shows a surface-planing machine with a traveling bed, on which the stuff is carried beneath the cylinder, which has three cutters. The front roll has independent weights. The machines will plane $\frac{1}{8}$ inch to 10 inches in thickness, and 24 to 30 inches width, according to size of machine.

Fig. 6081.



Rotary-Bed Surface-Planer.

The bed-rail is gibbed on the frame, and is raised or lowered by screws according to the thickness of the work.

Sur'face-print'ing. Printing from an inked surface in contradistinction to the plate-printing process, in which the lines are filled with ink, the surface cleaned, and the ink absorbed from the lines by pressure upon the plate. See COPPERPLATE-PRINTING.

The latter is universally adopted by the bank-notes of the United States, except some of the minor details, which are put on by a surface-printing.

The Bank of England notes, since January 1, 1855, have all been surface-printed.

Books, newspapers, woodcuts, and lithographs are all surface-printed. See BANK-NOTE ENGRAVING; STEEL-PLATE ENGRAVING.

Plate LXVII. illustrates several features of en-

graving, as well as affording a specimen of *surface-printing*.

The interior is a medallion head of Commodore Perry, engraved on a peculiar form of medallion-machine invented and made by G. W. Casilear of the United States Treasury Department, adapted to give several series of lines, thereby forming a network.

The usual form of medallion-machine is cited on pages 1417, 1418, and need not be re-described. Speaking in the most general terms, a tracer is made to follow the contour of the relief on the medal, and governs the motions of the diamond scriber which moves over the plate to be engraved, the ascents and descents of the tracer resolving themselves into deviations from the straight line on the engraved plate, the tracer and scriber being connected, and moved simultaneously over their respective surfaces, and being set forward a given and equal distance between each stroke.

In Casilear and Smith's medallion ruling-machine, for ruling two or more lines, there are two right-angle slides crossing at $22\frac{1}{2}°$, each slide with a screw and index, to give the proper width of line to the ruling. The medallion and plate to be ruled are placed on the table of the top slide; in ruling the cross lines, the movement is given either at the angles of $22\frac{1}{2}°$, 45°, or $67\frac{1}{2}°$. The selection of the angle determines the form of mesh of the network produced, whether square or lozenge. The portrait (Plate LXVII.) is the production of this machine.

The border around the portrait is the production of the rose-engine, or geometric lathe, described on pages 1983, 1984, and 963. The action of the cutting-tool in the rose-engine is to make lines the product of a combination of motions of the bed-plate, and the possible variations are almost infinite. Plate LXIV., STEEL-ENGRAVING, shows a number of specimens of its work: the ornamental panel behind the letters "Washington"; the oval immediately above the work on the upright sides of the border. Plate LXIV. is printed, not as a *surface*-plate, but in the manner usual with steel-plates, by filling the lines with ink, cleaning and polishing the surface of the plate, and then laying the paper upon it and passing both through the press (Fig. 1445), when the paper absorbs the ink from the lines of the plate.

The rose-engine work around the portrait, if printed from by the surface-process directly as it was engraved, would give a black surface with a fine tracery of white lines; but, to adapt it to show its fine lines colored on a white ground, a counterpart impression in steel must be made, in which the lines are salient, not depressed, and this by transfers is made so to appear in the plate, that by printing the portrait and its border in a single operation of *surface-printing*, we have the *portrait* white-line work on a dark ground, and the *border* dark-line work on a white ground.

The author is indebted for this unique specimen to G. W. Casilear.

Sur′face-roll′er. (*Calico-printing.*) The engraved cylinder used in calico-printing.

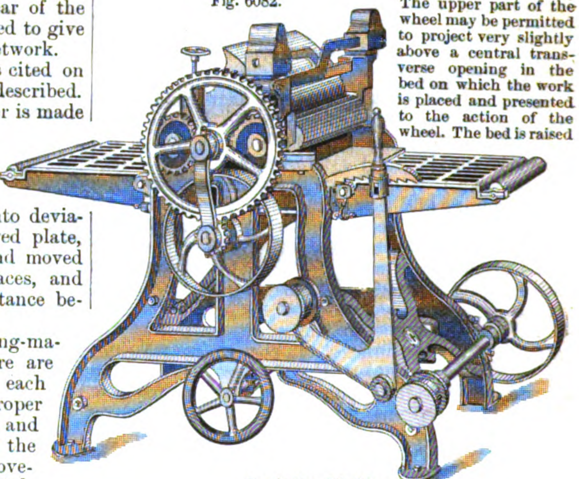
Sur′fac-ing-ma-chine′. 1. (*Wood-working.*) A machine for planing timber. The piece is fed by weighted corrugated feed-rolls to rotary cutters, which smooth its surface; bearing rollers at each end of the machine steady and equalize the motion of the piece (Fig. 6082).

The belt of the driving-pulley is thrown in or out of action by a tension-roller connected with a hand-lever manipulated by the operator. The table or platen may be raised or lowered by two screws gearing with a cross-shaft operated by a hand-wheel.

2. (*Metal-working.*)

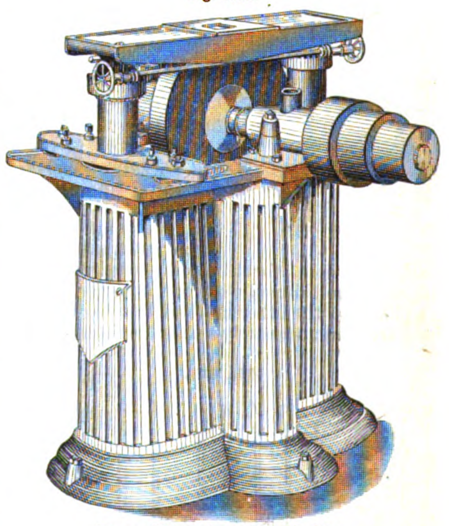
The machine (Fig. 6083) is designed for finishing off metallic surfaces by grinding. It is provided with a wheel faced with tanite. (See TANITE.) The upper part of the wheel may be permitted to project very slightly above a central transverse opening in the bed on which the work is placed and presented to the action of the wheel. The bed is raised or lowered by means of two worms which engage worm-wheels at the upper ends of two screw-standards entering circular openings at either end of the compound pillar which forms the base of the machine.

Fig. 6082.



Surfacing-Machine.

Fig. 6083.

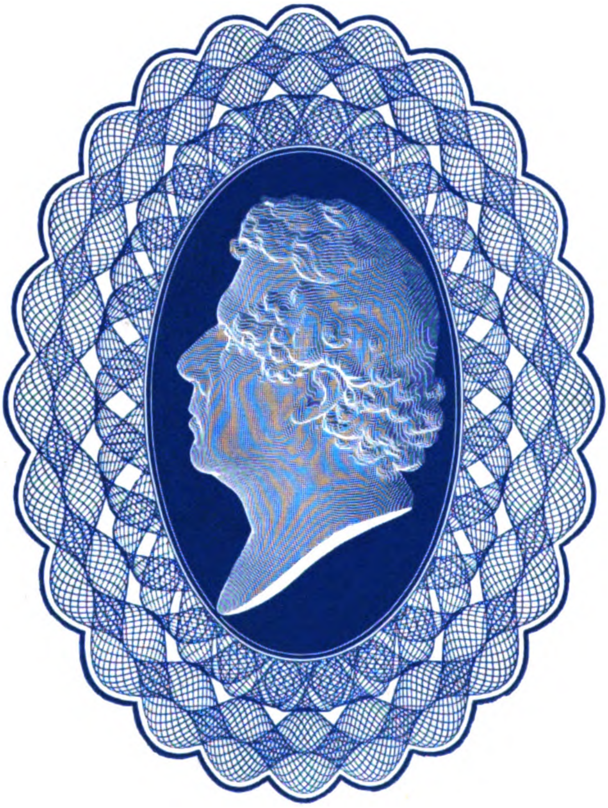


Emery-Wheel Surfacing-Machine.

Surf-boat. A peculiarly constructed boat for landing or pushing off through the surf. See CATAMARAN; LIFE-BOAT; MASSOOLAH-BOAT.

Surge. (*Nautical.*) The swell on a windlass-barrel upon which the cable or messenger *surges* or slips back.

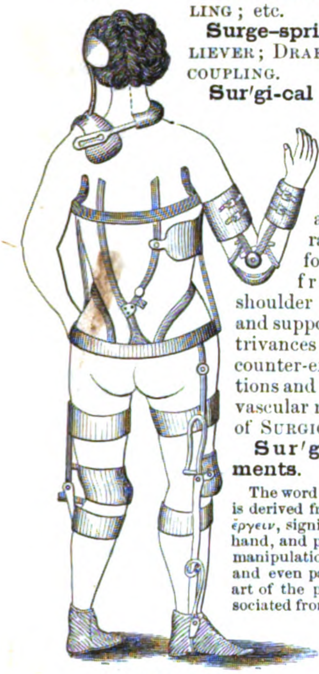
Surge-re-liev′er. A spring interposed between an object subjected to sudden strain and a relatively immovable object or one difficult to start. Such are placed on some pulley-blocks, to prevent their being snatched away; in harness, between the trace and the wagon; in cables, to take off suddenness of the jerk upon the bitt, windlass, capstan, or cable-stopper. See patent 27,505, March 13, 1860. See also



MEDALLION HEAD OF COMMODORE PERRY.

PLATE LXVII. SPECIMEN OF SURFACE PRINTING. *See pp.* 2458, 2459.

Fig. 6084.



Surgical Appliances.

DRAFT-SPRING; SPRING-COUPLING; etc.

Surge-spring. See SURGE-RELIEVER; DRAFT-SPRING; SPRING-COUPLING.

Sur'gi-cal Ap-pli'an-ces. (*Surgical.*) Apparatus — perhaps rather as distinct from instruments — embracing bandages, splints, apparatus for weak, deformed, luxated, or fractured limbs; shoulder and spinal braces and supporters; specific contrivances for extension and counter-extension; for deflections and local muscular and vascular relaxation. See list of SURGICAL INSTRUMENTS.

Sur'gi-cal In'stru-ments.

The word *surgeon*, or *chirurgeon*, is derived from the Greek χείρ and ἔργειν, signifying to work with the hand, and plainly indicative of the manipulations, topical treatment, and even palmistry. The healing art of the physician was early dissociated from that of the operative surgeon, as appears in the oath of Hippocrates, who forbade the practice of lithotomy to the physician. In a condition of things still more remote, the medicine-man was a priest, as he is to-day in Egypt, India, China, and Japan, and among savage and half-civilized peoples.

The surgeons of Egypt are the earliest of whom we have record. The *basso-rilievos* of Thebes display instruments and operations similar to those of the present. Venesection and circumcision are among the earliest mentioned. The art of embalming, as of healing, was practiced by the priests, and the physicians of note were deified both in Egypt and in Greece. Asclepias in the former, or Esculapius, in the latter, were demi-gods, the latter being reputed to be the son of Apollo, and to have accompanied Melampus and Chiron as surgeons on a warlike expedition, about 1242 B. C., fifty years before the fall of Troy. Machaon and Podalirius, two sons of Esculapius, were army surgeons with the Greeks in the Troad. Damocedes, 600 B. C., was taken prisoner by the Persians, and became court physician in Persia, reducing a dislocation of the ankle for Darius, and removing a cancer for his queen Atosa. Herophilus and Erisistratus, of Alexandria, made that school famous in the third century, B. C., and are reputed to have dissected the human body. The tourniquet, catheter, lithontriptor, and ecraseur were probably used by them. Galen practiced in Rome in the second century, A. D.

Fig. 6085 shows a number of surgical instruments discovered by the Russian physician, Dr. Savenko, in 1819, in the Via Consularis, Pompeii. The instruments are in the Museum of Portici. They were discovered in a house supposed to have belonged to a surgeon. They are, —

a b, two probes (*specillum*) respectively six and four and a half inches long.

c, a cautery of iron, four inches long.

d e, two lancets (*scalpellum*) of copper, four and a half and three inches long.

f, a small copper amputating-knife, with a wavy edge. The illustration (taken from *Revue Médicale*, for 1821, Vol. III. page 427) shows it out of proportion; it is two and a half inches long, one inch broad, and has a thick back adapted to be struck by a mallet.

g, a scalpel, with a probe point.

h, an iron needle.

i, an elevator for raising depressed portions of the skull.

j j k l, different kinds of forceps; *l* is a tenaculum forceps, with a running ring.

m, hair tweezers.

n, esophagus forceps.

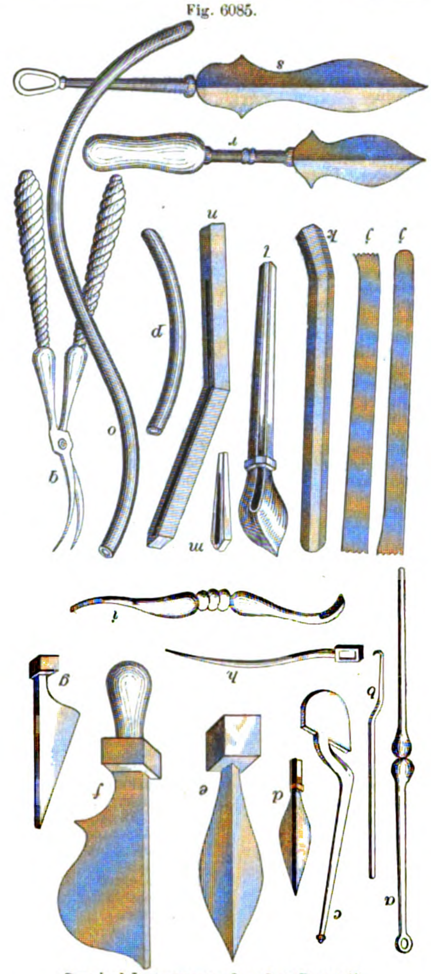
o p, catheters (male and female).

q, uvula forceps.

r s, spatulas.

The library of the Surgeon-General's office, Washington, D. C., has been formed since the close of the war, and now contains about 39,000 volumes, besides about 20,000 pamphlets.

Fig. 6085.



Surgical Instruments found at Pompeii.

It is really the National Medical Library of the United States, is catalogued and managed like the Congressional Library, and is intended for the benefit of the entire profession of the country. It is a very good practical working library, and is especially rich in periodicals.

From the priests the profession of surgery seems to have passed to the barbers, the term *barber-surgeon* being much older than that of surgeon. The fourth Lateran council, in 993, forbade the "shedding of blood" by the priests, and thus continued in force the old distinction between medicine and surgery which was enforced by Hippocrates, and is yet jealously maintained in European countries. Farther papal interference by the seventh Lateran council in 1131, and the Council of Tours in 1163, disassociated the clergy from medicine, which then fell to the apothecaries, as surgery had to the barbers, who were also keepers of the baths. French and English charters and municipal regulations show that the profession was gradually assuming systematic proportions, court and army surgeons becoming of note, the *chirurgeon* proper, who also studied medicine, gradually edging away from the mere *barber-surgeons*, who simply shampooed, bled, blistered, cupped, drew teeth, and bound up the wounds of the victims of the frequent frays. The chirurgeon proper wore a robe and cap, when, in 1572, bluff King Harry granted the Royal College of Physicians of London the power of licensing practitioners in the city of London and within seven miles thereof, — a right still extant.

The distinction between *chirurgiens* and *perruquiers* was fairly drawn by enactment in France, *temp.* Louis XIV., and in England in 1745, by act of Parliament, *temp.* George II

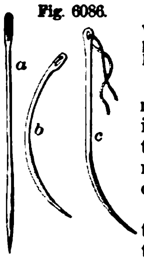
Fig. 6086.



Surgical Needles.

A surgical needle, of the usual bent form, was disinterred at Pompeii in 1819, in company with a variety of surgical instruments: lancets, catheters, probes, forceps (Fig. 6085).

Sur'mark. (*Shipbuilding.*) *a.* A mark drawn on the timbers at the intersection of the molding-edge with the ribband-line; the stations of the ribbands and harpings being marked on the timbers.

b. A cleat temporarily placed on the outside of a rib, to give a hold to the ribband by which, through the shores, it is supported on the slipway.

Sur-vey'. *a.* An examination of a tract as to extent, contour, divisions, etc.

b. A plan showing the said features, or some of them.

A *trigonometrical* survey is one made by triangulations, as the coast survey of the United States, the ordnance survey of England.

In a *geodetical* survey, the curvature of the earth is taken into account.

Maritime or *nautical* surveying concerns the coast, and gives bearing of prominent objects, positions of shoals, depths of water, etc.

Plane surveying does not take the curvature of the earth into account, as does *geodetic*.

Topographical survey deals with the positions of planes on the surface of the earth.

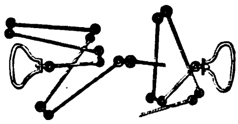
Surveyor's chain.
Theodolite.

Sur-vey'or's-chain. This chain, called *Gunter's*, after the name of the person who adapted it, is 4 rods or 66 feet long, made of Nos. 6 to 9 wire, and has 100 links. 10 of these square chains are equal to an acre. $66 \times 66 \times 10 = 43{,}560$ feet $= 1$ acre; or, counting by links, $100 \times 100 \times 10 = 100{,}000$ square links $= 1$ acre.

Fig. 6087.



Surveyor's-Chain.

The chain is divided every 10 links by notched brass marks, so that the fractions may be readily distinguished.

Chains 100 feet long, divided into 1-foot links, are also used by civil engineers.

Other apparatus is used where extreme accuracy is required.

The *decempeda*, or 10-foot pole, was the standard land-measure of Rome.

The base line for the trigonometrical survey of Great Britain was laid down by General Roy on Hounslow Heath, and is 5.2 miles long, nearly. It was measured at first with pine rods; but as these were found to be affected by the hygrometrical changes of the atmosphere, it was again measured with glass tubes 20 feet in length, furnished with a peculiar apparatus for making the contacts. In the subsequent measurement of the same line for the Ordnance Survey, two steel chains of 100 feet in length, and made by Ramsden, were employed. One of these was kept as a measuring-chain; the other was kept for the purpose of comparing the measuring-chain with it before and after the operation. In the act of measuring, the chain was laid in a trough supported on trestles, and was stretched with a weight of 56 pounds. The same apparatus was employed in measuring five other bases in different parts of the country, for the purpose of verifying the accuracy of the work.

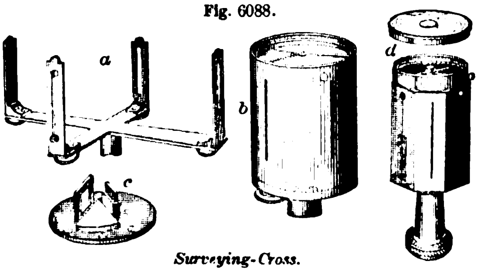
For the measurement of the Lough Foyle base in the survey of Ireland, nearly 8 miles in length, Colonel Colby employed a compensating apparatus formed of bars of different metals, so arranged that the distance between the two points viewed by compensation microscopes remains constant under all changes of temperature. For account of measurements of degrees of latitude, see ODOMETER.

"The method of triangulation in a great survey, by means of quadrilaterals, is purely American in its origin, having been first introduced by the late Professor Bache." — PROF. PEIRCE.

Sur-vey'or's-com'pass. The measuring-compass was invented by Jost Bing of Hesse, in 1602. See CIRCUMFERENTOR; THEODOLITE.

Sur-vey'or's-cross. An instrument employed for establishing perpendicular lines in surveying. It has four sights fixed at right angles upon a brass

Fig. 6088.



Surveying-Cross.

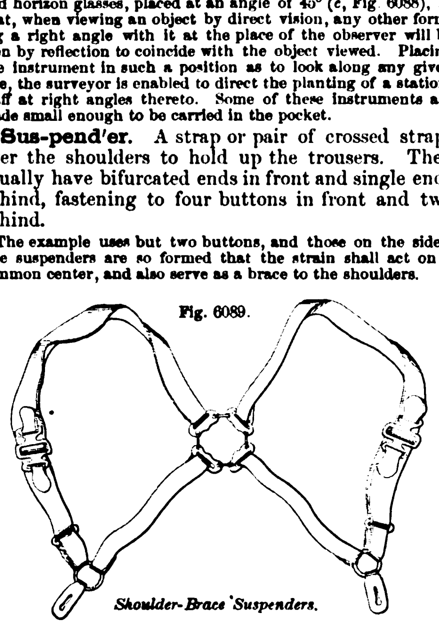
cross, which can be screwed to a tripod or single staff. The instrument is adjusted so that one pair of sights coincide with a given or base line, when a line perpendicular to the former can be easily observed, traced, or set out by viewing through the other pair of sights (a, Fig. 6088).

A cylindrical or octagonal box of brass, called the *optical square*, *b d*, is used for the same purpose as the instrument with four sights on the brass cross. The box has four vertical slits answering to the four sights just mentioned, and inside the box are the two principal glasses of the sextant, the index and horizon glasses, placed at an angle of 45° (c, Fig. 6088), so that, when viewing an object by direct vision, any other forming a right angle with it at the place of the observer will be seen by reflection to coincide with the object viewed. Placing the instrument in such a position as to look along any given line, the surveyor is enabled to direct the planting of a station-staff at right angles thereto. Some of these instruments are made small enough to be carried in the pocket.

Sus-pend'er. A strap or pair of crossed straps over the shoulders to hold up the trousers. They usually have bifurcated ends in front and single ends behind, fastening to four buttons in front and two behind.

The example uses but two buttons, and those on the sides. The suspenders are so formed that the strain shall act on a common center, and also serve as a brace to the shoulders.

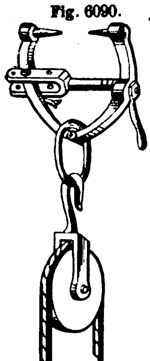
Fig. 6089.



Shoulder-Brace Suspenders.

Sus-pend'ing-clutch. A grapple to be fixed to a beam in a barn or warehouse, for the purpose of suspending hoisting-tackle.

Fig. 6090.



Suspending-Clutch.

Sus-pen'sion-bridge. A bridge sustained by flexible supports secured at each extremity.

Suspension-bridges have been used from a period of great antiquity in China, Thibet, and South America. Turner, in his "Voyage to Thibet," gives an account of one at Tchin-chien, near the fort of Chuka, about 140 feet long, and which afforded passage for equestrians. It was supported by five chains, covered with pieces of bamboo. These bridges have also been mentioned by old travelers in China.

A bridge over a river in the province of Yunnan, China, is said to have been first built 2,000 years ago. A much larger one, spanning the river Pei, was built during the Ming dynasty. It consists of a number of chains stretched across the river and secured to the rock on each side; these are stayed and strengthened by other chains attached at various parts of the span and fastened to points above and below, to prevent swaying. A plank-floor is laid on the chains, and is repaired at intervals of three to five years by the Imperial government. Its span is said to be several hundred feet. One of this kind, mentioned by Kirchen, is 330 feet long, and is said to have been built A. D. 65.

Bamboo-bridges exist in Japan. One over the Fujikaira River is stated to be about 100 feet above the river; its span being 60 and width 4 feet.

Humboldt refers to the bridges of ropes used by the native Americans, and called *cimppacha*, from *cimppa*, ropes; and *chaca*, a bridge. The ropes of one, referred to by this distinguished German, were 3 or 4 inches in diameter, and made from the fibrous roots of the American agave. They are anchored by fastening on the shore to the trunks of trees, and the track is formed of bamboos laid transversely. They are subject to dangerous lateral swaying, and Humboldt advises to cross them on a run, keeping the body well forward, and in single file. He says that a guide and traveler walking at different rates, especially if the latter stop and grasp the balustrade-ropes, will throw the bridge into convulsions.

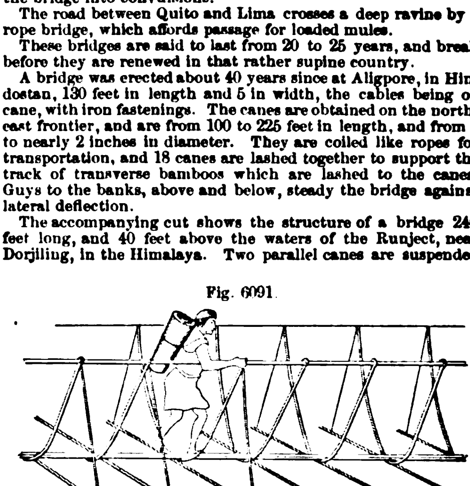
The road between Quito and Lima crosses a deep ravine by a rope bridge, which affords passage for loaded mules.

These bridges are said to last from 20 to 25 years, and break before they are renewed in that rather supine country.

A bridge was erected about 40 years since at Alligpore, in Hindostan, 130 feet in length and 5 in width, the cables being of cane, with iron fastenings. The canes are obtained on the north-east frontier, and are from 100 to 225 feet in length, and from 1 to nearly 2 inches in diameter. They are coiled like ropes for transportation, and 18 canes are lashed together to support the track of transverse bamboos which are lashed to the canes. Guys to the banks, above and below, steady the bridge against lateral deflection.

The accompanying cut shows the structure of a bridge 240 feet long, and 40 feet above the waters of the Runject, near Dorjiling, in the Himalaya. Two parallel canes are suspended

Fig. 6091.



Cane-Bridge, Nepal, India.

between a fig-tree on one side of the stream and strong posts on the other side. From these canes are suspended loops in which are the canes forming the floor, and the proper relations of the parts is maintained by cross-ties, which stretch apart the suspension-canes, which are formed by a species of rattan, 20 or 30 yards long, and knotted together, the other pieces being fastened together by strips of the same plant.

Several suspension-bridges, formed of iron chains supporting loops on which planking is laid, are mentioned by Hooker in his "Himalaya Journals." One crossed the Mywa, a western affluent of the Tambur in Nepal; another the Newa, in which the chains were clamped to the rocks on either shore, and the suspended loops occurred at intervals of 8 or 10 feet.

Suspension-bridges in Europe are mentioned by Scamozzis in his "Del Idea Archi," 1615.

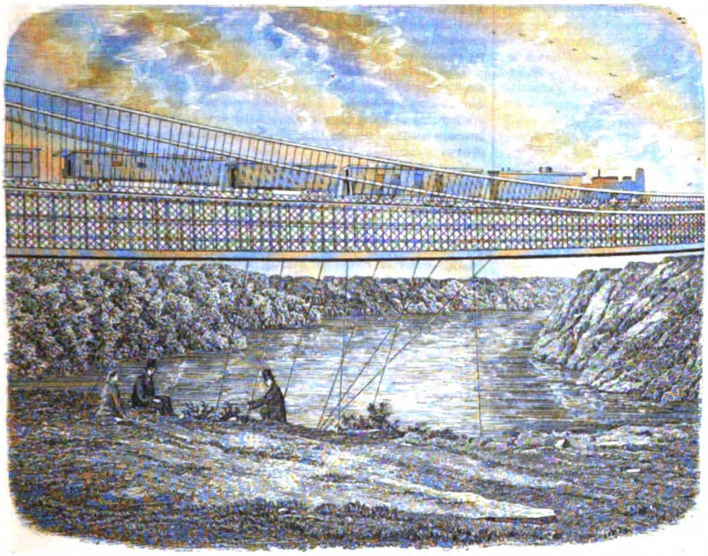
The principles of their construction were laid down by Bernouilli (born at Bâle, Switzerland, 1654; died in same city, 1705).

The first chain-bridge in England appears to have been laid across the river Tees about the year 1741; its length was 70 feet, and breadth rather more than two; it was a mere foot-bridge, and seems to have been a very rude affair. Finlay constructed a chain-bridge in this country in 1796, over Jacob's Creek, between Uniontown and Greensburg, Pa., taking out a patent in 1801; in 1811 eight bridges had been built on his plan, which does not seem, however, to have recommended itself to the public generally, as we hear no more of it after that date. In 1819 a bridge, supported by cables, was constructed across the Tweed at Berwick, Eng., by Sir Samuel Brown; it had 449 feet span. Telford's bridge, over the Menai strait, was finished in 1826. It was suspended by rods of iron, 5 in a set, 4 of these constituting a link of the chain; these were connected by bolts and chain-plates. The entire length of the chain was 1,710 feet, weight 3,876,784 pounds. (See plate at TUBULAR BRIDGE.) The distance between the centers of the pyramids at each end was 579 feet 10 inches; the deflection of the chains in the middle 43 feet; and the hight of the roadway above high-water mark 102 feet. It was calculated to bear a burden of 782 tons, in addition to its own weight, without injury. The bridge at Fribourg in Switzerland was opened for travel, August 23, 1834; its span from pier to pier is 880 feet, and hight above the water 167 feet. It is supported by four iron wire cables, each consisting of 1,056 wires, and cost about $ 125,000. 15 pieces of artillery, drawn by 50 horses, and accompanied by 300 people, were crowded together as closely as possible, first at the center, and then at each extremity, causing a depression of 39½ inches, but no sensible oscillation was experienced.

The Roebling Niagara suspension railway-bridge has a span of 821 feet; it is suspended by wire cables, and stiffened by timber trussing, containing between the abutments 600 tons of wood and 400 tons of iron. The passage of an ordinary train, estimated to weigh 80 tons, caused a deflection of .41 foot, of which Mr. Barlow computed .182 foot was due to the elongation of the cables (a, Fig. 6096).

This bridge has two floors, one 19 feet above the other, leaving a clear space of 15 feet between them. The lower one is used for ordinary purposes, while the upper one is laid with a

Fig. 6092.



Niagara Suspension-Bridge, from the Top of the Bank on the Canadian Side.

railway-track and provided with footpaths; the flooring of this is 245 feet above the surface of the water. Two cables support each roadway, making four in all, which are mutually connected, so that the strain of a load is distributed among the whole. These are 10¼ inches in diameter, composed of 7 strands of 520 wires each, every wire being calculated to bear a strain of 1,648 lbs., or 12,000 tons in all.

The upper cables are brought, by means of braces, to within a distance of 13 feet from each other at their centers, and the suspenders inclined inward, so as to give a broader base to the structure and assist in assuring its stability.

Instead of a pier at each end, a separate tower is provided for each pair of cables, thus greatly reducing the amount and cost of the masonry.

The upper and lower floors are connected by wooden posts arranged in pairs, and having between them sufficient room for the passage of diagonal truss-rods of wrought-iron 1 inch in diameter, passing from the top of one pair of posts to the bottom of the fourth pair from it, and distributing the pressure, the posts being 5 feet apart, over a space of 20 feet on each side; these have screw threads and nuts on their ends, so as to be capable of being screwed up in case of shrinkage of the timber. There are also a number of diagonal wire stays extending from the top of each tower, and intended to prevent vertical oscillation. Smaller stays attached to the under side of the bridge are anchored to the rocks below.

The new bridge, near to the Niagara Falls, is designed for carriages and foot-passengers. On the United States side, the towers are within a few hundred feet of the falls. In length it exceeds the lower bridge 450 feet, being 1,250 feet in the span. The towers are 105 feet high, and are built in pairs 13½ feet apart. Unlike the heavy stone columns of the lower bridge, they are light wooden trestles, 28 feet square at the base and tapering to the top. They are roofed and weatherboarded.

The bridge is sustained by two cables, which were swung in the winter of 1867-68, when the ice filled the river below the falls. The lower bridge is sustained by four cables, the upper one by two, each of which is composed of seven strands of twisted steel wire, each strand measuring 2⅜ inches in diameter, which together form a cable about 9 inches thick.

The dimensions of the bridge are: The span from rock to rock is 1,190 feet. The span between the centers of the towers is 1,268 feet. The length of the suspended platform is 1,240 feet. Hight above the surface of the river, 190 feet. The length of the central portion of the platform resting on cables is 635 feet. The deflection of cables at center causes a rise and fall of the bridge from changes in temperature of 3 feet. The length of the cables between the points of suspension is 1,286 feet; length of the cables between anchorages is 1,828 feet. Length of cables and anchors, 1,888 feet. Hight of towers above rock on Canada side 105 feet, and on American side 100 feet. Base of towers, 28 feet square, and top 4 feet square.

The width of the roadway between the parapets is 10 feet. The bridge is supported by two cables, composed of two wire ropes each, which contain respectively 133 No. 9 wires, of 9 pounds to the linear foot; the diameter of the cable is 7 inches. The total weight of the suspended portion of the cables is 82 tons net. The aggregate breaking strain of the cable is 1,680 tons net, and that of the stays 1,320 tons net, making the total supporting strength of the cables and stays 3,000 tons. The number of suspenders is 480, with an aggregate strength of 4,800 tons. The weight of the suspended roadway, including weight of cables and stays, is 250 tons. The ordinary working load is 50 tons, and the maximum load is 100 tons; permanent and transitory load, 350 tons (*d*, Fig. 6093).

The first bridge over the Ohio was the suspension-bridge at Wheeling, erected by Ellet, in 1848; this was blown down in 1854; it had a span of 1,010 feet.

The present Wheeling bridge is 21 feet 8 inches lower at the Bridgeport, O., end than at the Wheeling, West Va., end.

The Nashville, Tenn., bridge has a similar inequality.

The suspension-bridge over the Cumberland, at Nashville, has a span of 650 feet; the roadway being 22 feet 8 inches wide, consisting of a carriage-way, with a foot-path on each side. It is supported upon two cables, each 8 inches in diameter.

The Cincinnati suspension-bridge was built by John A. Roebling of Trenton, N. J., who has constructed so many others on the suspension principle. The piers are of stone, 200 feet high, and 86 by 52 feet at the base, containing 32,000 perches of masonry. Roadways of massive stone-work, arched part of the way, form the approaches to the bridge at each termination, and constitute the shore supports for the cables, which are anchored far below the ground surface and the ends of these abutments. Each of these contains 13,000 perches of stone, which, added to the 64,000 perches contained in the two towers, gives a total of 90,000 perches of stone-work in the bridge. The distance from abutment to pier is 281 feet; that of the main span across the channel-way of the river is 1,057 feet, the total length of the roadway being 2,252 feet, with a width of 36 and hight above low water of 100 feet (*c*, Fig. 6093).

The bridge is suspended from two cables, each composed of seven strands, each strand containing 740 wires, ⅛ inch in thickness, each wire of which is computed to have a tensile strength of 1,700 lbs., the whole forming a cable of 12½ inches diameter.

Imbedded nearly fifty feet below the surface, under each side of both abutments, are the large, square cast-iron plates to which are fastened the anchor-bars connecting these plates with the shoes at the ends of the cables. These anchor-bars are 10 feet long, 9 inches wide, and 1¼ inches thick, laid in rows of sixteen, side by side, in eight or nine lengths, and connected to each other, and to the shoes and anchor-plates by sockets and cross-bars.

The total cost of the bridge is estimated at $ 1,750,000.

The cables pass through grooves in saddles, supported by iron plates imbedded in the tops of the piers, and having rollers beneath them so as to allow a slight motion to the plates.

The bridge-way is suspended from the cables by suspenders, placed at distances of five feet on each side, the center ones being 1¾-inch iron rods, and those toward the ends 1⅛-inch wire ropes, attached to iron straps passing around the cable.

The roadway is of wood, having a carriage-way in the center and foot-paths at each side.

The bridge over the East River, now in progress, connecting the cities of New York and Brooklyn, is to have a total length of about 5,862 feet from the foot of Chatham Street in New York to the corner of Main and Fulton Streets in Brooklyn. The foundations for the piers on each side are obtained by sinking caissons in the river, near the shore, and excavating until the solid rock is reached. (See CAISSON.) The towers will be 280 feet high; the clear span between them 1,600 feet. The cables are, however, to be carried back 1,337 feet on the New York side, and 837 feet on the Brooklyn side, and anchored in solid walls; their total length will thus be 3,794 feet. They are four in number, each composed of parallel steel wires, forming a bundle nearly one foot in diameter, and, besides being anchored at the ends, are supported by stays from the tops of the piers. The bases of the piers at the water line will be 134 feet long and 56 feet wide; their dimensions at top 120 × 40 feet. Two arches in each, 32 feet wide, afford entrance to the bridge; these are designed to be 120 feet in hight. The piers will be of granite, and hollow, each containing over 900,000 cubic feet of stone, and weighing over 70,000 tons (*c*, Fig. 6093. See also FRONTISPIECE to Vol. I.).

The anchorages will be masses of stone 129 × 119 feet at bottom, and 117 × 104 at top, and carried up to a hight of 89 feet above the river. The cables will enter the masonry at an

elevation of 82 feet, and, after passing 25 feet into the wall, will be connected with the chains. These consist of cast-steel bars, 13 feet long, 10 inches wide, and 1¼ inches thick, arranged in ten sections, each containing 19 bars, forming four curved lines, extending from the cables to the anchor-plates, and connected by cast-steel pins six inches thick.

The four anchor-plates are located at the base of the masonry; they are cast-iron plates, with radial arms, and weigh about 25 tons each The anchor-walls have each two interior spaces 80 × 20 feet, divided into six stories, serving for warehouses above and an underground-railway passage on the lower story.

The roadway of the bridge will be 130 feet above high water, and 80 feet in width. It is proposed to have upon it two lines of track for passenger-cars, to be drawn back and forth at a high rate of speed, by a stationary engine on the Brooklyn side. The weight of the bridge is calculated at 8,483 tons; the maximum weight which could possibly be put upon it at 1,270 tons, and the average about 400 tons; the strain required to break the four cables, nearly 60,000 tons.

The cost is estimated at $ 6,675,000.

In Fig. 6093, the bridges represented are drawn to the same scale.

***a*, railway-bridge, Niagara River (1855).**

Sus-pen'sion-drill. (*Metal-working.*) A vertical drilling-machine having a frame which may be bolted to the ceiling, so as to be out of the way. Useful in locomotive and boiler work, etc.

Sus-pen'sion-hook. A portable hook to enable articles to be conveniently suspended from a nail.

In the example, a curved and a flat-bottomed hook are connected by a swivel, so that either can be turned down to suit the article to be suspended.

Sus-pen'sion-rail'way. A railway in which the carriage is suspended from an elevated track, one carriage on each side of a single track, so as to balance; or suspended between two tracks.

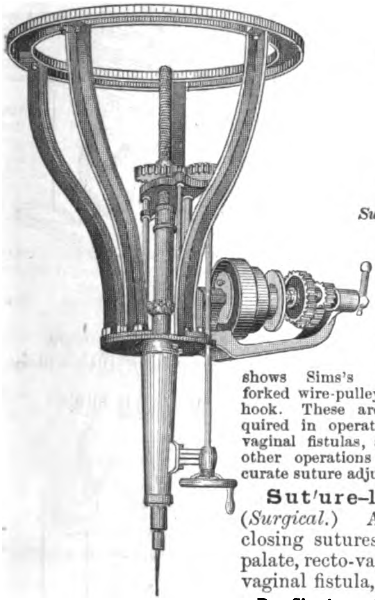
Patents representing each of these forms were taken out in England from 1821 to 1825. See ELEVATED RAILWAY; WIRE-WAY.

Sus-pen'sion-scale. One swung by pendent rods from levers above, in contradistinction to the usual platform-scales, whose levers are beneath. In the former case, the rod to the steelyard-lever comes from above; in the latter, it comes upward from the pit beneath. See also WEIGHING-SCALE.

Sus-pen'so-ry Band'age. A bag attached to a strap or belt, and used to support the scrotum, that the weight of the testes may not draw upon the spermatic cord.

Sut′ure-in′stru-ments. (*Surgical.*) Instruments employed for guiding and securing the wires

Fig. 6094.



Suspension-Drill.

Fig. 6095.

Suspension-Hook.

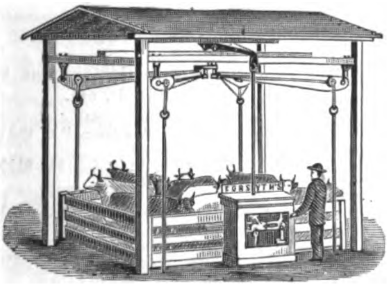
employed for holding together the edges of an incision.

Fig. 6097 shows Sims's wire-adjuster, forked wire-pulley, and a blunt hook. These are specially required in operations on vesico-vaginal fistulas, and useful in other operations requiring accurate suture adjustments.

Sut′ure-lig′a-ture. (*Surgical.*) A device for closing sutures, as in cleft-palate, recto-vaginal, vesico-vaginal fistula, etc.

Dr. Sims's method is as follows: The thread is passed through both sides of the incision; the two ends are brought out together, passed through a small hole in a *shot* (say size No. 1); the shot is then seized with a pair of strong forceps and pushed up the ligature until it comes in close contact with the incised edges, bringing them

Fig. 6096.



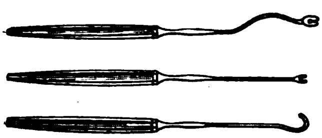
Forsyth Suspension Wagon-Scale.

in apposition or contact. The shot is then squeezed or pressed flat by the forceps, so that the suture is held tight. See also STAPHYLORAPHIC INSTRUMENTS.

See Dunglison's "Dictionary" for instances of capital operations in ligating.

Sut′ure-nee′dle. Fig. 6098 shows three of several different sizes; straight and more or less curved.

Fig. 6097.

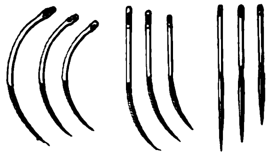


Suture-Instruments.

Sut′ure-pin Con-duct′or. (*Surgical.*) An instrument for guiding a pin or wire employed for holding together the edges of a wound, particularly in operations on the lips and face, where it is specially desirable to avoid leaving a conspicuous scar.

It consists of a slightly curved needle fixed in a handle, and somewhat eularged for a half-inch near its point. Its extremity is beveled off to a sharp point and perforated on the concave side. The edges of the wound having been brought together, the needle is passed through them with one band, and the pin or a soft iron or silver wire is engaged by its point in the perforation at the end of the conductor, and held there while the conductor is withdrawn, thus compelling the pin to follow the course of the conductor.

Fig. 6098.

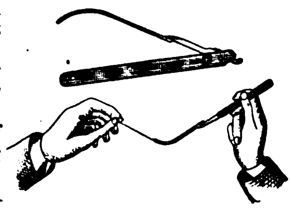


Suture-Needles.

Swab. 1. (*Nautical.*) A bundle of yarns used as a mop upon the decks.

2. (*Founding.*) A soft brush made of some strands of gasket tied together at one end and beaten and combed out at the other. It is used by the molder to wet the parting edge before *drawing* the pattern, and also to moisten parts of the mold requiring repairs.

Fig. 6099.



Suture-Pin Conductor.

3. (*Surgical.*) A pledget of lint or a spatula covered with cloth; used to clean or moisten the mouth of the sick, or cleanse a wound.

4. (*Ordnance.*) A cleaner or sponge for the bore of a gun. In the example, the disk of rubber is expanded laterally by vertical compression, and maintained in that condition by the springs which engage the shoulders of the recesses.

Fig. 6100.

Gun-Swab.

Swab-pot. (*Founding.*) An iron vessel containing water and the founder's swab.

Swad. (*Mining.*) A thin layer of stone or refuse coal at the bottom of the coal-seam.

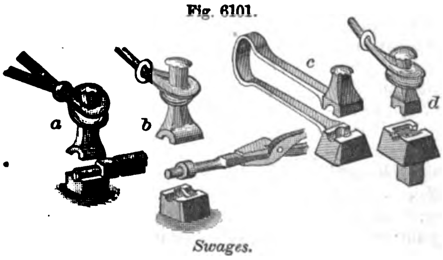
Swage. (*Forging.*) A tool having a face of a given shape, the counterpart of which is imparted to the object against which it is forcibly impressed.

When used by blacksmiths and other forgers in metal, it is either placed on the anvil so as to impress the hot metal, which is laid thereon and struck by a hammer or monkey; or, the work being laid on the anvil, the face of the swage is held upon it, and the back of the swage receives the blow.

Swages (and other tools), whose tangs fit into square holes in the anvil, are the *bottom tools* of the blacksmith. Those with a withe around them, operating *on* the metal and *struck* by the hammer, are *top tools*; together they form *collar-tools*, or *collar-swages* (*a b*, Fig. 6101).

c is a spring-swage; *d*, a *guide-swage*.

Fig. 6101.



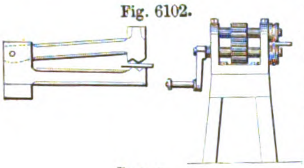
Swages.

Long swages are used in rounding and welding gun-barrels and other wrought-iron tubing.

Other swages operate in drop or lever presses upon sheet-metal; forming the *struck-up* tinware, such as pie-pans, lids for vessels, and a great variety of domestic and ornamental articles.

Swages of various ornate forms are used by jewelers in drop-presses for making links of chains, jewelry, etc., especially that cheap kind which is made of hollow plates soldered at the edges, and sometimes filled with a cheap metal.

Fig. 6102.

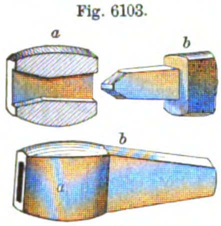


Swage.

Fig. 6102 shows a swage for raising beads on the edges of sheet-metal. The tail is held in the jaws of a vice; the upper jaw of the swage is pivoted, and is struck with a hammer while the metal is drawn beneath it.

The other figure is a device for effecting the same result in a neater and more expeditious manner. The metal is drawn between two grooved rolls; one is turned by a crank, and has a gear-wheel on its shaft meshing with a second wheel on the shaft of the other.

Fig. 6103.



Saw-Swage.

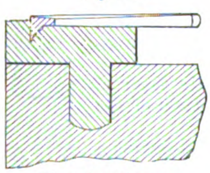
The device, Fig. 6103, is used for spreading the teeth of saws. The tooth is inserted into one side of the splayed aperture through the block *a*; the other side serves as a guide to the swage *b*, which, while the saw is firmly held, is struck with a mallet, spreading and turning up the point of the tooth and enabling it to bite into the wood more readily.

Fig. 6104 is a swage for making calks on horseshoes. The upper side is struck by a hammer, driving the metal into the depressions.

Fig. 6105 is a swage and block for making watch-backs. The bezel is made continuous with the back by the annular rebate on the cameo-die.

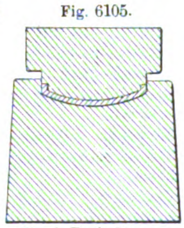
Fig. 6106 is a swage for sharpening saw-teeth. The transverse pin which passes through the end of the stock has notches or dies corresponding to the width and shape of the teeth. The dies operate upon the under side and two edges of the tooth, and the projecting jaw of the stock operates upon the upper side.

Fig. 6104.



Horseshoe-Swage.

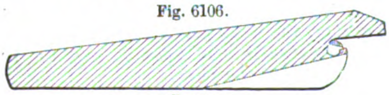
Fig. 6105.



Watch-Back Swage.

Fig. 6107 is a swage for bending nozzles of milk-cans, etc.

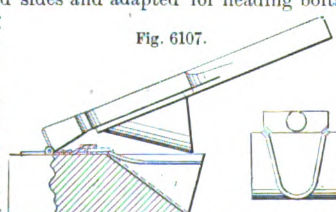
Fig. 6106.



Swage.

Swage-block. A large perforated block of iron, having grooved sides and adapted for heading bolts and swaging objects of larger size than can be worked in the ordinary heading tools and swages fitted to the anvil (Fig. 6108).

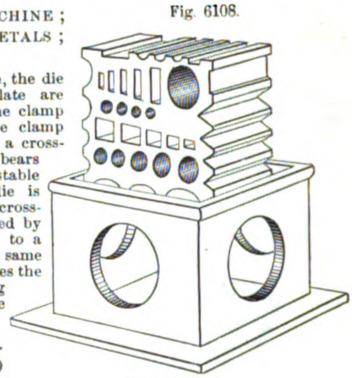
Fig. 6107.



Die for Bending Nozzles.

Swag'ing-ma-chine'. (*Metal-working.*) A machine for bringing sheet-metal to form by means of a blow or pressure in a direct line. See STAMPING-MACHINE; SPINNING-METALS; etc.

Fig. 6108.



Swage-Block.

In the example, the die and its bed-plate are raised against the clamp and plunger, the clamp being secured to a cross-plate which bears against adjustable springs. The die is secured to a cross-head, reciprocated by link attachment to a crank on the same shaft which carries the eccentric giving motion to the die.

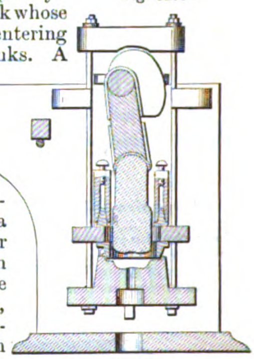
Swal'low. 1. (*Nautical.*) The groove around a tackle-block for the strap. Also called the *score*.

2. (*Mining.*) A cavern or opening into which water disappears.

Swal'low-tail. 1. (*Fortification.*) An advanced work whose salient portion has a re-entering angle and converging flanks. A *priest's cap*.

2. The points of a burgee.

Fig. 6109.



Swaging-Press.

Swan-pan; Schwam-pan. The abacus or counting-table of the Chinese. It consists of a square frame of wood or bamboo, with a division across it, and 10 transverse wires, upon each of which, above and below the division, are 5 beads; each bead representing a number (as the digits do with us), and each wire giving a particular value to the number, like units, tens, hundreds, etc.

The *yow-yow* is a smaller kind of *swan-pan*.

The abacus was the usual "reckoning-board" of the Greeks and Romans. (See ABACUS.) It is now the principal means of computation in China, Tartary, and Thibet. The Abbé Huc relates: —

Fig. 6110.

Swallow-Tail.

"The Thibetans, for small amounts, count on their chaplets; shopkeepers use the Chinese *swan-pan*, but the learned employ Arabic ciphers, which appear very ancient in Thibet. We [Mons. Gabet and himself] have seen Lamanesque manuscripts containing tables and astronomical calculations in this notation." They use the "5" reversed, resembling our cedilla (ç).

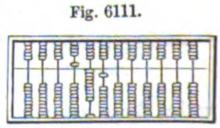
The adoption of the Indian numerals with *place value*, and the cipher, made the abacus unnecessary. Abbé Huc gives an amusing instance of the collision of the Arabic numeration and the *swan-pan*, at Kou-kou-kho-ton (Bluetown), in Chinese Tartary, where the Chinese merchant, in dealing with the Abbé as a supposed Tartar, had purposely made a mistake on the *swan-pan* to the extent of 1,000 sapecks, equal to 50 cents. The Abbé showed him his calculation in figures, which were utterly incomprehensible to the merchant; but a third party verifying the Abbé's computation by a correct manipulation of the *swan-pan*, the wonder became a marvel.

The Indian (Arabic) figures and numeration were introduced by Roman missionaries into the astronomical college of Pekin.

The knotted cord was used as a means of notation in the reign of the Chinese Emperor Fuh-hi 2852 B. C. (DU HALDE.)

Hence the rosary, common in Thibet and in Europe. See ROSARY; PRAYING-MACHINE.

Fig. 6111.



Swan-Pan, or Chinese Abacus.

In addition to what is said under ABACUS (which see), it may be stated: Upon a bas-relief of the Capitol is a Trajan and a Plotina, and near them a young man holding an abacus, upon which are three ranks of counters, 7, 1, and 6; his forefinger touches one of the second row. The counters, *calculi*, were of ivory or bone, a little convex; others of porcelain of various sizes, covered with green or blue enamel, pierced, and ornamented with figures on each side. Another set are square, round, toothed, and of different sizes, some with a cross.

Fig. 6112.

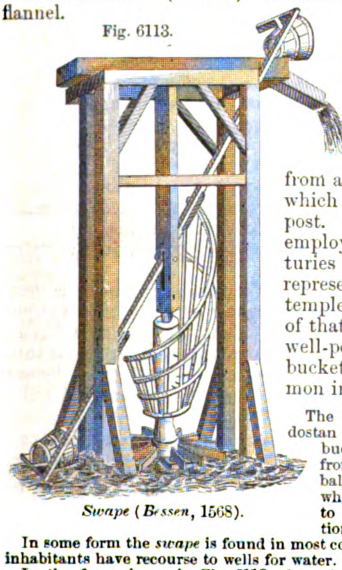
Swape (Asia Minor).

Swan's-down. (*Fabric.*) *a.* A trimming in which the fine, soft feathers of the swan and other aquatic birds are set with the quill end in the meshes of the goods, so as to make the down as a nap upon the backing of fabric.

b. A fine, soft, thick woolen cloth, made in imitation of *swan's-down*, a long nap being raised upon the surface.

Swan-skin. (*Fabric.*) A kind of fine twilled flannel.

Fig. 6113.



Swape (Bessen, 1568).

Swape. 1. The *shadûf* of the Arabs. See SHADOOF.

A bucket on the end of a line from a balanced pole which rests on a post. It has been employed for 40 centuries in Egypt; is represented on the temples and tombs of that country. The well-pole and oaken bucket are yet common in America.

The *picotah* of Hindostan is a pole and bucket suspended from the end of a balanced stage, on which a man walks to give the oscillation. See Fig. 3701.

In some form the *swape* is found in most countries where the inhabitants have recourse to wells for water.

In the form shown in Fig 6113, the pole is oscillated by a spiral bar on a vertical post, which is rotated by a horizontal water-wheel. The buckets ascend alternately, and each is emptied as it reaches the edge of the trough, the contact with which tips it and discharges the water.

2. A sconce, or light-holder.

3. A pump-handle.

4. A long oar, or *sweep*.

Sward-cut'ter. 1. (*Agriculture.*) A plow to turn over grass lands.

2. A mower for lawns. See LAWN-MOWER.

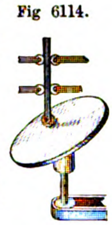
Swarf. Iron filings.

Swash-bank. (*Hydraulic Engineering.*) The crowning portion of a sea-embankment.

The lower portion is the footing, which has five base to one perpendicular. This supports the *outburst bank;* base two to perpendicular one. The *swash-bank* has the same proportions, and a level top four to five feet wide, if not required for a road. In Holland the *swash-bank* can hardly be said to exist, as the name is derived from the fact that the crest of a breaker occasionally *swashes* over. In that low country the dikes are of enormous size, more elevated than the common sea bank of other countries, and form sites for roads and canals. See DIKE; SEA-WALL.

Swash-plate. (*Machinery.*) A rotating, circular plate, inclined to the plane of its revolution so as to give a vertical reciprocation to the rod, whose foot rests thereupon, and which moves between lateral guides.

Fig 6114.



Swash-Plate.

Swath'er. (*Agriculture.*) A device attached to the front of a mowing-machine for the purpose of raising the uncut fallen grain and marking the line of separation between the cut and uncut grain. See Figs. 31–36, Plate XXXIII., page 1492.

Sway-bar. (*Vehicle.*) A bar on the hind end of the fore hounds of a wagon; the sway-bar rests on the coupling-poles and slides thereon as the wagon turns. A *slider;* a *sweep-bar*.

Sway-brac'ing. The guys of a suspension-bridge to prevent lateral swaying.

Sweat'ing-bath. A vapor-bath for sweating persons. A *stove* or *sudatory*.

Sweat'ing-fur'nace. (*Metallurgy.*) A liquation furnace of peculiar construction, in which a

Fig. 6115.

Swather for Mowing-Machine.

Fig. 6116.

Sweating-Furnace.

matte of copper and argentiferous lead is heated to deprive the copper of the metals combined therewith. The cupreous masses are placed upon the sole above the channels *f f*, which are filled with wood. The door being closed, the wood is fired, the draft being regulated by flues opening into the chimney. The argentiferous lead is separated by liquation, and the lead is oxidized, converting it into litharge, and falls to the bottom of the channels *f f*. The black copper which results is treated in a reverberatory furnace, and the argentiferous lead is cupelled.

Sweat'ing-house. A separate apartment, where vapor-baths are obtained.

Sweat'ing-ir'on. A scraper to remove sweat from horses. A similar instrument used by the

gymnasts of a former age was known as a STRIGIL (which see).

Sweat'ing-room. A room devoted to the use of a vapor-bath.

Sweep. 1. A counter-weighted pole, poised upon a fulcrum-post, and used to raise and lower a bucket suspended from the longer end. It is also written *swape*.

It is the shadûf of the Nile, and is known with us as the *well-pole* or *well-sweep*. See SHADOOF.

2. The lever of a horse-power or pug-mill.

3. (*Shipwrighting.*) The mold of a ship where she begins to compass in at the rung-heads. A part of the mold curved in the arc of a circle.

4. (*Nautical.*) *a.* A long oar used on board ship to assist the action of the rudder during a calm, or

Fig. 6117.

Sweep.

in an emergency; or to assist the motion of the ship, as in the ancient galley.

b. A circular frame on which the tiller traverses in large ships.

5. (*Founding.*) A movable templet used in loam-molding. See Fig. 3189.

6. (*Metallurgy.*) A name formerly applied to the *Almond* (*Allemand*) furnace.

Sweep-bar. (*Vehicle.*) A name sometimes applied to the *sway-bar* or *slider* of a wagon. See SWAY-BAR.

Sweep'ing. (*Nautical.*) *a.* Dragging an anchorage ground with the bight of a rope to recover an anchor, or to ascertain the position of a wreck.

b. Propelling a vessel by means of large oars.

Sweep'ing-ma-chine'. See STREET-SWEEPING MACHINE; CARPET-SWEEPING MACHINE.

Sweep'ing-ta'ble. (*Metallurgy.*) A form of ore-separator in which the slime, after agitation by fans in a chest with water, is flowed on to a sloping table and sorted by gravity by means of a sheet of water passing over the table. See Fig. 2096.

Sweep-net. One of considerable extent for drawing large areas.

Sweep-saw. A saw having a thin blade stretched by a frame or bow, and capable of cutting in a *sweep* or curve. (See FRAME-SAW; BAND-SAW; SCROLL-SAW.) Otherwise known as a *bow-saw*, or *turning-saw*. See also JIG-SAW.

Sweep-wash'ings. The refuse of shops in which gold and silver are worked. These metals are separated by mechanical means and amalgamation.

Sweet'en-ing-cock. (*Nautical.*) A faucet attached to a pipe passing through a ship's side, and admitting water to wash out the bilge-water passages.

Sweet'meat. (*Leather.*) The paint applied to leather in making what is called PATENT-LEATHER (which see).

Sweet-po-ta'to Cul'ti-va'tor. A form of cultivator adapted for hilling up the plants by passing each way, throwing the earth right and left.

Swell. 1. (*Music.*) *a.* A contrivance for giving a gradually increasing and diminishing sound to a wind-instrument by varying the volume of air which passes to the pipes or reeds.

This is accomplished by varying the size of the blast aperture, by a *knee-stop*, as in the parlor organ, or by a pedal in the church organ.

b. One of the three aggregated organs which are combined in an instrument of large power. The other two are the *great* organ and the *choir* organ. The key-boards form three banks; the *swell* above, the *great* organ, the *choir* organ below. The *swell* consists of an organ shut up in a box on three sides, and on the other side inclosed by *louvres*, which are opened and shut by a pedal, so as to give a *crescendo* and *diminuendo* effect. The *great* organ has the most important and powerful stops. The *choir* organ has light and solo stops.

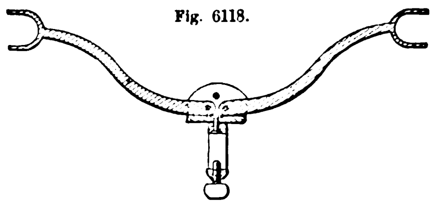
2. (*Ordnance.*) An enlargement of a gun near the muzzle. It is now suppressed in many forms of ordnance.

3. An enlarged or thickened portion of a gun-stock.

Swift. 1. A revolving reel with arms parallel to the axis, and affording a frame whereon to wind yarn, silk, or other thread.

Specifically: a hexagonal frame on which *hank-silk* is reeled, preparatory to winding on bobbins;

Fig. 6118.



Silk-Swift.

and from which it is unwound by the traction of the revolving bobbins.

In Fig. 6118, the swift is clamped to the table, and its arms may be swung up to receive any sized skein.

2. The main card-cylinder of a flax-carding machine.

3. (*Nautical.*) *a.* A tackle used in tightening standing rigging.

b. A rope encircling the ends of the capstan bars to prevent their flying out of their sockets.

Swift'er. (*Nautical.*) *a.* A rope used to confine the bars of the capstans in their sockets.

b. A rope encircling a boat, parallel to its water line, or on the shear line. It stiffens the boat, and acts as a fender. The girth ropes, spoken of by St. Luke, were passed around the vessel like hoops, to prevent the spreading of the frames. "They used helps, undergirding the ship." — Acts xxvii. 16.

c. A shroud from the head of a lower mast to the ship's side, before the other shrouds, and not confined by the cat harpings.

Swig. (*Nautical.*) A pulley with ropes which are not parallel.

Swim'ming-ap'pa-ra'tus. In the sculptures of Nimroud the soldiers are represented swimming across rivers by the aid of inflated skins.

A float or dress to sustain a person in the water. See LIFE-PRESERVER.

Webb's swim across the Straits of Dover, without artificial floats, and Boynton's trip with a life-preserver dress, are recent feats (1875). The former, which is by far the more remarkable, occupied three tides; his point of landing was 21¼ miles distant, but the length of ground swum over was 39½ miles. Time, 21 hours 22 minutes.

As an aid in teaching swimming, a stout wire resembling a telegraph-wire is now hung just above the water, and drawn tight. On this travels a grooved pulley or "door hanger," and from this hangs down an elastic cord that is fastened to a belt worn by the swimmer. This permits free use of his limbs, gives sufficient support, and allows him to move forward along the length of the wire with ease.

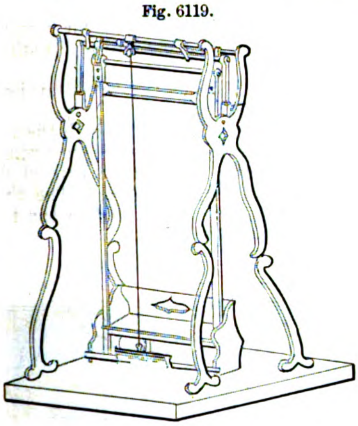
Swim'ming-tub. (*Calico-printing.*) A tank of colors, with a floating diaphragm of fabric, on

which a block is laid to color its surface. Also used in making paper-hangings.

Swing. 1. A seat suspended in the loop of a rope attached overhead.

In the example, the seat is suspended from rods, and the movable footboard is connected by a rope

Fig. 6119.



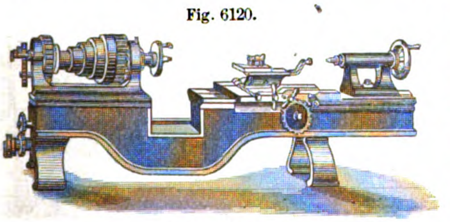
Swing.

with a vibrating-frame, and actuates springs which oscillate the swing.

2. (*Vehicle.*) The tip outward from the vehicle of the top of a wheel.

This becomes necessary, owing to the taper of the *spindle* on which the wheel runs. The lower side of the spindle is made horizontal, to obviate any tendency of the wheel to slip in or out, and enable it to

Fig. 6120.



Gap-Bed Lathe.

rest squarely in the box of the hub. This gives a tip to the wheel, which is more or less, according as the taper is greater or smaller; no swing being necessary where the spindle is cylindrical. See DISH; GATHER.

The wheel is made *dishing*, so that each spoke, as it arrives at the bottom, may stand perpendicularly beneath the axle.

3. (*Lathe.*) The distance from the *head* center of a lathe to the bed or ways, or to the rest. The *swing* determines the diametric size of the object which is capable of being turned in the lathe; anything larger would interfere with the bed. This limit is called the *swing of the bed*. The *swing of the rest* is the size which will rotate above the rest, which lies upon the bed. In the illustration is shown a *gap*, the bed being cut away to increase the *swing*.

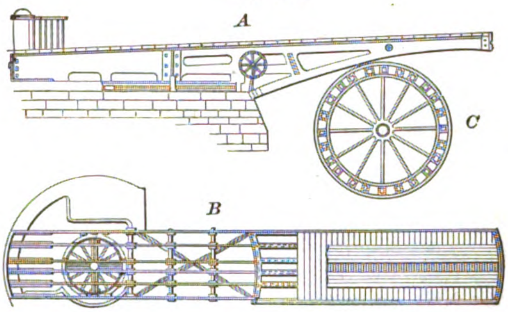
Swing-beam. 1. (*Railway Engineering.*) A cross-piece suspended from the truck, and sustaining the car-body, so that it may have independent lateral motion.

2. (*Carpentry.*) A cross-beam supporting an overhead mow in a barn.

Swing-bridge. A swivel-bridge, spanning a canal or dock entrance, and opening horizontally to allow a vessel to pass.

It was invented by Nicolas Bourgeois for the ditch

Fig. 6121.



Swing-Bridge.

of the Tuileries. His reward was a pension of 1,200 livres per annum.

Draw or *swing bridges* are required over dock entrances, canals, or other navigable waters, to allow the passage of vessels with standing masts.

The *swing-bridge* is balanced, and rotates in a horizontal plane. It is usually in two sections, each of which, when opened, is landed on its own side of the dock, the extended ends of the two meeting in the middle when brought into line, and affording a bridge across the water-course.

The tail of the bridge at the St. Katharine's docks, London, works around 240°; the clear opening between the walls is 44 feet 9 inches; the rise in the middle is 3 feet. The turning is effected by a wheel, running horizontally on a number of rollers that run upon a circular cast-iron bed. It is worked by a winch and pinion operating on a segment-rack. The bridge is well balanced, and easily swung upon its central pivot by a single attendant.

A, Fig. 6121, is an elevation; *B*, a plan; *C*, an enlarged view of the circular bed.

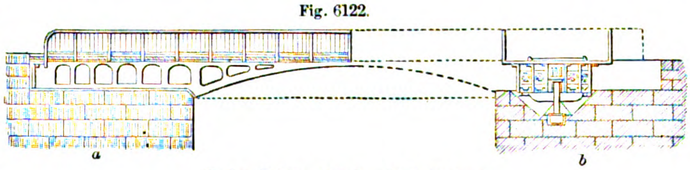
A swing-bridge on a large scale was constructed on the Great Western Railway of Ireland, to cross the entrance to Lough Atalia. It has two spans of 60 feet each, and is balanced on a central pier of 34 feet diameter.

See Humber, "On Iron Bridges."

Fig. 6122 is the iron swing-bridge over the entrance-lock to the West India Docks, London.

Plate XLI., page 1721, is a view of a swing-bridge on the Amsterdam, Utrecht, and Cologne Railway where it crosses the Yssel, near Westervoort, Holland.

Fig. 6122.



Swing-Bridge, London Dock Entrance.

Fig. 6123 is a view of the swing section of the Mississippi bridge at Keokuk, Iowa.

Swin'gel. The swinging piece of a flail. The *swipel*.

Swing'ing-boom. (*Nautical.*) The span which distends the foot of a lower studding-sail.

Swing'ing-saw. A saw swinging in an arc from an axis overhead.

A weight assists in the effective stroke. (Fig. 6124; see also Fig. 6127.)

Swing-jack. A jack for replacing cars on the track; the bottom of the standard is a cylindrical segment, and has a toe working in a slot in the base of the jack.

A pair are used, and the car being lifted while the standards are vertical, the latter are canted to or *swung* over, bringing the wheels of the car in line with the rails. (Fig. 6125.)

Swing-knife. A wooden sword $1\frac{1}{2}$ to 2 feet long, and 8 to 10 inches broad, used to scrape the woody portion from flax, a handful of which hangs over a groove in a standing board known as the *swing-stock*.

Swin'gle. 1. The effective end-piece of a flail. A *swiple*.

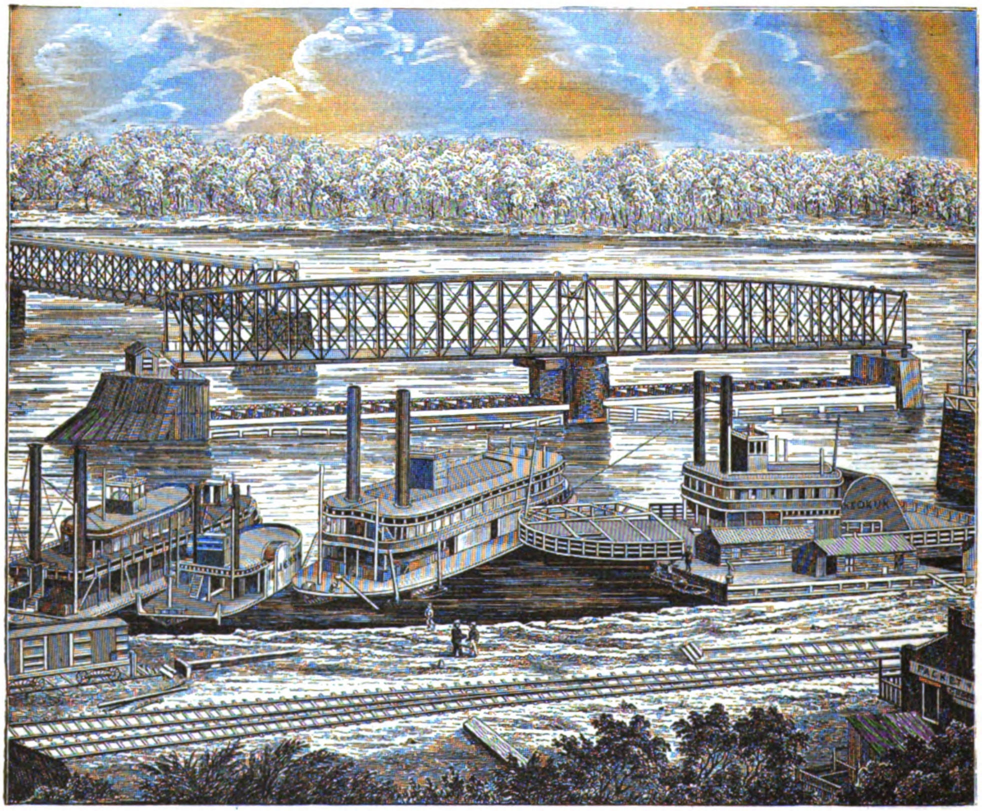
2. An instrument, like a sword, for beating flax; hence the terms, *swingling-knife*, *swingling-staff*, *swingling-wand*.

3. The wooden spoke of the wire-drawing barrel, or the roller of a plate-press.

Swin'gle-tree. The bar to which the ends of a horse's traces are attached. See SINGLE-TREE.

Swin'gling-tow. The coarse part of flax, removed by the *swingle* or *scutcher*. The *shives* are removed from the *hare* in the brake; the *tow* from the finer flax in the *scutcher*.

Fig. 6123.



Railway-Bridge over the Mississippi, Keokuk, Iowa.

Swing Mold-board Plow. A plow whose mold-board may be shifted to throw the soil to the right or to the left as may be required.

There are several modes of accomplishing this: —

1. By making the plow double, and lowering one or the other to work.

2. By turning the iron portion on an axis, so as to make the sole the landside, and *vice versa*, the mold-board officiating for each in either relation, in one case turning the soil to the right, and in the other to the left.

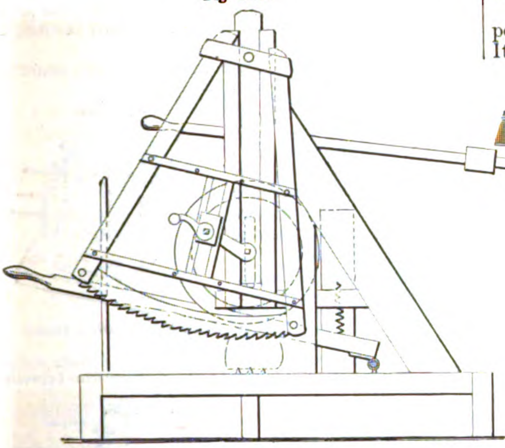
3. Plows having no special mold-board, and in which the colter merely is shifted so as to loosen the furrow slice on that side to induce it to tip over on the other as the share lifts it.

The object is to enable the team to return in and alongside the furrow last made, — an object which is especially desirable in plowing steep hillsides where the furrow can only be thrown *down* hill. See HILLSIDE-PLOW; TURN-WREST PLOW.

Swing-nose Ba'sin-fau'cet. A faucet for standing washbowls. The water is turned on or off by rotating the spout on its vertical axis. In the example, the tube answers the fourfold purpose

of handle, plug, cap, and outlet. The hub is screwed

Fig. 6124.

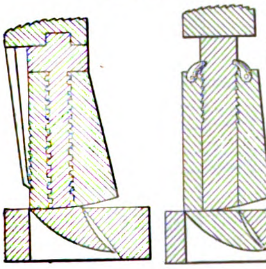


Swinging-Saw.

and packed upon the stand-pipe, upon whose top its valve is compressed to close the outlet.

Swing-pan. (*Sugar-making.*) (Fr. *Chaudière à bascule.*) A hinged sugar-pan with a spout. When the sirup is to be discharged, the pan is tipped by lifting one edge.

Fig. 6125.



Swing-Jack.

Swing-plow. 1. A turn-wrest plow. See HILLSIDE-PLOW.

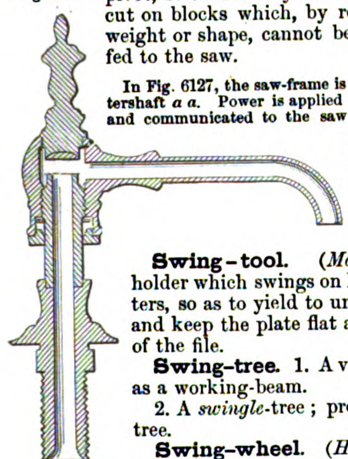
2. A plow without a gage-wheel. See PLOW.

Swing-press. A form of baling-press in which the box is suspended from above by a screw on which it winds as it is rotated. See Fig. 4744, page 2070.

Swing-saw. A buzz-saw hung on a pivot, so that it may be swung down to cut on blocks which, by reason of their weight or shape, cannot be conveniently fed to the saw.

In Fig. 6127, the saw-frame is pivoted by countershaft *a a*. Power is applied at the pulley *b*, and communicated to the saw through a belt from *c* to *d*. The saw is thus free to swing through an arc of about 70°, and is equally operative at all points of the arc.

Fig. 6126.



Swing-Nose Basin-Faucet.

Swing-tool. (*Machinery.*) A holder which swings on horizontal centers, so as to yield to unequal pressure and keep the plate flat against the face of the file.

Swing-tree. 1. A vibrating beam, as a working-beam.

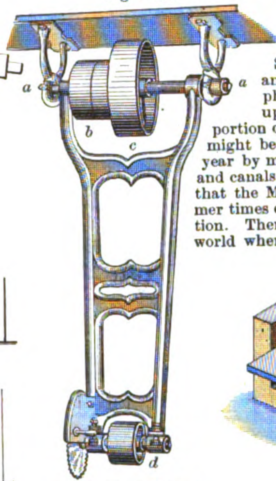
2. A *swingle*-tree; preferably *single*-tree.

Swing-wheel. (*Horology.*) The balance-wheel of a watch.

Swing-wheel File. (*Watchmaking.*) A file for dressing out the openings in the steel disk from which a balance-wheel is made. A *cross-file*.

Swipe. A water-elevator; the well-known well-pole and bucket. Known also as a swipe or SHADÛF. It was common in ancient Egypt, as in the modern; also in the country watered by the Tigris and Euphrates.

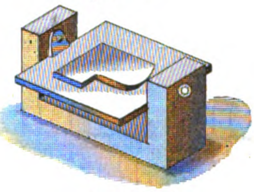
Fig. 6127.



Swing Cut-Off Saw.

So abundant is the supply and rapid the fall of the Euphrates and Tigris in their upper course, that the greater portion of the intervening country might be supplied during the whole year by means of dams at intervals, and canals. It was by careful method that the Mesopotamian Valley in former times carried such a large population. There is perhaps no part of the world where remain the evidences of

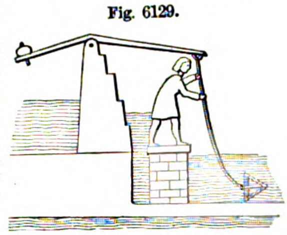
Fig. 6128.



Swing-Tool.

such a large population to the territory. For instance, in the tract of country between the Tigris and the upper Zab, which, says Rawlinson, is the only part of Assyria that has been strictly examined, are distinct remains of an Assyrian canal which has been carried through the more elevated ground by tunneling, and has been led for eight miles in a direction contrary to every other stream in the district. Sluices and dams regulated the supply. The hand-swipe, or *shadûf*, carried the supply to still higher levels. See SWAPE; SHADOOF.

Fig. 6129.



Swipe on the Tigris (Ancient Assyria).

Swip'le. The beating end of a flail.

Swiss Mus'lin. (*Fabric.*) A fine, open, transparent cotton goods.

Switch. 1. (*Railway.*) The movable rails which connect one line of rails with another.

Switches are known as *stub*-switches and *split*-switches.

In the *stub*-switch the switch-rail has square butted ends, as at *A*, Fig. 6130. The switch-rails require to be moved in direct apposition, or a train running in direction *a b* on rails *a a* would run off the track, were the switch-rails *b b* in connection with the siding, as shown.

In the *split*-switch, *B C*, the switch-rail is pointed, and somewhat automatic. *B* shows it as applied to a main track and siding; *C*, to three tracks, with either of which it may be made to coincide. A train on either of the tracks *c c c* will force over the switch, so as to run on to the main track *d*. A train going in the direction *d c* will run upon such one of the rails *c c c* as may at the time be adjusted in connection by means of the switches.

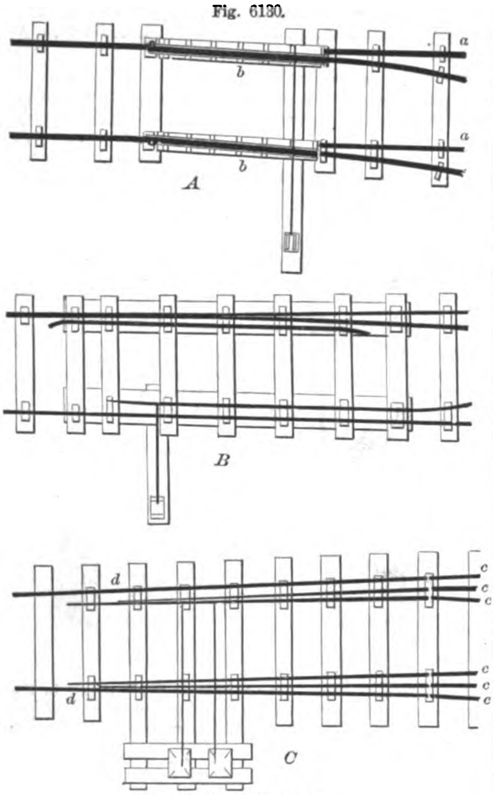
A Y-switch consists of a simple divergent track, which does not again run into the main track.

Switches have been designed to be set in motion by the approaching engine, the object being to restore the main-line connection when a switch has been carelessly left open to a siding. The idea has not been acceptable.

A *portable* switch is one which affords a temporary passage from one track to another, bridging the inside rails.

2. (*Telegraphy.*) A device for connecting one circuit with another, or for dividing a circuit into

Fig. 6130.



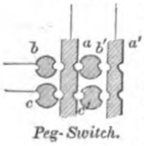
Railway-Switches.

two parts, or, in short, for altering any of the connections of a line or circuit. The ordinary *ground* or *lever* switch is a small metallic strip pivoted at one end, the pivot being connected by a wire to one portion of an electrical circuit. The other end of the strap can be turned to rest on an anvil or bed connected with the line desired to be brought into circuit.

The *plug*-switch is one made of pieces of metal connected each to its appropriate wire or part of circuit, but slightly separated from each other, so that the insertion of a plug or pin in the interval between them connects them.

Fig. 6131 illustrates the *peg-switch*. *a a'* are vertical notched bars, the first being connected with the line wire entering a station, and the second with the wire going out. *b b'*, *c c'* are metallic buttons to which are connected the instrument wires; all the buttons on the same horizontal line are connected together at the back of the switch. The cut shows the circuit open. To close it, with the office instrument in circuit, metal pegs are inserted in the orifices at *a b* and *a' c'*, causing the current to flow through *a b* to the instrument, and thence through *c' a'* to the main line. If desired to send through circuit without connecting the instrument, a peg is inserted only at *b' a'* or *c' a'*. By a modification of the connections, this form is adapted for a terminal station.

Fig. 6131.



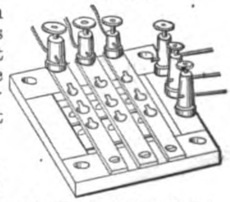
Peg-Switch.

By this means also any desired amount of battery power may be applied to one or more circuits by simply inserting metallic pegs in a graduated scale. Every new position in which the peg is placed changes the number of cups brought into connection with that particular line. The same apparatus is also arranged with spring catches, to enable the chief operator to make a connecting loop with any line, or to join two or more lines together by inserting metallic clips connected with the loop lines into the catches. Each line has two catches, and each will hold four clips, so that eight messages may be taken from one line at once. By joining other circuits with these, a still larger number of copies may be made of any one message. This system of switches enables the chief operator to place himself in connection with any wire, and to study the work of the operator without his knowledge. The apparatus is so simple and compact that the wires for several hundred lines may be brought within easy reach of one operator.

3. A key on a gas-burner to regulate the amount of gas passing, and, consequently, the light.

Switch-board. An aggregation of switches upon one base, so that any instrument in an office may be connected with any wire or any battery, or cut out altogether.

Fig. 6132.

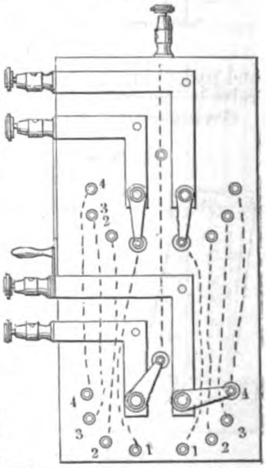


Telegraphic Switch-Board.

Fig. 6132 represents a switch-board made of wooden strips (non-conducting) and metallic strips (conducting), so joined in the shape of a frame as to bring the longitudinal metallic strips and the lateral metallic strips across each other for the purpose of making connections between them.

In Fig. 6133, the switch buttons are arranged in pairs corresponding to the number of batteries employed, including the buttons of each pole of a battery in one pair. The battery-pole and its button are connected by a wire.

Fig. 6133.



Telegraph-Battery Switch-Board.

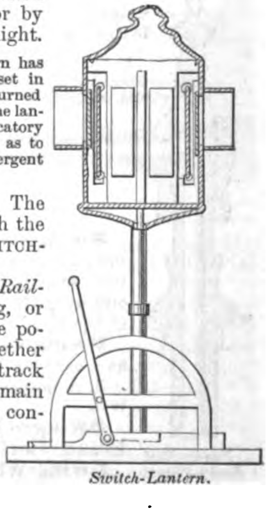
Switch'ing-en'gine. A *yard*-engine, or *donkey*-engine, used about a station or depot for making up trains or moving engines which have not steam up.

In Europe, tank-engines are commonly used, rendering unnecessary the tender which carries the water and fuel for the longer journeys of the usual locomotive duty. The European locomotive-engines for switching purposes have box frames made of wrought-iron plates made water-tight, and used to carry the water required by the engine. See TANK-LOCOMOTIVE.

Switch-lan'tern. A lantern on the lever of a railway-switch, to indicate the condition of the switch either by its position or by the display of a colored light.

In the example, the lantern has glasses of different colors set in tubes, so that only the one turned directly in front is visible. The lantern is rotated by the reciprocatory motion of the switch-bar so as to indicate which of several divergent tracks is open.

Fig. 6134.



Switch-Lantern.

Switch-lev'er. The handle and bar by which the switch is moved. See SWITCH-STAND.

Switch-sig'nal. (*Railway.*) A lantern, flag, or signboard indicating the position of a switch, whether open to the main or side track or to one of several main tracks. It is frequently constructed so as to be set by the motion of the switch, certain lights or

signals indicating the respective switches. See SWITCH-LANTERN.

In the example, the ends of the switch-rails lie in the recess beneath the tread, so that the flange of the wheel does not come in contact therewith. The counter weight restores the switch to position after movement. The switch-lever shaft is connected by cog gearing with the turning signal-shaft.

Fig. 6135.

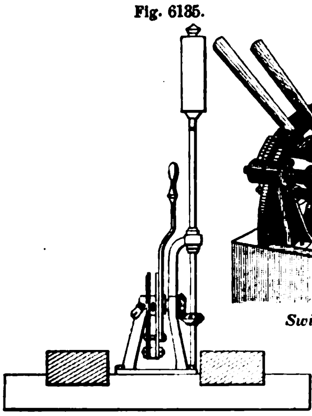


Fig. 6136.

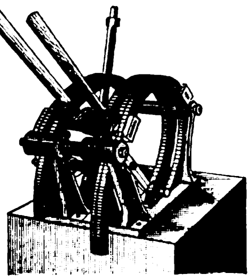
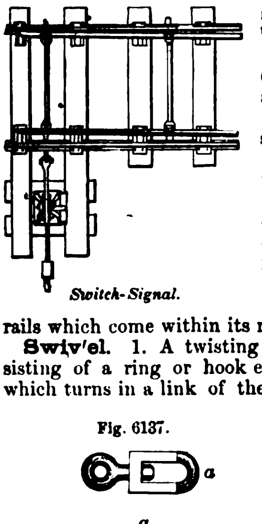


Switch-Stand.

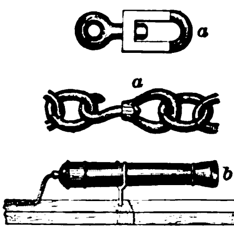


Switch-Signal.

Switch-stand. (*Railway.*) A fulcrum and locking-device for the levers whereby switch-rails are moved. The levers move in slots in arc-shaped guides, which latter have notches to hold the levers in certain positions which indicate the apposition of the switch-rails with one or another line of rails which come within its range of adaptation.

Swiv'el. 1. A twisting link *a* in a chain consisting of a ring or hook ending in a headed pin which turns in a link of the chain. The object is to avoid *kinking.*

Fig. 6137.



Swivels.

2. A small cannon *b*, whose trunnions are placed in a carrier, which is pivoted in a socket, so that by the two adjustments the gun may be pointed in any direction. A pivot-gun. See page 1722.

3. (*Nautical.*) A rest, having adjustment in azimuth, for supporting a small piece of ordnance on the gunwale of a boat or vessel.

4. (*Saddlery.*) A loop or runner through which the check-rein passes.

Swiv'el-bridge. A bridge which rotates on an axis, moving in a horizontal plane. See SWING-BRIDGE; PIVOT-BRIDGE.

Swiv'el-gun. (*Ordnance.*) One mounted on a pivot to traverse horizontally in a circle. See PIVOT-GUN, page 1722.

Swiv'el-hang'er. A form of shaft-hanger invented by Edward Bancroft, R. I., in which, to ensure the weight of the shaft being received over the entire length of the box, he hung the box on a universal joint, and made its axis of vibration coincide with the center of the box. This permitted the use of longer boxes than were before practicable, and the pressure per square inch on the surface was lessened.

Swiv'el-hook. (*Nautical.*) A turning hook strapped to a tackle-block.

Swiv'el-hook Block. A pulley block in which the suspending hook is swiveled to the block, so that the latter may turn to present the sheave in any direction.

Swiv'el-joint. A section in a chain or a joint on a rod, which allows the parts to twist without kinking or distortion.

Swiv'el-loom. A kind of loom (formerly) used for the weaving of tapes and narrow goods.

Swiv'el-plow. A plow having its land-side, sole, and mold-board on an axis, so that the combined portions may be turned over to throw the furrow to the right or to the left. Known in England as a *turn-wrest* plow; in the United States as a SIDE-HILL PLOW (which see). See also TURN-WREST PLOW, the British name for the implement.

Sword. 1. A cut and thrust weapon. Its use is of a very remote antiquity, dating as far back as the bronze age. Stone is not adapted for weapons of this kind, and they have not been found among the relics of peoples unacquainted with the use of metals. Artificers in flint could produce nothing better than a short knife. Swords of iron were made by the Chinese, 1879 B. C. This was about the era of Isaac, and three centuries before Cecrops.

Herodotus speaks of an "antique iron sword" as planted on the top of the mound of worship, used by the Scythians. The position was *phallic*, a form of deification familiar to that whole region. The sword found in the great tomb of Kertch was of iron. Their weapons, however, were usually of bronze.

The swords of the bronze age are always more or less leaf-like in shape, double-edged, sharp-pointed, and intended for stabbing and thrusting rather than for cutting. They have no hand-guards. (LUBBOCK.) *a* is an ancient iron sword, introduced to show the difference in shape. *e* to *k* have solid handles. *b c d* have thin handles intended to have *scales* of wood to round out the hand-hold. The handles are short, and are adapted for the use of a smaller-handed people than the present inhabitants of the lands where these specimens were gathered. *a* is an iron sword from a Saxon tomb, England; *b*, bronze sword from Ireland; *c*, from Sweden; *e*, Switzerland; *f*, Neufchatel; *g*, Scandinavia; *g h i j k*, Denmark.

For the sake of comparison are added: —
l m, spear-heads from Ireland
n o, Irish bronze daggers.
p q, bronze knives from Switzerland.
r, bronze razor-knife from Denmark.

The Egyptian sword was straight and short, from 2½ to 3 feet in length, having a double edge and a sharp point. It was used, as the monuments show, for cut, thrust, or as a dagger. The handle was hollowed in the center, increasing in thickness toward each end, and the end was surmounted by an emblem, such as a hawk's head or the symbol of Phrah.

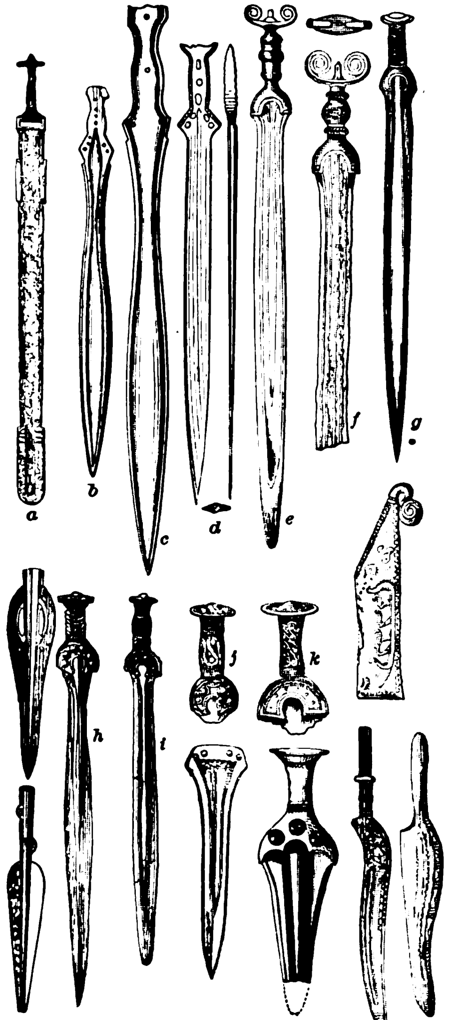
Ages ago the superiority of Damascus blades was proverbial. They were very thin, took an exceedingly keen edge, and were so elastic that they could be bent into a circle without retaining a permanent set. Their surface exhibited a series of fine wavy and spiral lines, which were apparently removed by grinding, but restored by the application of acids. From this circumstance it is inferred that they were, like their modern imitations, made by welding together thin laminæ or wires of iron and steel. The art is said to have been lost to Damascus when it was taken by Tamerlane, who carried away the artificers; and though swords are still made there, they do not enjoy the reputation which tradition assigns to those of the ancient manufacture. See DAMASK; STEEL.

When, A. D. 802, Nicephorus, son of Irene of Byzantium, attempted to throw off the yoke of the Saracens, he sent a letter to the Khalif Haroun al Raschid, in which, alluding to the game of chess, he said, "The queen considered you as a rook, and herself as a pawn," and accompanied the letter with a bundle of swords, which his messengers threw down at the foot of the throne. The Khalif smiled, and drawing his scimeter (*samsamah*), cut asunder the Greek swords before him; then dictated this answer: —

"In the name of the most merciful God! Haroun al Raschid, Commander of the Faithful, to Nicephorus, the Roman dog. I have read thy letter, O thou son of an unbelieving mother. Thou shalt not hear, thou shalt behold my reply."

He ravaged Asia Minor at the head of 800,000 soldiers, and

Fig. 6138.



Ancient Swords, etc.

dictated a humiliating peace. About this time Charlemagne was subduing the Slavi of the Elbe and the Avars of Hungary. The king of the Franks at Aix-la-Chapelle received from the great Haroun of Bagdad presents, consisting of the keys of the holy sepulcher, a consecrated standard of Jerusalem, a wheel-clock that struck the hours, an organ, an ape, and an elephant.

Scott, in the "Tales of the Crusaders," describes a meeting between Richard Cœur de Lion and Saladin. Saladin asks Richard to show him the strength for which he is famous, and the Norman monarch responds by severing a bar of iron which lies on the floor of his tent. Saladin says, "I cannot do that," but he takes a down pillow from the sofa, and, drawing his keen blade across it, it falls in two pieces. Richard says: "This is the black art; it is magic; it is the Devil; you cannot cut that which has no resistance." And Saladin, to show him that such is not the case, takes from his shoulders a scarf which is so light that it almost floats in the air, and, tossing it up, severs it before it can descend. George Thompson states that he saw a man in Calcutta throw a handful of floss silk into the air, and a Hindoo sever it into pieces with his saber.

Europe wondered much at the gorgeous profusion of the Orient, and even the "brand *Excalibur*" must have been of Eastern make, —

> "My brand Excalibur
> Which was my pride"
>
> "For all the haft twinkled with diamond sparks,
> Myriads of topaz-light, and jacinth-work
> Of subtlest jewelry."

No wonder Sir Bedivere coveted the sword of this old British chief and hid it "in the many-knotted water-flags," as related in the chronicle of the old harper who is always a little below concert pitch.

The famous sword of Orlando was said to have been the work of the fairies, and its name *Durandal* (*dur en diable*, "as hard as the devil") is indicative of its origin, and accounts for the fact (?) that he was able to cleave the Pyrenees with it. It was also called *Durandarte*, *Durindana*, *Durlindana*.

Curtana was another famous sword of Orlando. Its name was given to the "first royal sword" of England from a very early period; in the wardrobe accounts for 1488 it is so designated.

Morglay (*glaive de la mort*) was the sword of Sir Bevis of Southampton.

Tizona was the famous sword of the Cid.

Andrea Ferrara, so long believed to be the name of a celebrated Italian sword-maker, must be given up. *Andrea* is only an occasional prefix, and *Ferrara* is most probably a corruption of *ferrarium*, a weapon-smith, or cutler.

The Lord Mayor of London used to bear three swords, — a *common*, a *Sunday*, and a *pearl* sword. These were *not* famous in chivalric records.

Japanese officials of a certain grade wear two swords, the hilts projecting out a foot in front of the person of the wearer. One of them is a heavy, two-handed weapon, pointed, and sharp as a razor; the other short, like a Roman sword, and kept in the same serviceable state.

Swords and sabers have a *blade*, either straight or curved, with a *tang*, which is inserted into a spindle-shaped piece of wood, covered with leather, and wrapped around with brass wire; these form the *gripe*, which, with the brass knob at the end called the *pommel*, constitutes the *hilt*. The hand is protected by the *guard*, which is a curved piece of metal, consisting of from one to three branches, and usually provided with a broad plate of metal, the guard-plate, at the point where it is attached to the blade.

The scabbard is the case, usually of leather or steel, into which the blade is inserted.

The blade of a sword consists of: The *tang*, which enters the hilt; the *shoulder*, which abuts against the end of the hilt; the *forte*, the half of the blade nearest the hilt; the *faible*, or *foible*, the half part nearest the point; the *point*; the *back*; the *flat*; the *edge*.

The hilt consists of (the parts varying in different kinds of swords): The *pommel*, or back piece; the *gripe*; the *bars* of the basket, in sabers; the *stool*, or *guard*-plate; the *bow*, in sergeants' swords and horse-artillery sabers; the *cross*, as in the old Highland claymore; the *linguets*, in foils and rapiers.

The successive operations in sword-making are forging, hammering, swaging, hardening, tempering, setting, grinding, glazing, hilting, and proving.

In the process of making swords, as practiced at the factories, pieces of Sheffield steel called *double molds*, each of the length of two blades, the ends for the tangs being of iron, are employed. These are cut or broken in the middle, the tangs are forged first, and afterward the blade. the furrow or furrows being formed at the same time. Twenty-five reheatings are required for this purpose. The blade is then heated and plunged into cold water, rendering the metal extremely brittle; again heated, and the distortions caused by the hardening corrected by rehammering, when it is again heated till its surface assumes the proper color, of which the workman is the judge, to insure its having the due hardness and flexibility when tempered, which is done by plunging it at this stage into cold water.

It is next ground. The stones employed for finishing the furrows have raised flutings suited to the furrows of the particular kind of blade to be operated on.

The polishing is performed upon wheels of various sizes, with lard-oil and flour of emery, the blade being frequently dipped into lime-dust during the operation. A brush-wheel, sprinkled with fine crocus-powder, imparts the final polish. The scabbards, if of metal, the hilts, and other metallic parts are treated in like manner.

In making the metallic scabbard, a piece of sheet-steel is laid over the top of an open vise, and beaten with a wedge-shaped wooden mallet, causing the edges to approach each other. The sides are then beaten on each side until the edges nearly unite, and the scabbard is slipped upon a mandrel and hammered until the joint is closed; it is then soldered, and the tip, or *drag*, and the bands are put on.

The *gripe*, or handle, is made of walnut, with a metallic strip at the back; it is shaped by files, a tenon for the ferrule made at the end, and *balled*, that is, surrounded with grooves, by means of a triangular file; the edges of these grooves being afterward rounded, or "balled," with another file. It is then drilled in a lathe, with a longitudinal hole for the tang, after which it is covered with dogfish-skin, secured by winding cord or wire around the gripe in the grooves between the balls.

The hilt, or guard, is cut from sheet-metal, and hammered into shape, then polished, and finally fixed to the sword. This operation is called mounting.

Sword-blades, resembling those of Damascus, are made at Solingen, in Germany. A fagot is first formed of alternate fine bars of iron and steel. It is drawn out, doubled, and twisted several times, and then formed into a ribbon. Two such rib-

bons are welded together, inclosing between them a thin blade of the best-cutting English steel. After polishing it, it is dipped in diluted sulphuric acid, to give it a pattern.

Sword-blades, resembling in appearance the Oriental blades, and equal to them in quality, have been made in Germany, by the process of Prof. Crevilli, of Milan.

"A long, flat piece of malleable steel, 1½ inches in breadth and ¼ inch in thickness, is first bound with iron wire, at intervals of ½ inch. The iron and steel are then incorporated by welding, and repeated additions (10 to 20) of iron wire made to the forging, in the same manner as the first. The forging is then stretched, doubled, and welded; and the process is repeated as often as may be desired, when the material is brought to the shape required by the hammer on the anvil.

"By filing semicircular grooves on both sides of the blade, and again subjecting it to the hammer, a beautiful rosette-shaped damask is obtained. By special manipulation the pattern may be made to assume other forms. The pattern is brought out by the application of aqua fortis and vinegar. An idea of the extraordinary tenacity of these blades may be formed from the fact, that out of 210 blades examined by a military commission, and each of which was required to bear three cuts against iron and two against a flat wooden table, not a single one snapped or had its edge indented." (See WOOTZ; DAMASKEENING.)

2. (*Weaving.*) One of the bars dependent from the *rocking-tree* and supporting the *lay*.

3. The scutching-blade of the flax-dresser. See SCUTCHER.

Sword-bay'o-net. A bayonet with a blade like a sword, and capable of being detached from the barrel and used like a sword.

Sword-belt. The waist-belt from which a sword is slung.

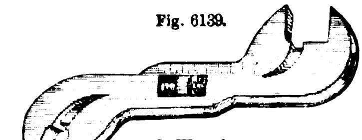
Sword-cane. A cane with a concealed sword.

Sword-knot. A knotted ribbon on a sword-hilt.

S-wrench. A spanner or wrench of an S-shape, to enable it to reach parts not so readily approached by the ordinary monkey-wrench. It has two jaws of different angles, and an adjusting screw in the stock.

In Fig. 6139, the respective pairs of jaws are operated by a right and left screw and thumb-piece. Scales are placed on the

Fig. 6139.



S-Wrench.

respective halves, which have a motion on each other, each piece having an inner and outer jaw of the respective pairs.

Sym'bol-print'ing. (*Telegraphy.*) A system of printing in dots and marks (see MORSE ALPHABET) or other cipher, as distinct from printing in the usual Roman letter. (See PRINTING-TELEGRAPH.) The *dots* and *dashes* of the Morse, or similar system, may be produced by pressure on, or penetration of the paper (Morse), or by a chemical action at the point of contact of the styles (Bain), or the passage of the electric current.

Sym'pa-thet'ic Ink. A colorless ink, the writing made with which is made visible by a subsequent operation, — warmth, or other reacting stimulant. See INK, page 1187.

Sym-phys'e-o-tome. (*Surgical.*) Fr. *Couteau symphysien.* A knife used in operation of the division of the *symphysis pubis* to enable the pelvis to open and permit delivery; the *Sigaultian section.*

Sym'pi-e-som'e-ter. Invented by Mr. Adie of Edinburgh. It consists of a column of oil supported by atmospheric pressure, and rising, not like the mercury of the barometer into a vacuum, but against a body of hydrogen gas, which acts like a spring against the column of oil; and as the elasticity of the hydrogen varies with every change of temperature, a movable thermometer-scale is attached for making the necessary corrections.

The glass tube *b* is about 18 inches in length and $\frac{7}{100}$ of an inch in internal diameter. At the upper extremity is a cylindrical vessel *a*, 2 or 3 inches long and half an inch in internal diameter. The lower extremity is turned upward, and terminates in a vessel *c*. The hydrogen is contained in the space *b a*, and the oil, colored red with alkanet, occupies the space between *b c*.

The sympiesometer is graduated by placing it together with a standard barometer and thermometer in a glass vessel, in which the pressure of the air can be varied at pleasure. The top of the column is marked at the points where the barometer shows 27, 28, 29, 30, 31 inches respectively. The spaces between the marks, coinciding with the inches of mercury, are then subdivided into 100 equal parts each, and the great range makes the instrument valuable for recording minute variations, subject to correction, depending on the variation in the volume of the hydrogen due to changes of the temperature. A graduated sliding scale assists in reaching the corrected result.

Fig. 6141 is another form of the instrument.

Fig. 6140.

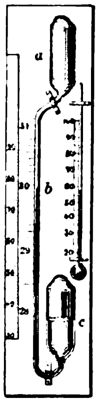


Fig. 6141.

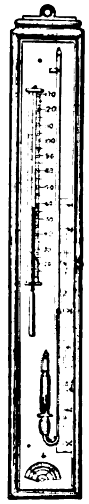


Sympiesometers.

Syn-cli'nal Line. (*Mining Engineering.*) The axis of valley curvature of strata, at which the beds which are tilted in opposite directions are supposed to meet. Opposed to *anti-clinal.*

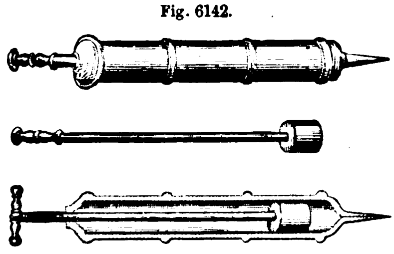
Syn-os'te-o-tome. (*Surgical.*) A dismembering-knife.

Sy'pher-ing. (*Shipwrighting.*) Lapping the chamfered edge of one plank over the similarly chamfered edge of another, so as to form a joint with a plane surface.

Sy'pher-joint. (*Carpentry.*) A lap joint for the edges of boards, leaving a flat or flush surface.

Sy'ren. See SIREN. See also "Tyndall on Sound," London, 1875, pages 61, 82, and frontispiece; also "London Engineer," January 21, 1876.

Fig. 6142.



Syringe, by Hero.

Syr'inge. 1. A small hand-pump for ejecting water. Well described by Hero in his "Spiritalia." He describes it for injecting a liquid, or, by an inverse operation, withdrawing pus from a wound. Fig. 6143 shows the squirts which formed a part of the horse-play of the carnivals and sports of the Middle Ages.

See under the following heads: —

Catarrhal syringe.
Catheter-syringe.
Condensing-syringe.
Ear-syringe.
Elastic-bulb syringe.
Enema-syringe.
Exhausting-syringe.
Eye-syringe.
Garden-syringe.
Hemorrhoidal syringe.
Hypodermic syringe.
Injection-syringe.
Ointment-syringe.
Penis-syringe.
Probe-syringe.
Squirt.
Transfusion-syringe.
Universal syringe.
Vaginal syringe.

2. (*Surgical.*)

Fig. 6143.

Squirts.

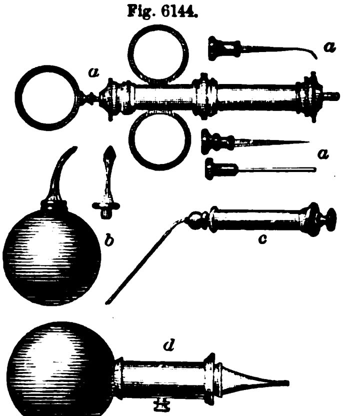
a. Anel's silver eye-syringe with silver and gold points.
b. Liebold's subpalpebral syringe.
c. McFarlan's lachrymal syringe.
d. Rubber-bag ear-syringe.

Clotworthy's syringe, August 24, 1875, has a removable nozzle over the rounded end of a vaginal syringe. It may be used for either sex.

Wheelock's, April 11, 1865, has orifices to discharge the liquid backwardly.

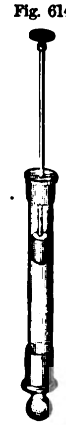
The pneumatic syringe is an instrument for illustrating the compressibility of gases. It consists of a strong glass tube hav-

Fig. 6144.



Syringe.

Fig. 6145.



Pneumatic Syringe.

ing a tightly fitting piston, which, on being forced down, compresses the gas into a bulb proportional to the amount of pressure applied.

Reed's syringe for cattle is used for injecting medicine, or as a stomach-pump. It does not differ materially except in size from the ordinary surgical apparatus for an analogous purpose. When used as an injector, the induction end of the syringe is plunged in a bucket containing the medicament, and the injection-tube is introduced through the esophagus into the paunch, to which the medicine is directed. When used to relieve a distended paunch, the long tube is secured to the induction end of the syringe, and the fermenting pultaceous mixture and gas are ejected at the side of the cylinder.

Syr'inge-case. A box for the compact stowage of the surgical syringe. The injecting-tubes rest in the notches of a tray, which has an aperture to allow the projection of the upper part of the bulb.

Syr'inge-en'gine. One used as a fire-engine some centuries since.

Syr'inge-valve. A peculiarly constructed valve used in syringes. The valve-guide stem has an end knob, by which its falling out is prevented.

Syr-ing'o-tome. (*Surgical.*) A bistoury, concave on its edge, and terminated by a long, flexible, probe-pointed stylet. Formerly used for *fistula in ano*, by incision.

Syr'inx. (*Music.*) A wind-instrument, consisting of a row of parallel reeds of varying lengths, and played by blowing into their open, upper ends. Their varying lengths determine their pitch. The usual number was seven, but some are found having from three to nine.

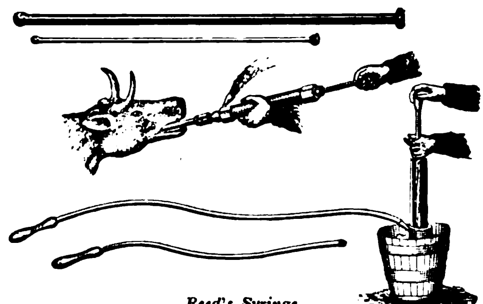
Probably the *ugab* of the Hebrew Bible, which in our version is rendered *organ*. The *sumphonia* of the Hebrew (*zampogna* is the Italian bagpipe) was probably a syrinx with bellows, — the rudimentary organ.

The pandean pipes, eight in a row, and of graduated lengths, are shown on old monuments and gems.

A syrinx with bellows is shown on one of the ancient terra-cotta exhumed at Tarsus, Asia Minor. It is supposed to be 2,000 years old, as coins of the second century B. C. were imbedded in the earth in its vicinity.

The Peruvians had a syrinx with eight pipes. One specimen of the instrument was about four inches wide, the longest

Fig. 6146.



Reed's Syringe.

pipe having also about that length. They were made of cane or stone. The one above referred to was made of a talcose stone, and was peculiarly ornamented. It was found on the breast of a skeleton in one of the *huacas*, or Peruvian tombs. Four of the tubes had lateral finger-holes, by stopping which the tones were lowered a semitone. It appears to have been called the *huayra-puhura*, whatever that may mean. It had one more pipe than the classical or the modern instrument.

Fig. 6147.

Syringe-Engine.

The *syrinx* is shown in English MS. of the ninth and tenth centuries. In one of the eleventh century, the tubes are inserted in a boat-shaped box.

The syrinx was used by the Romans as a noisy improvement on hissing, in condemning bad actors; the English *cat-call* and the American *whistle* are its legitimate successors. The occupants of our peanut galleries, however, use it indiscriminately for praise or blame.

It may be said of them, as Quince the carpenter says of Pyramus, —

"He goes but to see a noise."

Syr'up-stand. See SIRUP-STAND.

T.

Tab. 1. (*Fulling.*) One of the revolving arms which lift the beaters of a fulling-mill.

2. (*Shoe.*) A latchet or flap of a shoe or half-boot, formerly fastened with a buckle, of late by a string.

3. The metallic binding on the end of a shoe or corset lace. A *tag.*

Tab-a-ret′. (*Fabric.*) A stout, satin-striped silk goods.

Tab′by. (*Fabric.*) Silk or other stuff having an irregularly waved or watered surface produced by pressure, usually between engraved rollers in the mode of calendering, known as *tabbying.* There is but little difference between *tabbying, watering,* and *moiré,* the effect in each case being produced by the flattening of some of the fibers while the others remain undisturbed, causing the different parts to reflect the light unequally.

"My false taby wastecote with gold lace." — PEPYS, 1661.

Tab′by-ing. Passing fabrics between engraved rollers to confer a wavy or watered appearance. Analogous to *watering,* or *moiré.* See TABBY.

Tab′er-na-cle. (*Nautical.*) An elevated socket for a boat's mast; or a projecting post to which a mast may be hinged when it is fitted for lowering to pass beneath bridges.

Tab-i-net′. (*Fabric.*) A goods of silk and wool, adapted for window-curtains.

Ta′ble. 1. (*Furniture.*) A piece of furniture on which viands or work is placed, so as to be readily reached by persons sitting adjacent thereto.

Tables are known by size, shape, construction, material, purpose, etc., as,

Card,	Dining-room,	Self-waiting,
Carving,	Extension,	Steam-heated,
Center,	Folding,	Toilet,
Chess,	Ironing,	Work, etc.

The Egyptians used chairs and tables in what we consider the regular civilized way; neither reclining on couches, as in the lazy way of the later Romans, nor squatting on a rug, as the modern Oriental. Their tables were supported by central stems or by legs, the latter terminating in carved feet like those of lions or dogs. They were of metal, stone, wood, or ivory; were carved, painted, and gilded; square, round, or oblong.

The annexed cut shows one with a central post, where

Fig. 6148.

Egyptian Table (*from Wilkinson*).

Fig. 6149.

Egyptian Table (*from Salt's Collection*).

the figure of a captive forms the shaft, and a flat base the foot.

Fig. 6149 is a table in the collection of Mr. Salt, and is inlaid with ornaments of vines and the peculiar serpent figure that is represented in connection with wine. Possibly to suggest that it "stingeth like an adder," as they were fond of moralizing at their feasts.

The Romans used three-legged, four-legged, and central-stem tables (*monopodium*); also semicircular, lunette, and S-shaped tables (*sigmata*). Tablecloths do not appear to have been used by the Greeks or Romans.

A revolving table, to present the viands to the guests in rotation, was used in Varro's villa at Casinum.

For ancient tables, see Fosbroke's "Ency. Antiq.," I. 380 *et seq.*

2. (*Glass-making.*) *a.* The flat disk of crown glass which is made from a bulb on the end of a *blowing-tube,* transferred to a *ponty,* gradually and finally *flashed* into a disk by rotating in front of a FLASHING-FURNACE (which see).

b. The flat plate with a raised rim, on which plate glass is formed. See Fig. 1181.

3. A chess or backgammon board.

4. (*Diamond-cutting.*) *a.* A form of diamond-cutting. The top of the stone is ground flat with a corresponding flat bottom of less area, with its four upper and lower faucets cut parallel to each other. See DIAMOND-CUTTING.

b. The upper flat surface of a brilliant cut diamond; the zone facets around it are known as the *bizet.* The lower flat face, the *collet,* which converts the *culasse* into a truncated pyramid, is $\frac{1}{5}$ of the size of the table, and parallel therewith. See BRILLIANT.

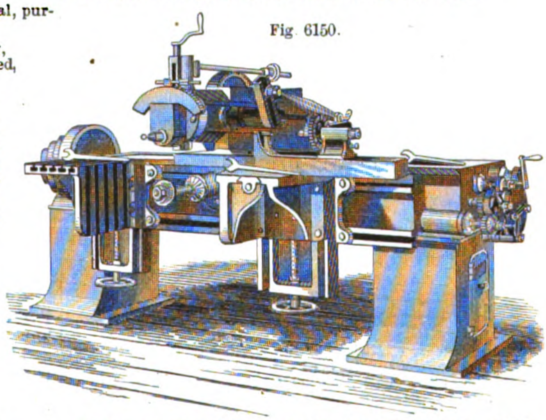
5. (*Architecture.*) *a.* A smooth, simple member or ornament of various forms, but most usually in that of a long square.

b. Table or *tablet moldings,* horizontal bands or moldings, such as base-moldings, strings, cornices, etc.

6. A tablet. Formerly a board, slab, or leaf to contain writing. The term is nearly obsolete as a writing surface, but is still useful as indicating lists and calculations, generally in lines and columns.

7. (*Weaving.*) The board or bar in a draw-loom to which the tails of the harness are attached.

Fig. 6150.



Shaping-Machine (*N. Y. Steam-Engine Co.*), *with Two Tables.*

8. (*Machinery.*) The part on which work is placed to be operated upon; the term *bed* is also used to designate the large flat table of a planing-machine. Shaping-machines have single or double beds, the latter being lighter than one continuous one of equal reach, besides having an additional adjustability, as shown in the figure, where an object of irregular shape may be supported to present an accurately horizontal surface while it rests upon two tables of varying hights.

The shaping-machine shown in Fig. 6150 has a cutting-bar with 16 inches stroke, and the head has a traverse of 6 feet, with quick return-motion. The stroke is adjustable to anything less than 16 inches. It has two tables for holding work, both of which are movable up and down by screw and hand-wheel, and longitudinally by means of rack and pinion, with ratchet-lever.

Fig. 6151.

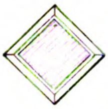


Table-Diamond.

Ta'ble-an'vil. A small anvil adapted to be screwed to a table for bending plates of metal or wires, making small repairs, etc. See STAKE.

Ta'ble-di'a-mond. (*Diamond-cutting.*) *Table-cutting* is adopted with flat, thin gems, which have not sufficient protuberance to be cut as *rose diamonds* or brilliants.

Ta'ble-fork.

The table-fork is a modern invention. Many centuries before its common use the article was known. It appears to have been a matter of taste and cleanliness with some persons in Constantinople as early as the eleventh century. One of silver, from a ruin on the Via Appia, is engraved by Caylus, as a classical antique. They are stated to have been brought from China to Italy, where, in Coryatt's time, they were of silver, iron, and steel, and used by gentlemen. They are mentioned in a charter of Ferdinand I., king of Spain, A. D. 1101, and in the wardrobe accounts of Edward I. of England. See also FORK.

Forks are made from rods of steel, about ⅜ inch square. The tang and shank are first roughly formed, and cut off with about an inch of the square rod, which is drawn out flat to the length of the prongs. The shank and tang are then heated and shaped by means of a die and swage. The flat part is then brought to a white heat and swaged between two corresponding dies, one on an anvil and the other upon the face of a drop-hammer, like that of a pile-driver, which is let fall from a hight of 7 or 8 feet; the thin film left between the prongs is afterward cut out with a fly-press. The forks are then annealed, their prongs filed, bent to the proper curve, reheated, hardened by plunging in cold water, and afterward tempered at the heat at which grease inflames.

Fig. 6152.

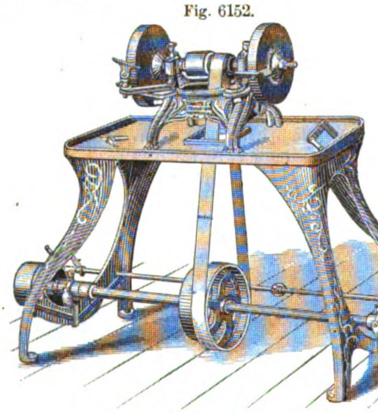

Table-Grinder.

Ta'ble-grind'er. A form of grinding-bench.

Ta'ble-knife.

Sharon Turner ("History of the Anglo-Saxons") observes, that "in all ancient pictures of eating, etc., knives are seen in the hands of the guests, but *no forks*." Their use at table was, no doubt, coeval with that of the table itself. Forks are of very modern introduction. Coryatt, in his "Crudities," published 1611, says: "I obserued a custome in all those Italian cities and townes through which I passed that is not vsed in any other country that I saw in my traules, neither doe I think that any other nation of Christendome doth vse it, but only Italy. The Italians and also most strangers that are commorant in Italy, doe alwaies at their meals vse a little forke when they cut their meate. For while with their knife, which they hold in one hand, they cut their meate out of the dish, they fasten their forke, which they hold in their other hand upon the same dish so that whosoever he be that sitting in the company of others at meate, shoul vnaduisedly touch the dish of meate with his fingers from which all others at the table doe cut, he will give occasion of offence unto the company as hauing transgressed the laws of good manners, in so much that for his error he shall be at least broue-beaten, if not reprehended in words."

Even when Heylin published his "Cosmography," 1652, they appear to have been a novelty in England, as, after speaking of the chopsticks used by the Chinese, he adds, "The use of silver forks, which is by some of our spruce gallants taken up of late, came from thence into Italy, and from thence into England."

In a curious class of knives of the sixteenth century, the blades have on one side the musical notes to the benediction of the table, or grace before meat, and on the other, the grace after meat. (See CARVING-KNIFE, page 492.)

The set of these knives usually consisted of four. They were kept in an upright case of stamped leather, and were placed before the singer, according to the adaptation of each part to the voice, indicated upon them.

In forming a table-knife, the blade is forged at the end of a bar of shear-steel, and then cut off. To it is then welded a piece of iron, which is shaped to form the bolster, shoulder, and tang. The bolster is formed between swages. The blade is then reheated and finished on the anvil, or smithed, as it is termed, stamped, tempered, and ground. The handle is then attached.

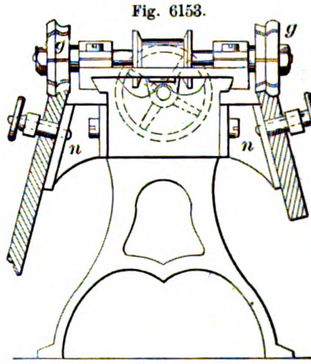
The manufacture of table-cutlery has of late years been introduced into this country, where a machine has been invented for forming knife-blades. This machine has been adopted in Europe.

Ta'ble-lathe. A small lathe attached by a clamp to a table and run by hand, or by a driving-wheel in a movable frame. See HAND-LATHE.

Ta'ble-leaf Joint. A peculiar form of furniture joint used in desk and table leaves, rules, and in some kinds of shutters. It has a molded edge, forming a *quarter-round*, the respective portions being *hollow* and *swelling*, so as to move on each other in manner of a knuckle-joint. The pintle occupies the position of the axis of the curved surfaces. Also known as a *rule*-joint.

Fig. 6153 shows a machine for planing the molding edges; the cutter-heads *g g* have the shape the converse of the one required on the material. The cutter-heads and mandrel are upon a sliding carriage, the work being dogged to the rests *n n*, whose inclination secures the proper presentation of the staff to the cutters.

Fig. 6153.

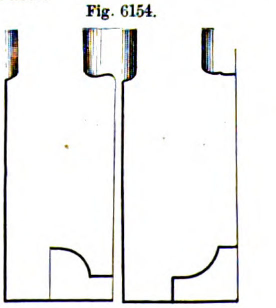


Machine for making Table-Leaf Joints.

Ta'ble-plane. (*Joinery.*) A furniture-maker's plane for making those joints on the flaps of table and side-boards called *rule-joints*.

The respective parts have *rounds* and *hollows*, and the planes are made in pairs, counterparts of each other.

Fig. 6154.



Pair of Table-Planes with Fence.

Fig. 6155.

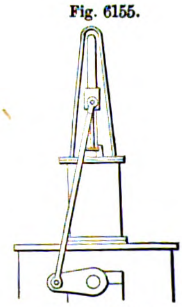


Table-Engine.

Ta'ble Steam-en'gine. A form of engine in which the cylinder is fixed upon a *table-like* base.

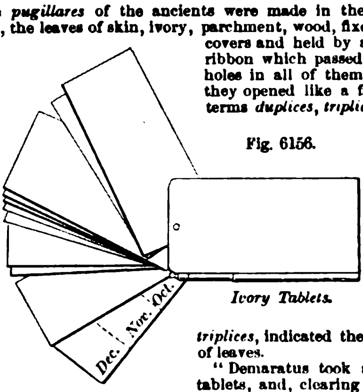
The piston-rod has a cross-head working in straight, slotted guides on the top of the cylinder, and is connected, by rods at each side, with two parallel cranks on the shaft under the *table*.

Tab'let. 1. (*Architecture.*) A coping on a wall or scarp.

2. A plate or slab for writing upon.

The *pugillares* of the ancients were made in the form of books, the leaves of skin, ivory, parchment, wood, fixed within covers and held by a wire or ribbon which passed through holes in all of them, so that they opened like a fan. The terms *duplices*, *triplices*, *quin-*

Fig. 6156.



Ivory Tablets.

triplices, indicated the number of leaves.

"Demaratus took a pair of tablets, and, clearing the wax away from them, wrote what the king [Xerxes] was purposing to do, upon the wood whereof the tablets were made; having done this, he spread once more the wax over the writing, and so sent it" — HERODOTUS, VII. 239.

Ivory is now commonly used.

Ta'bling. 1. (*Nautical.*) An additional thickness of canvas on portions of a sail exposed to chafing, or to strengthen the sail at certain points, as the edges.

2. (*Carpentry.*) A *coak* or tenon on the scarfed face of a timber, designed to occupy a counterpart recess or mortise in the chamfered face of a timber to which it is attached. See SCARF.

Ta'bor. (*Music.*) A small shallow drum used to accompany the pipe, and beaten by the fingers.

Tab'ou-ret. 1. An armless seat.

2. An embroidery frame.

Tab'ret. (*Music.*) A musical instrument of the small drum or tambourine class.

The word rendered *tabret* or *timbrel* in the King James version of the Bible is the *toph* of the Hebrew Scriptures; a word which is probably allied to *doff*, *diff*, or *adufe*, a small hand-drum of the East. The *toph* was evidently a tambourine or hand-drum, like the Egyptian *darabooka*, and is interesting in connection with the rejoicing of Miriam and the sad episode of the daughter of Jephthah.

Tache. A pan in a *battery* of sugar-pans.

All the pans in a battery are termed *taches*. The term is, however, often especially applied to the *smallest* of the five; that immediately over the fire from which the concentrated juice is transferred to the cooler, also called the *striking-tache*.

Ta-chom'e-ter. An instrument for measuring the velocity of moving bodies. Woltmann's, for measuring the speed of flowing liquids, has several spiral vanes on a shaft carrying an endless screw, which turns a series of geared wheels. On being placed in a current, the vanes assume a position perpendicular thereto, and their rotation actuates the clock-work mechanism which is graduated to indicate the velocity in miles per hour, or other units of measurement.

See SPEED-GAGE; SPEED-RECORDER; VELOCIMETER, etc.

Tack. 1. (*Nautical.*) *a.* The lower forward corner of a fore-and-aft sail.

b. The lower, weather corner of a *course*, or lower square-sail.

c. The rope by which the forward lower corner of a course or stay-sail is drawn forward and confined.

d. A rope by which the lower corner of a studding-sail is drawn outward and held to the boom.

2. *a.* A small, flat-headed, sharp-pointed nail. At the principal seat of the tack manufacture in England, it is not an uncommon feat for the workmen to forge 1,200 tacks so small as to be contained in the barrel of an ordinary goose-quill; their weight being about 24 grains. Tacks are known as *carpet*, *leathered*, *gimp*, *brush*, *broom*, *felting*. Their size is designated by the weight of 1,000, as 3 ounce, 6 ounce, 8 ounce, etc.

b. A short pin with a large flat head, used by draftsmen to hold a sheet of paper on the drawing-board; a *thumb-tack*; called also *drawing-pin*.

Tack-block. (*Nautical.*) A block for the tack of a sail. The studding-sail tack-blocks are at the ends of the booms.

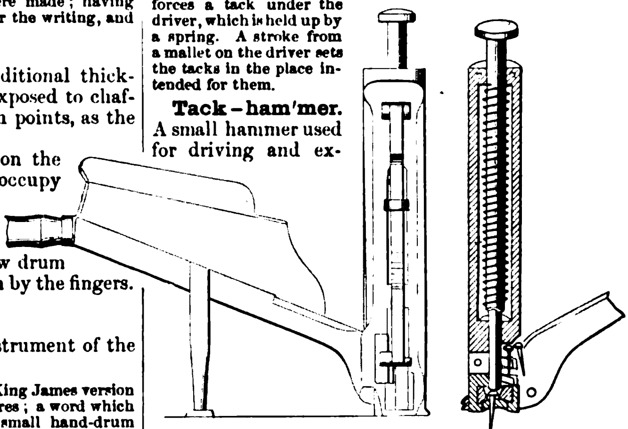
Tack-claw. (*Saddlery.*) A bifurcated tool for drawing tacks. It is especially used by saddlers and other workers in leather.

Tack-driv'er. 1. A tack-hammer.

2. A tool with devices for automatically presenting the tacks in succession, and driving them into place.

The example shows one which has an inclined plate serving as a hopper, by which the tacks fall into an inclined guide open at the bottom, which causes them to fall with their points downward. Two dies direct the tacks, and a slide forces a tack under the driver, which is held up by a spring. A stroke from a mallet on the driver sets the tacks in the place intended for them.

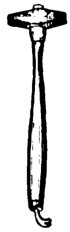
Fig. 6157.



Tack-Driver.

Tack-ham'mer. A small hammer used for driving and extracting tacks. The peen usually has either a thin edge, which may be inserted beneath the head of the tack, or is divided, to form a claw. In Fig. 6158 the claw is at the end of the handle.

Fig. 6158.



Tack-Hammer.

Tack'ing. 1. (*Metal-working.*) Uniting metallic pieces by drops of solder, to hold them in place until the solder is regularly applied to the joint.

2. Securing by tacks temporarily; as the pieces of a saddle or boot to the tree or last, to hold them in position for sewing.

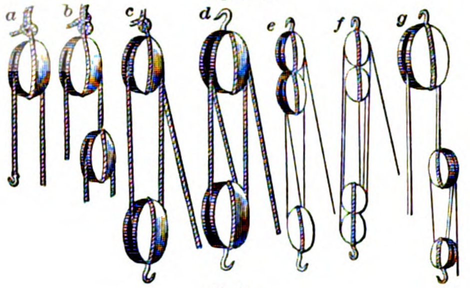
3. (*Nautical.*) Directing a vessel on to another tack when beating against the wind, so that the wind comes on the other bow.

Tack'ing-mill. A name of a kind of fulling-mill, *temp.* Edward IV.

Tack'le. An apparatus, or that part of an apparatus, by which an object is grasped, moved, or operated: as *gun-tackle*; *ground-tackle*; *fishing-tackle*; *plow-tackle*; *hoisting-tackle*; *reef-tackle*; *luff-tackle*; etc.

1. (*Nautical.*) A *simple tackle* consists of one or more *blocks*

Fig. 6159.



Tackles.

rove with a single rope. When two blocks are employed, one is the *standing block*, and the other the *running block*. The rope is termed the *fall*, and runs over the *sheaves*. The fast end of the *fall* is the *standing end*, the other the *running* or *hauling end*.

To *overhaul* a tackle is to separate the blocks by running out the rope.

Fleeting a tackle is to bring the blocks close together by hauling on the *fall*.

The block is bound with a *grommet* in the direction of its length. This is called the *strap*, and lies in the *score* of the block. If the strap be continued, so as to form a tail, it constitutes the block a *tail-block* or *jigger-block*. When a tackle has a *running block* of this character, it becomes a *jigger-tackle*.

As to kinds, the names founded upon structure: —

A *single whip* (*a*, Fig. 6159) is the simplest tackle. It consists of one *single* block and a fall. The standing block is made fast to a stationary object. The hook is applied to the load, and the power to the *fall*.

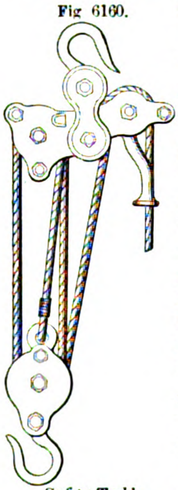
The *whip-on-whip*, or *whip-and-runner* (*b*), has two single blocks, one of which is a *standing* and the other a *running* block. The *fall* of the *standing* block is spliced round the block of the lower *whip*. The power is double that of a *single whip*.

The *double purchase*, or *gun-tackle purchase* (*c*), has two single blocks, the fall being rove through both, and the standing end being made fast to an eye on the bottom of the standing block.

The *reef-tackle* is a *double* purchase.

The *treble purchase*, or *luff-tackle purchase* (*d*), has a double and a single block, the fall being rove through one of the sheave-holes in the double block, then through the single block, then through the other sheave-hole in the double block, and is secured by splicing, or by an eye to the top of the lower block.

Fig. 6160.



Safety-Tackle.

The *yard-tackle* is a *treble* purchase.

A *twofold purchase* has two double blocks.

A *threefold purchase* has a *treble* block and a *double* one.

A *top-burton tackle* (*e*) is rove in the same manner as a luff-tackle purchase; the upper block of the burton is a fiddle-block, while that of the luff is a double one.

A *long tackle* (*f*) is composed of two long blocks, each of which resembles a pair of single blocks joined at their ends.

A *runner-tackle* (*g*) is the same purchase as a luff-tackle applied to a runner. A runner is a thick rope rove through a single block, and has usually a hook attached to one of its ends, and one of the tackle-blocks to the other; in applying it, the hook of the runner, as well as the lower block of the tackle, is fixed to the object intended to be removed.

The *garnet*-tackle is swung from the mainstay and used for getting boats or cargo on board or ashore.

The *jigger* is a block with a tail, for convenience of fastening it to an object.

A *tail*-block is also known as a *jigger*.

A *jeer* is a fourfold purchase used in swaying or striking the lower yard of a ship.

Fig. 6160 is a safety-tackle. To hold in suspension a load at any given elevation, a vibratory frame is hung in a suitable link of the stationary block, so that upon the cessation of pull upon the rope to raise the weight, the rope is swayed into a recess or gorge, and compressed there with a force proportionate to the weight. Upon the resumption of the pull upon the rope, it is swayed out of the recess, and the weight caused again to ascend.

As to kinds, the names founded upon place or purpose: —

Boom-tackle; used for rigging out or in the studding-sail booms, and consisting of a double and single block and fall.

Bowline-tackle; used to bowse out the main bowline.

Fish-tackle; one used in getting the anchor on to the gunwale.

Ground-tackle; anchors, cables, etc.

Gun-tackle; a purchase of two single blocks and fall, used for running guns in and out on shipboard.

Luff-tackle has a double and a single block and a fall. The *luff* is the weather leach of a sail.

A *pendant*-tackle is rigged from a pendant of the mast-head; used for hoisting cargo in or out of the fore or main hold, and for other purposes.

Port-tackle; used in tricing up the ports of the lower deck.

Quarter-tackle; used in hoisting aboard water, etc.

Reef-tackle; for rousing the reef-cringles of a sail up to the yard for reefing.

Relieving-tackle; a substitute for a disabled wheel and wheel-rope.

Rolling-tackle; used to steady the yards in a heavy sea.

Rudder-tackle; hooked to the rudder-pendant, to save the rudder if unshipped.

A *side*-tackle is used in working a gun, being hooked to a bolt on the side of the carriage.

Stay-tackle; hooked to the *triatic stay*.

Stock-tackle; hooked to the anchor-stock to rouse it on to the bows.

Tack-tackle; to bowse down the tack of a sail.

Top-tackle; used in swaying up a topmast.

Train-tackle; used in running in a gun, or to prevent its running out while being loaded.

Truss-tackle; that by which the truss of a lower yard is bowsed taut.

Winding-tackle; a purchase used in hoisting heavy articles or cargo.

Yard-tackle, a hoisting-tackle swung from a lower yard.

2. The appurtenances of a sport or work; as *fishing*-tackle, *plow*-tackle, *hoisting*-tackle, etc.

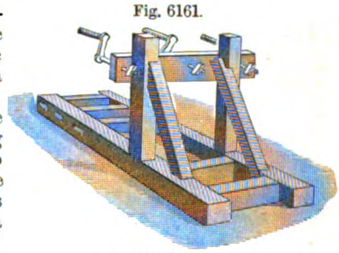
Tack-leath'er-ing Ma-chine'. A machine for attaching leather washers to carpet-tacks.

Tack'le-block. A pulley over which a rope runs. It usually consists of a sheave or sheaves in a shell. For varieties, see BLOCK; for applications, see TACKLE.

Tack'le-board. (*Rope-making.*) A frame at the head of a ropewalk containing the *whirls* to which *yarns* are attached to be twisted into *strands*. The *whirls* are also known as *winches* or *fore-lock hooks*, and there are generally three in a *tackle-board*, that being the number of *strands* which go to make a *rope*.

By another arrangement, the three whirls are rotated by a master wheel, the axes of the pinions being prolonged into hooks, and the main wheel is worked by a crank.

Fig. 6161.



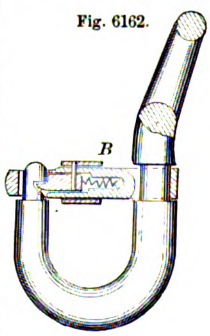
Tackle-Board.

Tack'le-fall. The rope which is rove through a block.

Tack'le-hook. The hook by which a tackle is connected to an object to be hoisted.

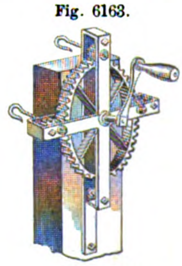
The example is provided with a

Fig. 6162.



Tackle-Hook.

Fig. 6163.



Tackle-Post.

mousing device *B* having an eye surrounding the shank of the hook, on which it has a motion both sideways and upward. An eye at the other end engages over the point of the hook, where it is held by a retractile spring-catch.

Tack'le-post. (*Rope-making.*) A post with *whirls* in a ropewalk, to twist the three strands which are laid up into a cord or rope.

Tack'ler. (*Mining.*) A small chain having a hook at one end and a ring at the other; four are made fast to the skip in order to hoist it up the shaft.

Tack-pull'er. A claw to draw tacks. A *tack-claw.* See TACK-HAMMER.

Tack-tack'le. (*Nautical.*) A purchase for hauling down the tack of a sail.

Tac-tom'e-ter. See ESTHESIOMETER; NERVE-NEEDLE.

Tæ'ni-a. (*Architecture.*) The band or fillet surmounting the Doric epistylium.

Taffe-ta. (*Fabric.*) A species of silken goods. See TAFFETY.

"Ashamed that she [Mrs. P] should be seen in a taffata gown, when all the world wears moyre." — PEPYS'S *Diary*, 1662.

Taf'fe-ty. (*Fabric.*) A rich, glossy silk stuff; plain, flowered, gold-striped, watered, or embroidered. The word is Persian.

Taff'rail. (*Shipwrighting.*) A transverse rail which constitutes the uppermost member of a ship's stern.

Tag. 1. A strip, having means of attachment to a bag or package, and on which an address may be written, printed, or stamped.

2. A metallic binding on the end of a boot-lace to stiffen and prevent raveling.

Tag-fast'en-er. A means of attaching a mark, tag, or label, to a bale, package, or other object or merchandise.

Fig. 6164 shows a number of different kinds.

***a b* are bent hooks, with barbs or catches to prevent retraction.**

***c d e* are wire clasps.**

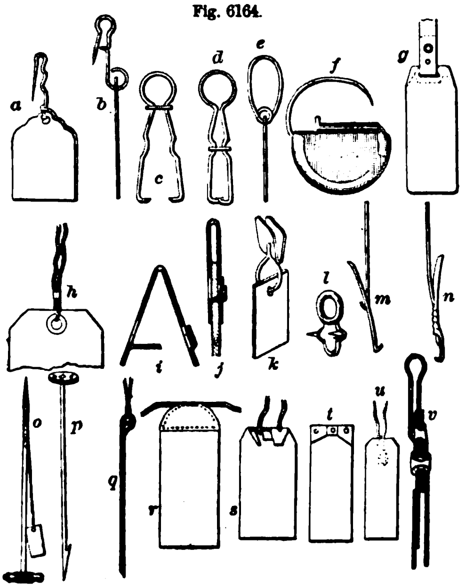
***f* is another form of clasp, with a metallic tag, in which the end of the bow locks.**

***g h k* are tied or riveted.**

***i j* are two views of a plate which perforates and locks upon a tag.**

***l* is an eye with riveting-spurs.**

Fig. 6164.



Tag-Fasteners.

***m n o p* are arrow-shaped spikes to be driven into a cotton or hay bale to hold the direction-tag.**

***q r s t u v* are tags of various kinds.**

Tag'ger. A device for removing the tag locks from sheep.

Tag'gers. Sheets of tin or other plate which run below the gage of the box or bunch to which they belong, and are consequently set aside as light, and used for other purposes.

Tag-hold'er. A device to attach a card or direction to a bale, package, or trunk. See TAG-FASTENER.

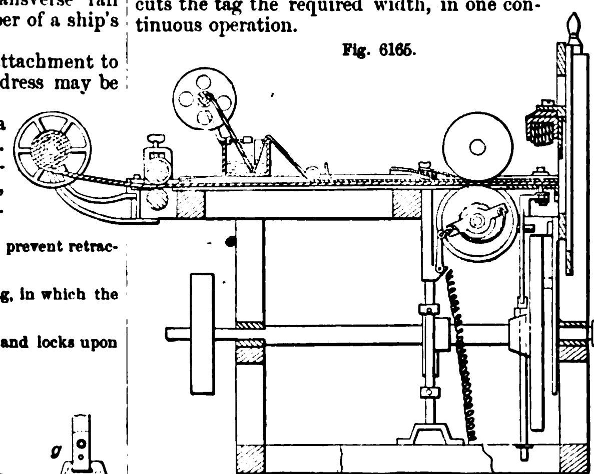
Tagl'ia. A certain system of pulleys, consisting of a set of sheaves in a fixed block, and another set in a movable block to which the weight is attached.

One cord goes around all the pulleys, one of its ends being fixed to a point in the system, and the other proceeding from one of the fixed pulleys drawn by the power.

Sometimes several are combined, so that one acts upon another, forming a compound taglia.

Tag-mak'ing Ma-chine'. The machine folds over the edge of paper required for the tag, inserts a tape, strips of fiber, or a cord, or both tape and cord at the same time; gums the fold down upon the tape, punches the eyelet, prints the address, and cuts the tag the required width, in one continuous operation.

Fig. 6165.



Machine for Making Tags.

Tag-nee'dle. A needle for securing tags to bales or bundles. The eye of the needle may be opened to the rear by so forcibly drawing the thread as to spring open the elastic piece which forms one side of the eye. See also NEEDLE, Fig. 3305; also *m, n, o, p*, Fig. 6164.

Fig. 6166.

Tag-Needle.

Tail. 1. The lower end of a slate or tile.

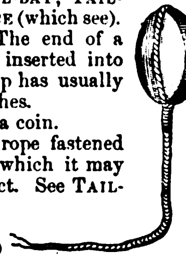
2. The end portion of a structure or work, as TAIL-BAY; TAIL-TRIMMER; TAIL-RACE (which see).

3. (*Masonry.*) The end of a stone step which is inserted into the wall; such a step has usually a *tailing* of nine inches.

4. The reverse of a coin.

5. (*Nautical.*) A rope fastened to a block, and by which it may be lashed to an object. See TAIL-BLOCK.

Fig. 6167.



Tail-Block.

Tail-bay. (*Hydraulic Engineering.*) That part of a canal-

lock between the tail-gates and the lower pond. See CANAL-LOCK.

Tail-block. (*Nautical.*) A block whose strap is prolonged into a tail, which is tapered, or the ends may be twisted into foxes and plaited together like a *gasket*. Blocks used for *jiggers* have a double tail, made in the same manner.

Tail-board. 1. (*Vehicle.*) The hind-end gate of a cart or wagon.

2. (*Shipbuilding.*) The carved work between the cheeks, fastened to the knee of the head.

Tail-crab. (*Mining.*) The capstan on which the spare rope of the crab is wound.

Tail-gates. (*Hydraulic Engineering.*) The lower pair of gates of a CANAL-LOCK (which see).

Tai'lor-ing-ma-chine'. A large sewing-machine adapted to a heavy class of goods. Several kinds of machines are made of such proportions as to adapt them to this work, and are illustrated under SEWING-MACHINE (which see).

The Wheeler and Wilson straight-needle machine is the "House" modification of the Wheeler and Wilson; preserving the Wilson feed, and the rotary hook in a modified form, in combination with a straight and vertically moving needle.

It differs from the ordinary Wheeler and Wilson, in having no *loop-check*, or other device for detaining the loop of the needle thread after it has been cast off the hook; it has an independent *take-up*, so that each stitch is completed before another is begun; its hook moves with a varying velocity, differing during each revolution from that of the main shaft, although it makes the same number of revolutions per minute. The needle is straight, and is driven by devices which cause it to pause entirely and move up and down with varying velocity at each stitch; the hook carries the upper thread around the bobbin, which contains the lower thread, interlocking the threads.

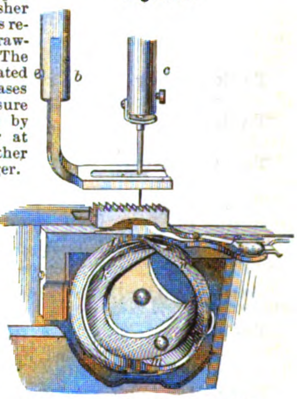
On the iron case is mounted the arm *a*, which holds the presser-bar *b* and the needle-bar *c*. The needle-arm *d* and take-up lever *e* are pivoted to the arm *a*, and actuated by cams on the main shaft beneath the iron plate forming the top of the case.

The upper or needle thread passes from the spool *f* along the bracket arm and by the thread-guide *g*, the tension-pulley *h*, the controller *i*, the jack *j*, over the front end of the take-up lever *e*, and through the eye of the needle. The lower thread is wound on the bobbin *B* (Fig. 6170), which is placed within the bobbin-case, and they are held in the cavity of the hook *k* by the ring-slide, the thread being drawn out in front.

In operating, the needle descends and thrusts a bight of the upper thread through the material, and then, rising to clear the hook-disk, it stands while the hook-point, having entered this loop, enlarges it by a quick motion, and carries it forward, at the same time the take-up descends and gives out the upper thread, which is drawn through the eye of the needle below the fabric. A half-revolution of the hook having now been quickly made, and the loop cast off over the bobbin (see *A*, Fig. 6170), and the needle, being entirely out of the material, the take-up rises quickly and draws up the loop. At the moment of drawing up the stitch, the apparatus for securing and regulating the under tension comes into play. A part of the hook-washer projects over the hook, and at each revolution presses upward against a bar attached to the frame of the machine. Through a hole in this bar (called the tension-finger) the lower thread passes.

While the stitch is drawing up, as soon as the loop has passed through the tension-finger, the under thread is clamped between the hook-washer and tension-finger, and is released as soon as the drawing up is completed. The under tension is regulated by a lever, which increases or diminishes the pressure upon the hook-washer by being brought to bear at will upon one or another point of the tension-finger.

Fig. 6169.



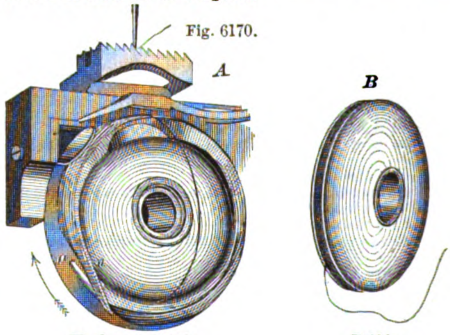
Hook and Feed, without Bobbin.

The thread is drawn through the needle while it is out of the material, giving it an advantage in sewing leather and starched fabrics with a small needle.

The presser-foot may be flat or a wheel, and is hinged or attached by a set-screw to the presser-bar.

In the Wheeler and Wilson family machine, the loop of one stitch is drawn up through the agency of the rotary hook in expanding the loop for the next stitch. In the House machine, each stitch is completed separately, the drawing up being done while the needle is out of the goods.

Fig. 6170.



Hook and Bobbin. *Bobbin.*

The rotating-hook differs from the ordinary Wheeler and Wilson hook in having a deeper cavity for the thicker bobbin, and in the cut *m*, which gives free course to the loop upon its being cast off and drawn up just as this cut revolves to the needle (*A*, Fig. 6170). The tail *n* of the hook overlapping the point *p* of the hook a trifle in front of it, acts as a guard in keeping off the bobbin-thread while the hook enters the loop of the needle-thread. It also draws a little thread from the bobbin, so as to leave it slack for free play.

Tai'lor's Chair. A legless chair, with seat, back, and knee-rest (Fig. 6171), adapted to the cross-legged position of the trade.

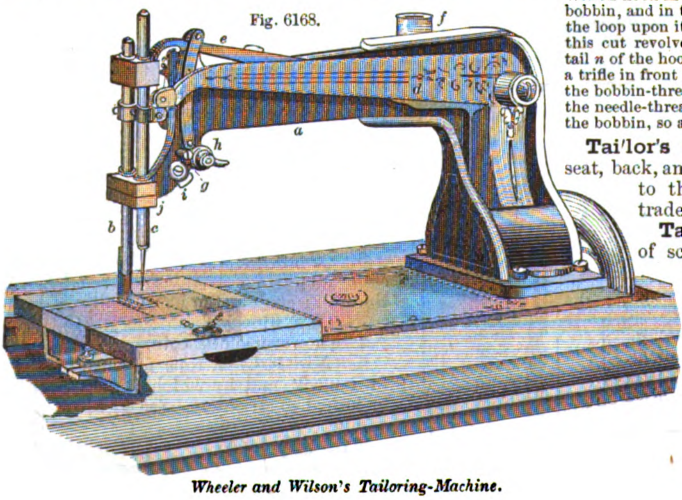
Tai'lor's Shears. A large style of scissors used in cutting woolen goods.

In the example (Fig. 6172), the upper blade and handle move upon a slotted fulcrum, which gives a *draw* cut. The edges are kept in contact by a spring. See also SHEARS; SCISSORS.

Tail-piece. 1. (*Lathe.*) The set-screw of the rear lathe-spindle.

2. (*Music.*) The block of a violin, guitar, or similar in-

Fig. 6168.



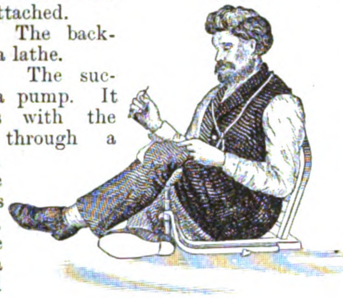
Wheeler and Wilson's Tailoring-Machine.

strument, to which the strings are attached.

Tail-pin. The back-center pin of a lathe.

Tail-pipe. The suction-pipe of a pump. It communicates with the pump-stock through a clack-valve, and in the case of metal pumps is in two parts, the upper one of which has a screw-thread at its lower end, by which it is secured to the lower part, the latter being cut to a suitable length.

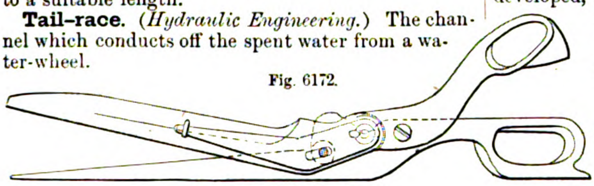
Fig. 6171.



Tailor's Chair.

Tail-race. (*Hydraulic Engineering.*) The channel which conducts off the spent water from a water-wheel.

Fig. 6172.



Tailor's Shears.

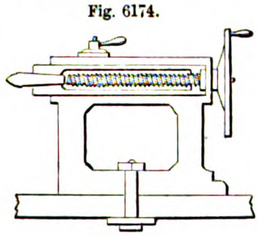
Tail-screw. (*Lathe.*) The screw which advances or retracts the back center.

In the commoner description of lathes the back center is at the end of the tail-screw, but in superior lathes the center is formed on a plug fitted in the end of a plunger, which is simply advanced and retracted in the barrel of the tail-stock by the rotation of the screw. The back center is held to its adjustment by the set-screw above.

Fig. 6173.

Tail-Pipe.

Fig. 6174.



Tail-Screw.

Tail-stock. (*Lathe.*) That head of a lathe which contains the non-rotating spindle, called the *dead-spindle.* At the other end of the lathe is the *head-stock*, in which is the *live-spindle.* The *tail-stock* is also called the *dead-head*, as containing the *dead-spindle.* See LATHE.

Tail-tack'le. (*Nautical.*) A luff-tackle, with a hook in the end of the single block, and a tail to the upper end of the double block. A *watch-tackle.* See TAIL-BLOCK.

Tail-valve. (*Steam.*) *a.* An air-pump valve in one form of condenser, opened by the steam entering the condenser, but closed by atmospheric pressure when a partial vacuum exists in the condenser.

b. The *snifting-valve* of a marine steam-engine.

Tail-wa'ter. The waste water discharged from the buckets of a water-wheel in motion.

Tain. 1. Thin tin plate. *Taggers.*

2. Tin-foil for mirrors.

Take. (*Printing.*) A portion of copy taken by a compositor at one time.

Take-horse. (*Mining.*) A vein of ore is said to *take horse* when it divides on each side of a body of non-metalliferous rock, called *dead-ground.*

Take-up. 1. (*Weaving.*) That motion of the cloth-beam in a loom by which the web is wound up as fast as the weaving proceeds. The *let-off* is the paying off of the yarn from the beam, and proceeds coincidently with the take-up. See LET-OFF.

2. (*Steam Navigation.*) The part between the smoke-box and the bottom of the funnel of a steamship.

3. (*Sewing-machine.*) A device in a sewing-machine to draw upon the upper thread to *take up* its slack while the needle is rising, or resting at its highest point, to tighten the stitch. The *independent take-up* is one which acts in its own time without being actuated by the needle-bar.

Tal'bo-type. (*Photography.*) A process invented by Fox Talbot, in which paper was sensitized by iodide of silver and exposed in the camera. The surface became the recipient of a latent image, which was developed, and was fixed by hyposulphite of soda. It was named by its originator, CALOTYPE (which see). It is the basis of the present photographic process. See PHOTOGRAPHY.

Talc. A mineral which occurs in granular and flaky conditions; a silicate of magnesia, or of magnesia and alumina; usually with the addition of iron. See Dana's "Mineralogy," ed. 1868, pages 452, 453.

The *massive* is known as *steatite*, *soapstone*, or *potstone*; the foliated approaches the character of mica, from which it is hardly distinguishable. The distinguishing test is that the thin laminæ of *talc* are flexible but not elastic; *mica* is very elastic.

Asbestus, or *amianthus*, is another closely allied mineral, occurring in many forms, the most characteristic of which is fibrous. See ASBESTUS.

Soapstone is used in slabs for stoves, and when powdered in composition for porcelain and for crayons.

Tal'i-pes-ap'pa-ra'tus. Club-foot is produced by eversion, inversion, or retroversion of the foot; and is known as *Talipes Valgus, Varus*, or *Equinus.* See CLUB-FOOT APPARATUS.

Talk'ing-ma-chine'. An acoustic instrument in which articulate differences of sound are produced.

Kempelen and Willis gained celebrity in this line.

Wolfgang von Kempelen, the inventor of the so-called automaton chess-player, which was only an ingenious deception, contrived a talking head, which contained wind-tubes and vibrating reeds, the latter set in motion by a bellows in the bust. The capacity of the machine was limited, but the following words and sentences were automatically enunciated without the intervention of a person to touch any keys: *opera; astronomy; Constantinople; vous êtes mon amie; Romanorum imperator;* etc. Tubes to imitate nostrils produced "*m*" and "*n*"; a funnel and a reed changed "*s*" into "*z*," "*sch*," and "*j*." Parts of the mechanism imitated the movements and action of the mouth, lips, teeth, tongue, palate, glottis, lungs, etc.

Faber's machine gives the correct pronunciation of the letters and elementary sounds, and enunciates phrases of six or eight words in the English, French, and German languages. Air is forced by a bellows, through a narrow aperture, into an iron windpipe, and thence into an artificial glottis, from whence it passes through a vent representing the human mouth, with movable jaws and a rubber tongue. Pipes and rubber tubes, operated by fourteen levers, are arranged to produce the various

Fig. 6175.

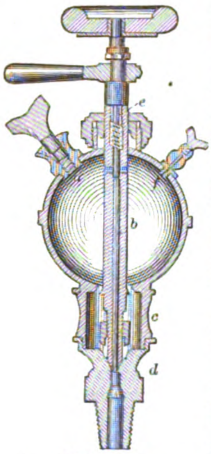
Tallow-Can.

sounds. The voice is shrill, monotonous, and unnatural, but in a majority of instances strikingly correct. Laughter is caused by a separate lever.

Tal'low-can. A vessel to hold melted tallow for lubricating purposes.

Tal'low-cup. A lubricating-device for journal-boxes, etc., in which tallow is employed as the lubricant.

Fig. 6176.



Tallow-Cup.

In that illustrated, the tallow is introduced through the aperture *a*, and steam admitted through the hollow valve-stem *b*; this melts the tallow, and when the upper valve is open, as shown, forces it down into the lower part *c* of the cup. On raising the stem, the upper valve is closed and the lower one *d* is opened, permitting the tallow to flow on to the part to be lubricated, the steam-opening in the valve-stem being closed by means of the screw-threaded rod *e*. *f* is the steam-escape opening.

Tal'ly. A notched stick employed as a means of keeping accounts.

Tally-sticks were used in ancient Egypt; one is in the Abbott Museum, New York. They were also employed by the Athenians.

In England they were long issued in lieu of certificates of indebtedness to creditors of the state. In 1696, according to Adam Smith, this species of security was at 40 to 60 per cent discount, and bank-notes 20 per cent.

Besides accounts, other records were formerly kept upon notched sticks, as almanacs, in which red-letter days were signified by a large notch, ordinary days by small notches, etc. Such were formerly common in most European countries. The Runic Clog-Almanack and the Saxon Reive Pope are of this class, and yet exist in Sweden, and in Staffordshire, England.

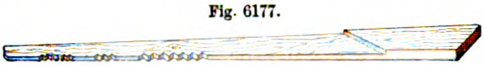
Somewhat similar was the ancient Briton *Coelbren y Beirdd*, the "billet of the signs of the bards."

The mode of keeping accounts by tallies was introduced into England by the Normans, 1066.

Seasoned sticks of willow or hazel were provided, and these were notched on the edge to represent the amount.

Small notches represented pence; larger, shillings; still larger, pounds; proportionately larger and wider, were 10, 100, 1000 pounds. The stick being now split longitudinally, one piece was given to the creditor, and the other was laid away as a record. When an account was presented for payment, the voucher was compared with the record.

Fig. 6177.



Exchequer Tally.

When paid, the *tally* and *counter-tally* were tied up together and laid away, accumulating for a long series of years. The history of the final abandonment of the system, and the catastrophe to which the disposition of this accumulation of rubbish led, is related by Charles Dickens, in a speech in favor of political and official reforms: —

"Ages ago a mode of keeping accounts in the Exchequer, by means of notched sticks, was introduced. In the course of time the celebrated Cocker was born and died; then Walkinghame, the author of the 'Tutor's Assistant'; then a multitude of accountants, actuaries, and mathematicians, who discovered and published means of account-keeping by ordinary arithmetic, far more ready, and which, in their every-day transactions, everybody used; but official routine looked upon these notched sticks as a part of the Constitution, and the Exchequer accounts still continued to be kept by these willow tallies. But, toward the end of the reign of George III., it occurred to some innovating and revolutionary spirit to suggest the abolition of this barbarous custom, and immediately all the red tape in all the public departments turned redder at the idea of so bold a conception; and it was not until the year 1826 that the custom of keeping these Exchequer accounts by willow tallies ceased. In 1834 it was found that a large accumulation of these tallies had grown up in the course of time, and the question arose what was to be done with these old worm-eaten, useless bits of wood.

"They were housed at Westminster. Common-sense would have suggested that they should be given for firewood to some of the poor miserable people who abounded in that neighborhood; but official routine could not endure that, and accordingly an order was given that they should be burned privately. They were burned in a stove in the House of Lords; but the stove being overheated by them set fire to the paneling of the room, the paneling set fire to the House of Lords, the House of Lords set fire to the House of Commons, and the two houses were reduced to ashes."

See also Clark's Commentary on Revelations ii. 17. See also BALLOT; ABACUS; ARITHMOMETER.

Tal'on. 1. (*Architecture.*) A form of molding, the same as OGEE (which see).

2. (*Locksmithing.*) The shoulder on the bolt against which the key presses in *shooting* the bolt.

Ta'lus. A slope: —

1. Of an embankment or earthwork in civil or military engineering.

2. Of a wall having a battering face.

3. A sloping heap of fragments at the base of an escarpment.

Ta'lus-wall. (*Masonry.*) A wall inclined on its face, either by decreasing its thickness toward the summit or by leaning it against a bank, as a *retaining* or *breast wall.*

Tam'bour. 1. (*Fabric.*) A species of embroidery in which threads of gold and silver are worked by needles in figures of leaves and flowers upon a silk stuff stretched over a circular frame, called a *tambour-frame.* This resembles a drum-head, and thus acquired its name. French *tambour*, "a drum."

2. A DRUM (which see).

Tam'bour-ine'. (*Music.*) An instrument of percussion, resembling a shallow drum with one head, and surrounded by small bells.

It is also known as the *tambour Basque*, and is a favorite instrument of the Italian peasants, the gypsies, and Basques. It is played in three ways: by striking; by rubbing its parchment with the ends of the finger, which gives a tremulous sound, and a jingling of the bells in the edge; by continuous rubbing with the thumb, which gives a wild, trembling sound.

The peculiar song of some insects, as the katydid, is produced in an analogous manner by the rubbing together of their wings.

On a sculpture at Dendera, in Egypt, is shown a musician playing on the tambourine. The Egyptian mode of playing was similar to the modern; and from the position in which it is held after striking, it is thought to have had the same tinkling disks in the rim. Among the ancient Egyptians its shapes were very various.

Fig. 6178.

Tambourine.

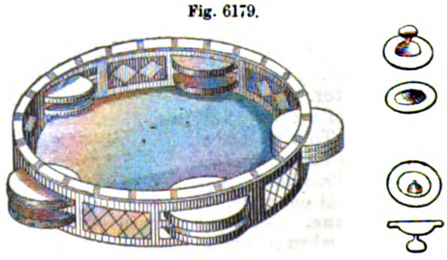
The *timbrel* of Miriam, the priestess, and sister of Moses and Aaron, was, no doubt, an Egyptian instrument. She and her attendants played on timbrels and sang the antiphone to the song of Moses and the congregation.

She "took a timbrel in her hand, and all the women went out after her with timbrels and with dances."

The ladies are now excluded from participation in Hebrew religious rites. The *tabret*, or *timbrel*, probably resembled the dasabooka of the Arabs, — a sort of *tam-tam*, or hand-drum; the *tympanon* of the Greeks.

Euripides celebrates "the skin-stretched circle of the tambourine of Phrygia, of the great mother Rhea."

Fig. 6179.



Arabian Deff and Castanets.

The modern Arabian *deff* does not differ materially from the European. It has a number of tinkling disks of metal set in slots in the rim, and is played by thrumming and shaking.

The name is derived from the Arabic *altambor*, and immediately is the diminutive of the French *tambour*, being considered a shallow drum with one head.

Tam'ine. Woolen cloth; *tammy*. Sometimes synonymous with *tawney*.

Tam'is. (*Fabric.*) *a.* A thin woolen stuff, highly glazed. *Taminy.*

b. A strainer or bolter.

Tam'my. (*Fabric.*) A glazed worsted cloth used for ladies' gaiters; also for a straining cloth.

Tamp'ing. 1. (*Smelting.*) Stopping with clay the issues of a blast-furnace.

2. (*Military Mining.*) Packing with earth, sandbags, etc., that part of the mine nearest to the charge to increase its effectiveness in a given direction.

3. (*Blasting.*) *a.* Filling up a blast-hole, above the charge, so as to direct the force of the explosion laterally and rend the rock.

b. The material used for the above purpose; it may be fragments of stone, earth, sand, or even water.

Lieutenant-General Sir John Burgoyne, of the English Engineers and Inspector of Fortifications, states that the desideratum in tamping is to obtain the greatest possible resistance over the charge of powder; if it could be made as strong as the rock itself, it would be perfection.

a. The different materials employed for tamping are: —

The chips and dust of the quarry itself. This is what is most commonly used, unless there be stone in it that strikes fire.

b. Dry sand poured in loose, or stirred up as it is poured in, to make it more compact.

General Burgoyne cites the favorable notice of sand in this connection, in the memoir of the works at Cherbourg, and also by a writer in the Journal of the Franklin Institute.

He also cites the experience of General Pasley, of the English Engineers, who condemns sand as utterly unfit.

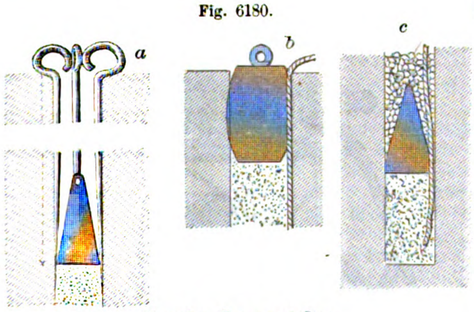
An extended series of experiments were made in the granite of Dalkey, Kingstown Harbor, Ireland, in which sands of various qualities and fineness were tried, as against the baked clay. The results of the experiments were all unfavorable to the sand.

c. Clay, well dried, either by exposure to the sun or by a fire.

d. Broken brick. It is used in small pieces and dust, and is improved by being slightly moistened with water during the ramming. It is pronounced inferior to the dried clay.

Several mechanical devices to assist in tamping have been suggested. The evident one would be a mere plug of a tapering shape, and driven into the hole. The most satisfactory of these devices has been an iron cone, with arrows around it, driven in as wedges. Another plan is a barrel-shaped plug, with a groove for the passage of the fuse. In a third instance, the iron cone was secured by tamping above it.

Fig. 6180.



Tamping Cones and Plug.

a, tamping-cone. *b*, tamping-plug. *c*, tamping-cone.

Tamp'ing-bar. (*Blasting.*) A bar of copper, brass, or wood, used in driving the *tamping* upon the charge in a blast-hole. Iron is to be avoided, as it sometimes strikes fire against a flinty or gritty piece of the tamping. See BLASTING-TOOLS.

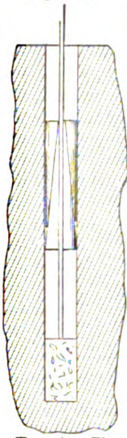
Tamp'ing-ir'on. A tool, prudently made of copper, by which the *tamping* is wadded down upon the cartridge or charge in a hole, for blasting. It is sometimes called a *driver*. A *tamping-bar*.

Tamp'ing-ma-chine'. (*Pipe-making.*) A machine for packing clay or the material for artificial stone into a mold. See STONE-PIPE MACHINE.

Tamp'ing-plug. A stopper for a hole in which a blasting-charge has been placed. It usually consists of a cone with barbs, or of a set of wedge-shaped blocks, which jam by the pressure from beneath.

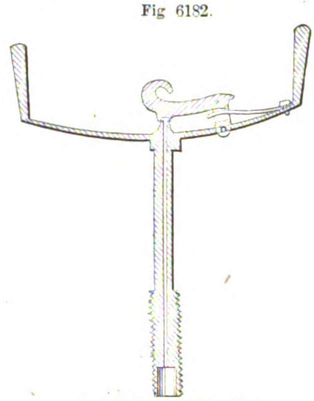
Fig 6182 is a tamping and blast plug, for splitting logs and stumps. The barrel is inserted into an auger-hole in the wood, and the contained charge exploded by drawing off the spring-hammer with a cord.

Fig. 6181



Tamping-Plug.

Fig 6182.



Tamping and Blast Plug.

Tam'pon. (*Surgical.*) A plug or stopper, of rag, sponge, etc., used in stopping hemorrhages.

Tam'-tam. *a.* The Oriental drum, consisting of a gourd covered with a lizard's skin.

b. A Chinese gong.

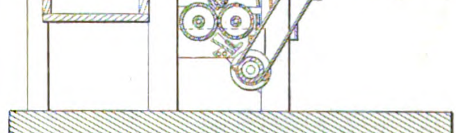
The composition, according to Klaproth, is, —

Copper	78
Tin	22 — 100

It is cast, and then tempered by being plunged, while hot, into cold water. The effect is the reverse of that with iron, as the metal is less brittle, and will bear the hammer.

The action of the hammer is to put the metal on a strain, the head having a tension like that of a drum.

Fig. 6183.



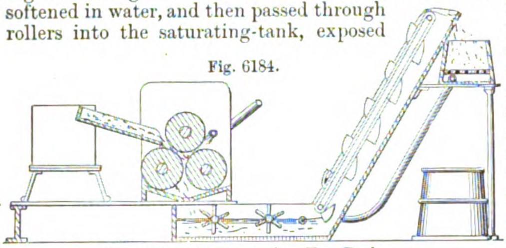
Apparatus for Desiccating Leached Tan.

Tan-bark Des'ic-ca'tor. A machine for drying leached tan-bark. It has an endless apron passing through a hopper placed over the leaching-trough, which carries the leached bark to another hopper, the latter feeding it between two hollow heated rollers which express the liquid.

Tan-ex-tract'or. A leaching device for extract-

ing the astringent matters from bark. The bark is softened in water, and then passed through rollers into the saturating-tank, exposed

Fig. 6184.

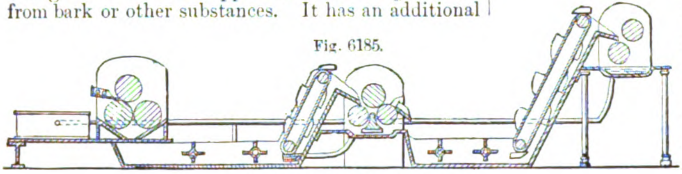


Apparatus for Extracting Tan-Bark.

in said tank to the action of beaters, elevated and passed through a series of leaches, where it is washed repeatedly until all the astringent properties contained therein are taken up by the wash.

Fig. 6185 shows an apparatus for making extracts from bark or other substances. It has an additional

Fig. 6185.



Apparatus for Making Extracts.

or secondary tank and two sets of squeezing-rollers combined with the crushing-rollers, saturating-tank, and elevator, so that the astringent qualities will be disengaged and the pulp left finally in a condition to be used as fuel.

Tang. The shank of a knife, chisel, file, etc., which is inserted in the haft.

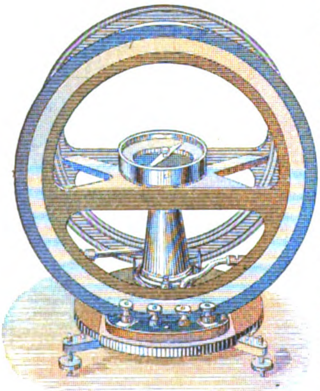
Fig. 6186.

Tang-Chisel.

Tang-chis'el. A chisel with a tang for insertion in a handle; in contradistinction to a socket-chisel, which has a hollow tang to receive the handle.

Tan'gent-gal'va-nom'e-ter. One in which the length of the astatic needle employed is so short, in comparison with the diameter of the surrounding copper ring through which the current to be measured is passed, that the intensities of currents may be regarded as proportional to the tangents of the angles of deflection of the needle. The tangents in this case serve as a direct measure of the comparative intensities.

Fig. 6187.

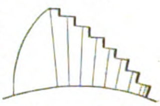


Tangent-Galvanometer.

Fig. 6187 represents Gaugan's instrument, in which two conducting rings are employed, the needle, in a case provided with a graduated circle, being supported centrally between them.

Tan'gent-scale. (*Ordnance.*) A species of breech-sight for cannon. Its base has a curvature corresponding to the circumference of the breech of the gun, and its face is cut into steps corresponding to angles of elevation. The proper hight for each step is found by multiplying the natural tangent of the elevation in degrees by the distance between the base-ring and muzzle-sight. In using the scale, the required vertical line is brought to coincide with a longitudinal line at the upper part of the breech, and the top of the front-sight is viewed over the center of the step, the breech being raised or lowered until the face of the step and top of the front-sight are in the same horizontal plane.

Fig. 6188.



Tangent-Scale.

Tan'gent-screw. An endless screw tangentially attached to the index-arm of an instrument of precision, enabling a delicate motion to be given to the arm after it has been clamped to the limb, and permitting angular measurements to be made with greater exactness than could be done were the movement entirely effected by hand.

Tan'gles. (*Nautical.*) A device used in dredging, for sweeping the sea-bed for obtaining delicate forms of marine life, too small or frangible to be obtained by ordinary dredging. The tangles, in a coarse form, has long been used in the sponge and coral fisheries.

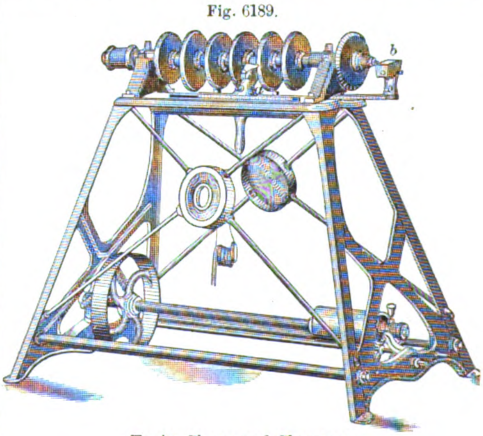
It consists of a bar 3½ feet long, supported on runners, and serving to drag after it a series of masses of hemp, each of which is a sort of mop. The fibers of the hemp entangle the smaller crustaceans and many of the more minute and delicate forms of marine life without breaking or injuring them as the dredge is apt to. Chains which are wrapped in the hempen swabs by their weight serve to keep the latter down to the work. Starfishes and sea-urchins, being prickly, are most readily caught by the tangles; in frequent instances immense masses of them are thus swept up and brought to the surface. See TRAWL.

Ta'nite. The trade name of a cement of emery and some binding material, used as a compound for grinding wheels, disks, laps, and in other forms.

Ta'nite-shap'er. A device for shaping and sharpening molding-bits, cutters, saws, and other wood-working tools.

It has a set of six emery-wheels, running between journals, and one overhung-wheel, all turning on a common spindle. The rest *a* may be fixed so as to work on either side of the table,

Fig. 6189.



Tanite Shaper and Sharpener.

or transversely thereto, and the rest *b* is adjustable to grind any desired bevel upon the overhung-wheel. The latter is specially intended for sharpening and gumming saws.

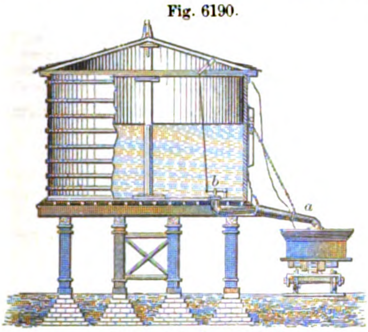
Tank. A vessel of large size to contain liquids.

1. (*Railroading.*) *a.* That part of a tender which contains the water. The tank varies in size, according to the power of the engine, and is from 500 to 1,600 gallons in capacity. See LOCOMOTIVE.

b. A reservoir from which the tank of the tender is filled.

Tanks for supplying locomotive-tenders with water are, when practicable, erected alongside of the track. They are generally made of wooden staves, like a large cask or tun, and supported

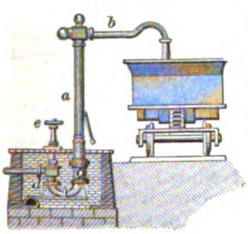
Fig. 6190.



Elevated Railway-Tank.

on a framework of wood, or upon a foundation of masonry. In Fig. 6190 the water flows into the tank from a stream or pond at a higher level, or is forced up by a pump, and is conducted by a spout *a* directly into the man-hole of the tender. The spout is usually attached to the tank by a hinged joint, so that it may be lowered to supply the water to the tender and then lifted out of the way of the engine and train. It is usually counterbalanced by a weight attached to a rope leading over a pulley at the upper part of the tank. A valve *b*, operated by a rope easy of access to the engineer, permits the water to flow when it is raised, and closes by its gravity.

Fig. 6191.



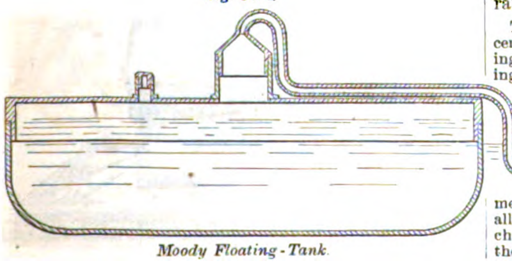
Water-Crane.

When there is no room for the tank near the track, it is placed in any convenient position at some distance from it, and the water conveyed by a pipe to a water-crane (Fig. 6191) located at the station. This consists of a vertical pipe *a*, with a horizontal branch *b* arranged to be swung around over the man-hole of the tender. It is preferable to have both pipes turn upon a joint at *c*, below the surface of the ground, as there is then less risk of freezing. The water is cut off at pleasure by a valve *d* operated by a hand-wheel *e*.

2. (*Nautical.*) Tanks for ships' use should be of galvanized sheet-iron; are usually rectangular in plan, four feet square, and from four to six feet deep. They hold from 400 to 600 gallons. A gallon is .1604 of a cubic foot. They are stowed at the bottom of the hold on a skeleton floor. Each has a man-hole in the top, and its shape is adapted to the part of the hold which it is intended to occupy.

3. (*Petroleum.*) The large development of the petroleum industry has given rise to various tanks, particularly designed for that class of oils which, in consequence of their combustible character, require particular care for their safe keeping. See OIL-TANK, page 1558.

Fig. 6192.



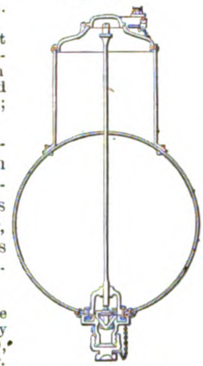
Moody Floating-Tank.

Some of the larger tanks for the storage of petroleum partake of the character of cisterns beneath the ground or floating in water. The main effort of ingenuity has been to prevent access of fire to the contents.

Moody's tank (Fig. 6192) has a dome upon its top from which extends a tube which terminates under water. By this means direct communication between the interior of the tank and the open air is avoided. See also OIL-TANK, Figs. 3386–3394.

Fig. 6193 shows the arrangement of Snyder's oil-tank for transportation; the valve-rod comes up through the dome to the level of the locked cover of the dome. See TANK-CAR; OIL-CAR.

Fig. 6193.



Snyder's Oil-Tank.

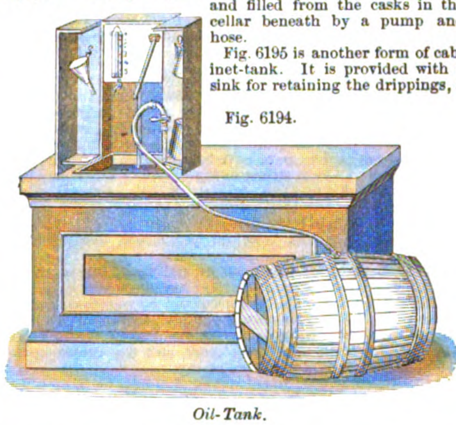
4. The term *tank* is also applied to a chamber or vessel in which a liquid is stored for dispensing or occasional use, as with oil, molasses, vinegar, wine, spirits, and other articles kept in stock, for sale in measured quantities.

Some of these are so large that the liquid may be dipped out, but usually it is drawn by a pump, as in Fig. 3370, page 1547, or by a faucet, as in Fig. 3385, page 1557. See OIL-CAN; OIL-TANK, in which three cuts occur.

Fig. 6194 illustrates the "cabinet" oil-tank, for stores, workshops, etc. It may be placed on an upper floor of a building and filled from the casks in the cellar beneath by a pump and hose.

Fig. 6195 is another form of cabinet-tank. It is provided with a sink for retaining the drippings, a pump, and a gage-rod, by which any shortage may be readily detected when the contents of a barrel or other vessel are emptied into it.

Fig. 6194.

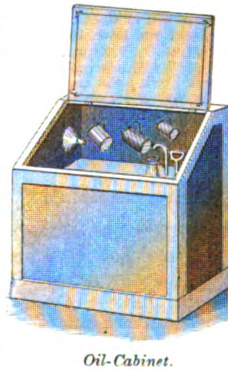


Oil-Tank.

5. (*Soda-water.*) A vessel used in measuring and dispensing sirups in soda-water apparatus.

To the glass vessel *A* is cemented a glass measuring-chamber *D*. The opening through which the vessel is charged is not seen in the drawing. When the rod is lifted by the handle *J*, the rubber *F* closes the upper opening in the measuring-chamber *D* and allows the liquid to be discharged at the opening *E*, the hollow rod *B* and its

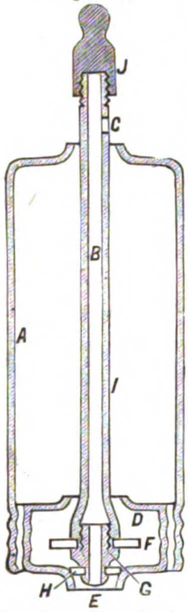
Fig. 6195.



Oil-Cabinet.

opening *C* serving as a vent for air to enter. When the rod is dropped, the washer *H* closes the opening *E*, and the chamber *D* again fills, the air in the measuring-chamber passing into *A* and collecting above the sirup. The rod *B* is of hard rubber or wood, as the sirup is not allowed to come in contact with metal.

Fig. 6196.



Matthews' Sirup-Tank.

6. (*Gas.*) The cistern of a gas-holder, in which the lower edge of the inverted chamber is beneath the water-surface, forming a *seal* for the gas. See Fig. 2178, page 951.

Tank'ard. A large drinking-cup; or a covered pitcher from which wine is poured into cups.

Properly, a large drinking-vessel, from which persons drank in succession, passing it around the table

In classical times, and during the Middle Ages, it was a mark of intimacy to drink in this way, and a mark of condescension or politeness, as the case might be, on the part of the head of a feast to offer it. Not like the equally festive but less familiar *wassail-bowl*, from which the negus, or punch, was ladled

"At wakes and wassails."

Ourselves do well remember the *loving-cup* with which the worshipful master pledged his guests and his lodge, and then, wiping the brim, laid the napkin in the handles, and passed it to the next, and so on around the table.

The *peg-tankard* seems to have been ordered by Edgar, a man of little merit, and not strong in the head any way: pins in the wooden tankard divided the drinks. "Betsy, wotever you do, drink fair."

The canons allude to it: —

"Ut presbyteri non eant ad potationes, nec *ad pinnas* bibant."

As the tankard held two quarts, and there were eight pins, the allowance was near half a pint to each, which might do if the brew were stiff. The moral was not very evident, for if any one went beyond the pin he was obliged to drink again. A fine tankard at Wardour Castle has on the lid the Virgin and St. John, one on each side of the cross, and the twelve apostles round the cup. Worshipful company.

"Of drinking-cups, divers and sundry sorts we have, some of elme, some of box, some of maple, some of holly, &c. Mazers, broad-mouthed dishes, noggins, whiskins, piggins, crinzes, ale-bowles, wassel-bowles, court-dishes, tankards, kannes, from a pottle to a pint, from a pint to a gill. Other bottles we have of leather, but they are most used amongst the shepheards and harvest people of the Country; small jacks we have in many alehouses of the citie and suburbs, tipped with silver, besides the great black-jacks and bombards of the court, which when the Frenchmen first saw they reported at their returne into their Countrey that the Englishmen used to drinke out of their bootes; we have besides cups made of hornes of beasts, of cocker nuts, of goords, of the eggs of ostriches; others made of the shells of divers fishes brought from the Indies and other places, and shining like mother of pearle. Come to plate, every taverne can afford you flat bowles, beakers; and private householders in the citie, when they make a feast to entertaine their friends, can furnish their cupboards with flaggons, tankards, beere-cups, wine-bowles, some white, some percell guilt, some guilt all over, others without of sundry shapes and qualities." — HEYWOOD'S *Philo-cathanista, or the Drunkard opened, dissected and anatomized,*" quarto, London, 1635, p. 45.

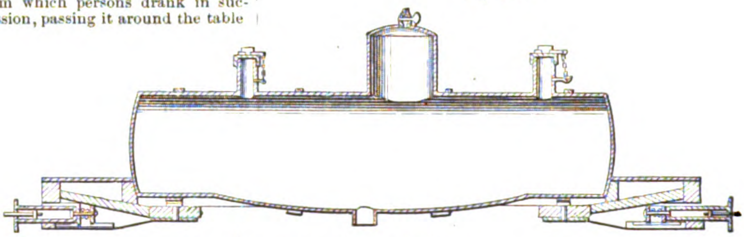
Drinking-pots of wood, with wooden hoops, are yet used in some parts of Britain.

A large drinking-glass was found in a Roman-British barrow, in Kent, England; a stained-glass one was excavated from a similar situation. Bede, Luitpraud, and Fordem record them.

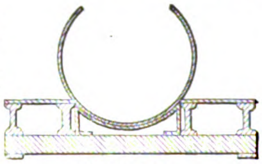
The *grace-cup* was handed round at the end of a meal.

Tank-car. (*Railway Engineering.*) A large tank

Fig. 6197.



mounted on a platform-truck, for carrying petroleum or other liquid. They are made in many forms, either of staves or of boiler-iron, usually the latter.



Oil-Tank Car.

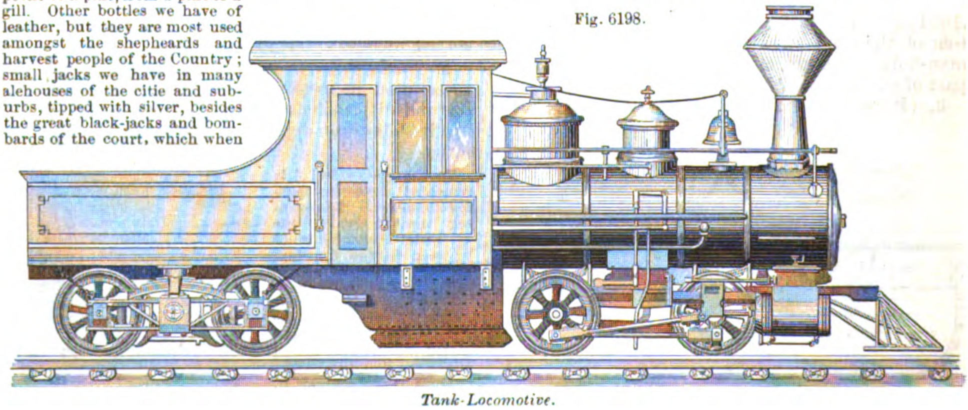
In the example, the cylindrical tube is bellied midway between its ends and on its lowest side. The tank has heads, a filling-gage, a safety-dome, and discharge-passage, which latter is at the convergent point of the bellying or lowest portion of the tank. See also OIL-TANK; TANK, 3.

Tank-en'gine. (*Railroading.*) A locomotive which carries the fuel and water it requires, thus dispensing with a tender. See TANK-LOCOMOTIVE.

Tank-lo-co-mo'tive. (*Railway Engineering.*) One having a tank or tanks enabling it to carry a supply of water sufficient for its own consumption without a tender. Such are used for yard-engines, for side-lines of limited length, and for ascending grades with moderate loads. The boiler and machinery are carried on the driving-wheels, and the variable weight of water and fuel on the tank-truck.

That illustrated is mounted on two bogie frames, the front

Fig. 6198.



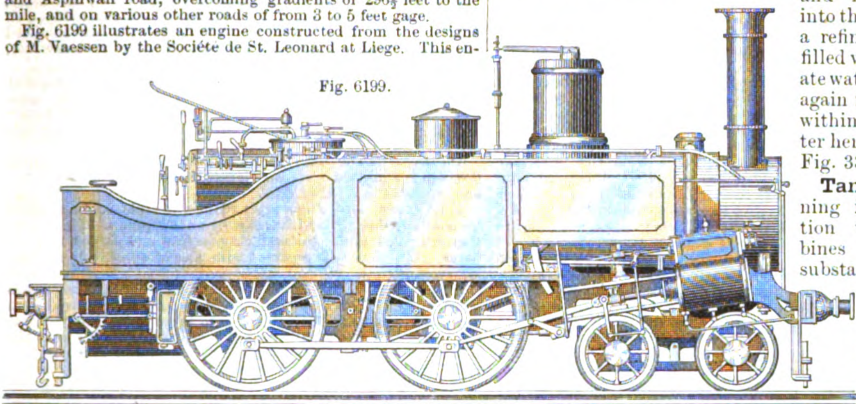
Tank-Locomotive.

one supporting the locomotive and the rear one the part in which the tank and coal-bunkers are located.

Engines of this kind have been employed on the Howland and Aspinwall road, overcoming gradients of 296½ feet to the mile, and on various other roads of from 3 to 5 feet gage.

Fig. 6199 illustrates an engine constructed from the designs of M. Vaessen by the Société de St. Leonard at Liege. This en-

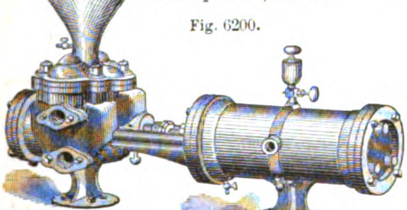
Fig. 6199.



French Tank-Locomotive.

gine is intended for the ascent of steep inclines and traversing sharp curves with a train on what M. Vaessen calls the universal system, patented by him. It was built for the Chemin de Fer Isabelle II., in Spain. The cylinders are 18.11 inches diameter and 24.16 inches stroke. The four driving-wheels are 6 feet 2 inches, and the truck-wheels 2 feet 11½ inches, diameter.

Fig. 6200.



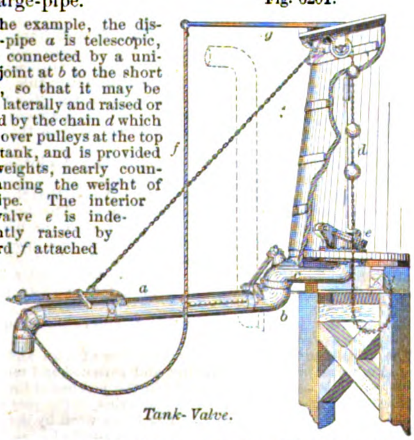
Direct-Acting Tank Steam-Pump.

Tank-pump. A form of steam-pump for the specific use.

Tank-valve. (*Railway Engineering.*) A form of valve used in locomotive water-supply tanks, for admitting water to the discharge-pipe.

Fig. 6201.

In the example, the discharge-pipe *a* is telescopic, and is connected by a universal joint at *b* to the short pipe *c*, so that it may be swung laterally and raised or lowered by the chain *d* which passes over pulleys at the top of the tank, and is provided with weights, nearly counterbalancing the weight of the pipe. The interior clack-valve *e* is independently raised by the cord *f* attached



Tank-Valve.

to the lever *g*, which has a connecting-rod leading to the valve.

Tank-ves'sel. A vessel whose hold forms a cistern for carrying molasses, oil, or other liquid. A brig constructed on this plan discharged her cargo of 88,000 gallons of molasses by means of pumps and hose leading into the reservoir of a refinery, was refilled with Cochituate water, and sailed again from Boston within 27 hours after her arrival. See Fig. 3376.

Tan'ning. Tanning is an operation which combines with the substance of the skin any other compound which has the property of rendering it imputrescible and elastic. The agent most generally employed is a soluble vegetable extract termed *tannin*, which forms insoluble compounds with the albumen, gluten, gelatine, and other components of the skin.

Tannin is yielded by the bark of oak, willow, and many other trees (see list, page 2493). The bark of oak is by far the most usual source of tannin. Catechu, valonia, and many other inspissated vegetable extracts are also used.

Another class of agents which fortify the fibrous portions of skins against the joint attack of warmth, air, and moisture are minerals which seem to act as preservative salts on the gelatino-fibrous structure of the skin. Such are alum and salt, and copperas. See TAWING.

It is difficult to determine the origin of this art, and it is somewhat confused by translating words referring to hides as if they meant *tanned* hides, that is, *leather*.

Skins and raw hides were first used and were afterward softened by means probably substantially similar to those adopted by the North American Indians. The art was reduced to a scientific basis by Sir H. Davy.

The pounding of skins, and sewing them up and inflating them, or filling them with *tanning* or *tawing* liquor, is shown in the ancient paintings of Kourna, Thebes.

Simeon of Joppa was a tanner, and dwelt by the seaside. Elijah and John Baptist wore leather girdles, perhaps *raw hide*. Strabo refers to the dresses of the Massaytan islanders as being of bark, owing to their having no cattle, and also to the skins used by other people. Pliny's statement of the materials used in treating leather shows that both the *tanning* and *tawing* operations were practiced.

Alum, sulphates of iron and copper, gall-nuts, bark of pomegranate, lotus, wild-vine roots, leaves of sumac, erythron, Rhus coriaria, and many inspissated juices.

The Saracens used alum. Du Cange mentions bark-mills and ground bark.

The art of tanning, though practiced immemorially in Europe, undoubtedly originated in the East, which, until very recent times, had almost a monopoly of the finer kinds of leather. In 1730, a man was sent from France to the Levant to learn the process of morocco manufacture, and in 1749 the first European morocco manufactory was established at St. Hippolyte, in Alsace; the art was not fairly developed in France before 1797.

This manufacture was subsequently introduced into England and Germany. In 1761, McBride of Dublin, and, in 1770, Johnson, introduced the use of dilute sulphuric acid for swelling the hides.

Sumac was used in the first half of the eighteenth century, *divi-divi*, from Caraccas in 1768. Catechu at a much later period. Steam-heating vats seem to have originated in America, but formed the subject of a French patent of 1822. The quick process was proposed by McBride in 1759, but he extracted the tanning material with lime-water. It was not until 1793-95 that the active principle requisite to the success of the process — tannic acid — was recognized by Deyeux and Seguin of Paris. It was rendered practical by Fay in England, 1790, and Seguin in France, 1795, and improved by Desmond, Brewin, Cant, and Miller. In 1839 the use of lime from gas-purifying works, previously suggested by Professor Boettger of Frankfort, was introduced into Berlin.

Half-dried sole-leather was formerly rendered compact and, to some extent, flexible, by being beaten by hand with hammers. In Switzerland, as early as 1800, water-power hammers, and, subsequently, stamps were employed. In 1842, Berendorf

of Paris invented pressing-stamps, which were supplemented by Harvey and Debergue with a roller, which effected the same purpose by its being rolled back and forth over the leather.

Fresh-slaughter hides are washed and scraped on the flesh side; salted hides are sometimes scraped, but dry hides do not require this treatment. Each of the latter kinds is soaked in water 10 or 14 days, and occasionally rubbed or beaten to supple them.

The skins are then placed in pits containing lime-water of 3 or 4 different degrees of strength; they are gradually transferred from the weaker to the stronger solutions, until, in the course of two or three weeks, the lime has dissolved the hair-sheath and, by combining with the fat, formed an insoluble soap. They are *handled*, that is, taken from the pits, and allowed to drain for an hour or two each day. When the hair is readily separable, they are removed from the pit and scraped upon the *beam*, a stand having a rounded upper surface, with the *unhairing-knife* (this is a curved, two-handled scraper, fitting the convexity of the beam); the hair comes off easily, its removal leaving a *grain*. Flesh and fat remaining on the other side are cut off with the *fleshing-knife*, which has a sharp convex edge; this process is termed *fleshing*. The hides are then washed in water, scraped, to get rid of adhering lime, the ears and projecting parts cut off, when they are ready for the tan-pit. The use of lime is objectionable, as it dissolves portions of the skin which would make good leather, makes the surface unequal, and interferes with the action of the tan. Various plans have been tried to avoid its use, among others smoking, causing an incipient fermentation which loosens the hair; piling the hides together and covering them with spent tan or litter, and allowing partial putrefaction to take place; and exposing them to air, kept constantly damp by the spray of water. In some cases weak acids are used, as very dilute sulphuric acid, sour milk, pyroligneous acid, fermented barley, rye-water, and bran; the two latter are sometimes used after liming. The effect of weak acids is to swell the pores, enabling the tanning liquor to penetrate them more readily. This process is termed *raising*: the liquid commonly employed consists of 1 part sulphuric acid to 1,000 parts water. A moderate heat is applied, and the process is completed in 24 hours.

A new English process to open the pores and render the tanning by bark more expeditious, —

1. Remove hair and particles of flesh.
2. Cleanse from the action of lime.
3. Place in a vat, flesh sides up, and cover each hide with bran, in quantity varying from 6 to 14 oz. to each hide, according to size, and cover with water.
4. Ferment. This will take two days or more, according to the weather.
5. Remove and scrape.
6. Steep in a vat, with 5 pounds ground Italian mustard and 5 pounds barley-meal to each 100 weight of hides. Here they remain from 24 to 48 hours, according to size.
7. Hang up to partially dry, and then proceed with the process of tanning by bark.

The tan-yard contains a number of wooden-lined vats, whose tops are level with the surface of the ground. Into these the hides and the ground bark, or ooze previously extracted therefrom, are put. In the old method the alternate layers of hides and of bark were placed in the pits, which were then filled up with water. When the strength of this appeared exhausted, the vat was emptied and supplied with fresh bark and water; this was repeated many times, the process occupying as much as 15 months. It, however, produced superior leather.

It is now customary to prepare the oozes and conduct them to the vats by pipes. The process consists in passing water through a stratum of the ground bark, until all its soluble matters are removed. Usually cold, but sometimes hot or tepid water is employed. Steam is conducted by a pipe beneath a pit containing the tanning material and water, and provided with a perforated false bottom, through which the extract percolates and is drawn off. In another method nearly spent bark is digested in water, at a moderate heat, and the weak ooze is transferred to a pit containing bark which is less spent, and so on until it is finally pumped into a pit filled with fresh bark.

It is common to introduce the skins into nearly spent ooze and transfer them successively to those which are stronger. Those in which the tanning is effected are called *handler-liquor*; stronger oozes, used for giving the *bloom* on the surface, are termed *layer-liquor*.

The skins are usually placed in horizontal layers, but are sometimes suspended vertically. In the process of *handling*, the hides are taken out with blunt-pointed, long-handled hooks, placed one over another, on a sloping rack over an adjacent pit, and permitted to drain for one or two hours.

When ooze instead of bark is employed, the hides are handled frequently.

By one plan, the skins are handled twice a day in the first liquor: once in two days in the second liquor; and once a month in the third liquor.

To save the trouble of handling by hooks in and out of the pit, various devices have been introduced. Several are illustrated under TANNING-APPARATUS.

1. (*Keasley*, 1845.) The hides are suspended from the bars of a frame which is periodically lowered into the liquor and raised therefrom.

2. The hides are temporarily tacked together, so as to form a chain, which is passed down into the vat and then up over a roller, by which they are kept in continuous motion.

3. (*Cagswell*.) The hides are arranged in a vat, laid flatly, except that the edges are a little raised to give the hide a dish form. The hides are packed in sawdust, and the ooze admitted above is allowed to percolate through the hides and sawdust, passing off at the bottom.

4. (*Spilsbury*, 1831.) Each hide is clamped in a rectangular frame, its edges being so nipped as to make it water-tight. Two frames are so clamped together as to make a thin water-tight box into which the ooze is admitted, to percolate through the hides, by hydrostatic pressure.

5. (*Drake*.) The hide is sewed up to form a bag, into which the ooze is admitted from an elevated cistern. The bags may be suspended in a vat of ooze.

6. (*Knowles and Duesbury*.) Hides are placed in a vessel from which the air is withdrawn by an air-pump. The ooze is then admitted under hydrostatic pressure and forced into the pores. The process is repeated with ooze of constantly increasing strength.

7. (*Herapath*, 1837.) Hides are sewed together into an endless band, and are passed between rollers, as they are removed from one pit to another. The object is to press out all of the ooze and open the pores for the reception of the ooze of the next pit.

8. (*Squire*.) Hides are placed in a horizontal cylinder, four fifths full of hides and hot ooze. The cylinder rotates at the rate of 6 or 8 revolutions per minute, and has interior ledges to tumble the hides as it rotates. The ooze is renewed from time to time, but fresh bodies of atmospheric air are excluded.

9. (*Nossiter*, 1844, *English*.) Each hide is contained in a frame which occupies a horizontal position in the pit of ooze. The frames are laid in, one over another, and circulation for the ooze is permitted all around them. The object is to keep them from contact, and the time is said to be shortened one half.

10. (*Berenger and Sterlingue, French*.) A series of 8 vats are made to communicate, so that the space between the false bottom and the bottom of No. 1 discharges, by a pipe, into the top of No. 2, No. 2 in the same manner to No. 3, and so on throughout the series, the contents of No. 8 being pumped into No. 1.

No. 1 is first charged with bark and hides and filled up with water. After a period, say from 15 to 21 days, No. 2 is similarly filled, and a quantity of strong ooze is introduced into No. 1, which displaces its former liquid contents and causes them to overflow into No. 2. After a similar interval of time (15 to 21 days), the pit No. 3 is charged with bark and hides, and strong ooze being poured into No. 1, its liquid contents are driven into No. 2, which overflow into No. 3. Again there is an interval, when No. 4 is charged, and so on until No. 8 has been charged and has laid its allotted time under the first liquid. No. 1 is by this time ready to be drawn, and is recharged with fresh bark and hides, the filling of No. 2 with ooze acting throughout the series of pits, the contents of No. 8 being pumped into No. 1, which has now become the last of the series.

11. (*Turnbull*, 1845.) The hides are tanned by endosmotic and exosmotic action, being sewed into the form of bags, filled with weak ooze and suspended in vats of strong ooze. The inequality of density causes a circulation of both liquids through the tissues. The weakness of one and the strength of the other solution must be maintained to preserve energy of action.

12. (*Schynder*.) The hide is indented by means of an instrument having 200 to 300 needles to the square inch. It is then exposed to the action of tan-liquor, which is led by the perforations to the interior portions of the hide.

13. The method employed by the Baskirs and Kirguises of Asia is a *substitute* for tanning, but may be here mentioned. The hair is detached by a knife. The skins are suspended in a pit, from parallel cords. Smoke is introduced into this pit by a tunnel from another pit, in which a fire is made. The fire is a smudge of dry and decayed wood, and both pits are covered in so far as is consistent with a draft sufficient to keep the smoke in effective action.

Two or three weeks are required to put the hides into a tough and lasting condition, impermeable to water.

14. The *Pampas Indians* stretch the hides, so that they shall not shrivel while drying in the sun's rays. The brains are also dried. At the end of the hunting season the hides are steeped, the hair shaved off; the wet hides and powdered brains being placed in an earthen pot and heated to *about* 95°. The villains have no thermometers. The cerebral matter is converted into a kind of soap, and forms a lather which renders the skin pliable.

The skins are then stretched by thongs, and rubbed frequently during the process of exsiccation.

The Esquimaux use in tanning the urine of man and beast. The skins are prepared in the fur, and softened and tanned in urine, which is usually kept in tubs in the porches of their huts for use in dressing deer, seal, and other skins, in the preparation of which they show great skill. The boots worn by the Esquimaux are generally made from seal or walrus hides, and resist water.

A number of distinguished chemists and practical tanners have attempted, and, to some degree, succeeded, in tanning leather by the application of minerals, obviating the use of the vegetable extract, *tannin*.

Of these may be cited the methods of Bordier and Cavalin, and the alum process.

1. *Bordier's Process.* The hides, being *unhaired* and *bated*, are steeped in a solution prepared as follows: —

224 pounds of bruised copperas are dissolved in 15 gallons of boiling water, in a copper kettle. This being transferred to a vat of 44 gallons capacity, 44 pounds of sulphuric acid (sp. gr. 1,848) are added, and to this gradually added 44 pounds of black oxide of manganese, in powder, the solution being constantly stirred.

The mixture is thinned with water and the hides steeped therein. The effect is to impregnate them with an insoluble sub-sulphate of peroxide of iron, and render the animal fiber imputrescible. From 3 to 8 days are required for the process.

2. *Cavalin's process* is to impregnate the cleaned and unhaired hides with a solution of

Bichromate of potassa.......	10 pounds.
Alum	20 pounds.
Water......................	180 pounds.

They are immersed 4 days, being handled and rubbed every day.

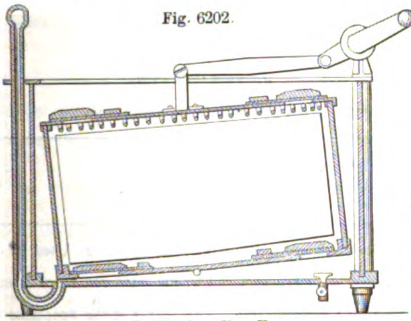
They are next steeped in a solution of

Protosulphate of iron..........	1 pound.
Water..........................	1 gallon.

The hides are not allowed to touch in the vat, but are taken out every 12 hours and drained, the process being repeated till the leather is formed.

The iron base is peroxidized in the hide by means of the chromic acid, which is itself reduced to the state of sesquioxide,

Fig. 6202.



Oscillating Tan-Vat.

and remains with the iron and a portion of the alumina base, firmly united with the tissue.

3. The alum process consists in applying to the skins a saturated solution of alum and salt, followed by dressings of flour, yolk of eggs, oil, etc. See TAWING.

For tanning *in vacuo*, see patents: —

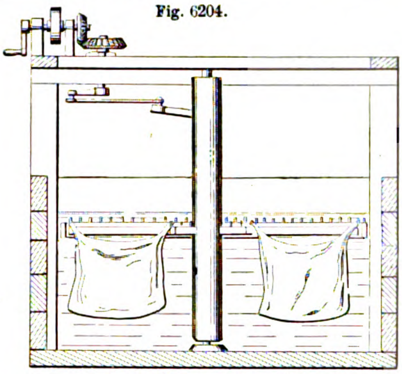
Plunging-Vat.

Fig. 6204.

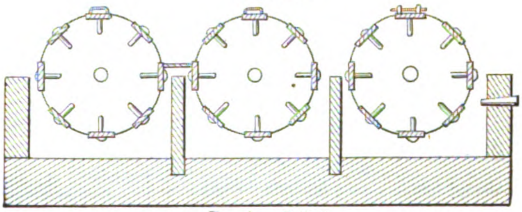


Rotary-Movement Tan-Vat.

Symonds' process for utilizing the useful matters which are not withdrawn from the bark by steeping, consists in burning the spent bark and conducting the products of combustion into a trough filled with water, where the solid and soluble portions are retained.

Tan'ning-ap'pa-ra'tus. A vat with devices for moving the hides in the liquor, or for circulating the liquid about the hides, in order to expose them to

Fig. 6205.



Tanning-Cylinders.

fresh quantities as the liquid in immediate contact with the hide parts with its tannin. Several forms of apparatus have been made, some of which are here illustrated.

1. *Oscillating Movement.* The hides are suspended in a box whose top and bottom are provided with valves opening upward; the box is oscillated upon a horizontal axis in a tank of tanning-liquor, and the motion causes a constant upward flow of the liquor, whose gravity is ascertained by an indicator attached.

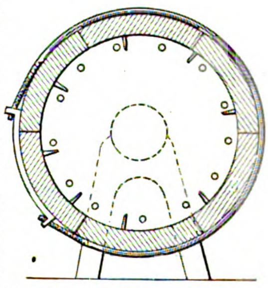
2. *Vertical Movement.* In Fig. 6203, the hides are distended upon cloths within wired frames *D D*, and, being suspended from a beam, are subjected to the action of rammers *B B* within the vat, by which they are alternately squeezed and released, causing the circulation of the liquor and the absorption of tannin by the hides.

3. *Rotary Movement within Vat.* The hides are suspended on the pins upon the rim of a horizontal wheel which has oscillation within the tank by an arm of its shaft, which is connected by a rod to a crank upon a shaft extending to the outside.

4. *Rotary Movement of Vat.* The hides are placed in open-sided rotating cylinders, which are partly submerged in vats containing tan-liquor, and have inwardly projecting pins to work the hides.

In Fig. 6206, the barrel is studded inside with pins, and has a perforated false bottom near one end, through which the tanning liquid flows in passing from the tubular induction-gudgeon to the hides within the cylinder. The liquor passes out through the other gudgeon.

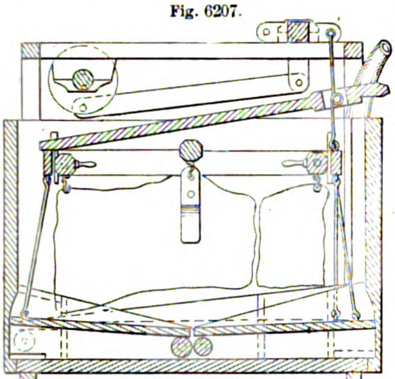
Fig. 6206.



Revolving-Cylinder for Tanning Hides.

5. *Circulation of Water by Pumps.* Fig. 6207 has a series of lifting-pumps, arranged in and operated at the bottom of the vat, for raising the heavier and stronger liquids from the bottom to the top of the vat, and thus by mixing render it of more

Fig. 6207.



Tan-Vat with Pump.

uniform strength throughout. The tanning-liquid is thrown against the hides, suspended in the air, by a force-pump, in a column or in spray.

6. *Vacuum Process.* Air being exhausted from the tank, the liquor is allowed to enter and penetrate all the interstices between the hides and also the pores of the skins. The exhaust is by means of pumps, or, as in the example, by a pipe with stop-cocks to a separate steam-condenser.

In Fig. 6209, the hides or skins are smoothly stretched or folded in an air-tight vat, and stratified with bark or matting interposed. The air being exhausted and the liquor admitted, the tank can be reversed and adjusted at will by manual power, or at set times by mechanism rotating the vat on its longitudinal axis.

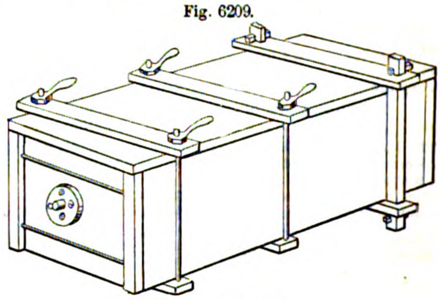
Tank for Tanning in Vacuo.

Fig. 6209.



Vacuum Tan-Vat.

TANNING-MATERIALS, DYE-STUFFS, ETC.

Common Name.	Botanical Name of the Genus or Species of the Plant used or producing the Article.	Native Place, or where chiefly grown.	Qualities, Uses, etc.
Alder bark..........	Alnus glutinosa........	Britain, etc......	The bark produces a yellow or red color. Used in dyeing and tanning.
Alkanet root........	Anchusa tinctoria.....	Shores of the Mediterranean	Used as a dye to stain woods Its red color is easily imparted to oils, etc.
Aloes...............	Aloe (various)	E. Indies........	Afford a brown dye. The leaves of the Socotrine aloe give a violet color that does not require a mordant to fix it.
Aniline	A product of coal-tar..	Discovered in 1826 by Unverdorben.	From it have been obtained mauve, magenta; also blue, green, violet, and black. See TAR.
Argol	Vitis vinifera....	Europe, etc	The coarse cream of tartar produced in casks in which wine has been stored. Used in dyeing.
Arnotto.............	Bixa orellana	S America	Red colored pulp covering seeds of the plant afford an orange or yellow dye for silks, and to color cheese, butter, and varnishes.
Barberry root, etc. ..	Berberis vulgaris, etc...	Europe, etc	The root, stems, etc., afford a yellow dye The bark is used in tanning.
Barwood............	(See Camwood)		
Bedstraw	Galium verum	Europe, etc	The flower tops afford a yellow dye with alum mordant; the roots a red dye.
Beech-bark	Fagus (various)	Europe and N. America	The tannin yielded by this bark makes a white but inferior leather, and is used only in places where oak is scarce.
Birch	Betula (various)	Europe and N. America	For tanning Russia leather, the inner bark is much used, especially on account of the brown oil which it yields, to which this leather owes its smell and durability
Brazil wood.........	Cæsalpinia brasiliensis	West Indies, Brazil, etc.	The heart-wood affords a red dye. Used also to make red ink.
Broom..............	Cytisus scoparius, or Sarothammus scoparius, and Genista tinctoria......	Europe	Used in dyeing yellow. For tanning, and for house brooms.
Buckthorn..........	Rhamnus (numerous) ..	Europe, etc......	Affords dyeing materials. Sap green from the berry, and yellow from the bark.
Campeachy wood....	(See Logwood.)		
Camwood	Baphia nitida........	W. Africa.......	Called also barwood. Affords the red dye used for English bandana handkerchiefs.
Catechu	Acacia catechu.........	E. Indies........	A resin-like extract obtained from the bark, wood, and leaves. Used in dyeing and tanning. The leather is very permeable to water, light and spongy, hard, and of a dark reddish-fawn color. The characteristic deposit, from oak bark and a few other tanning agents, known as *bloom*, is not produced by catechu.
Chica...............	Bignonia chica.........	S. America... ..	Affords a red pigment. Used to give an orange red to cotton goods.
Coal-tar colors.......	....	....	Aniline, mauve, magenta, solferino, are all products of coal-tar.
Cochineal...........	Opuntia cochinillifera ..	Mexico	The cochineal insect (*Coccus cacti*) feeds on this species of cactus, and affords a valuable scarlet and crimson dye.

Common Name.	Botanical Name of the Genus or Species of the Plant used or producing the Article.	Native Place, or where chiefly grown.	Qualities, Uses, etc.
Cork-tree	Quercus suber	Spain and Portugal	The *liber*, or inner bark, may be used for tanning.
Crottel	Parmelia omphalodes	Europe	A lichen growing on rocks and trees. Used to produce a brown color.
Cudbear	Lecanora tartarea, etc.	Sweden, etc.	A lichen growing on rocks at high elevations. Used to give a purple color — which is very fugitive — to woolen goods.
Cutch	(See Catechu.)		
Divi-divi	Cæsalpinia coriaria	S. America	The fruit-pod of the leguminous shrub is a powerful astringent. Used in tanning. Leather prepared by this substance is very porous, and sometimes tinged brown, unless the air be excluded in the process of tanning.
French berries	(See Buckthorn.)		
Fustet	(See Sumac.)		
Fustic	Maclura tinctoria, or Morus tinctoria	W. Indies, Brazil, etc.	Wood affords a yellow dye.
Galls	Quercus infectoria	Asia Minor	There are several kinds of galls, or gall-nuts; all produce gallic acid. Used in dyeing black, ink-making, tanning, and as a styptic. The gall is an excrescence produced on the species of oak named by the puncture of the insect, *Cynips quercusfolii*.
Gambir, or Terra japonica	Uncaria gambir	E. Indies, Malay Islands, etc.	Used in dyeing and tanning. Contains a principle called *catechine*. It was formerly called *terra japonica*, as it was supposed to be an earth from Japan. It is the inspissated juice of a slender-stemmed, vine-like shrub with oval leaves and clusters of pale purplish flowers. The leaves and branches are boiled to obtain the astringent extract, which is condensed by evaporation and dried in little squares. It is used by the Malays as a dye, a salve, and a masticatory with betel-nut and tobacco.
Garancine	Rubia tinctoria	S. Europe, etc.	The dye-principle of madder; obtained from it by the action of sulphuric acid.
Gum-trees	Eucalyptus (various)	Australia	Contain an astringent principle which can be used in tanning.
Heather	Calluna vulgaris	Europe	Affords a yellow dye.
Heaths	Erica (various)	Europe	Some kinds used in tanning.
Hemlock bark	Abies canadensis	N. America	In union with oak-bark, is supposed to produce the best leather. Hemlock alone produces leather inferior to that prepared with oak-bark, and, besides, imparts to it a red color. In America, it is largely used as a substitute for the bark of the oak.
Henna	Lawsonia inermis	Africa, Arabia, etc.	The powdered leaves used to dye leather, etc., a reddish yellow or orange. In Egypt, it is employed by the women to give an orange color to the nails.
Indigo	Indigofera anil, tinctoria, etc.	India	A very valuable blue dye.
Kelp	Fucus vesiculosus, etc.	Sea-shores	The ash of various kinds of sea-weed. Affords soda, etc.
Kermes	Quercus coccifera	S. Europe	The kermes (*Coccus ilicis*) feeds on the leaves of a species of oak, and affords a red dye. Its use is of very ancient date.
Kino	Pterocarpus marsupium / Pterocarpus erinaceus	E. Indies, Africa.	Used as a yellow dye for cotton in the East Indies.
Lac-dyes	Ficus religiosa, etc.	E. Indies	The *Coccus lacca*, by puncturing trees of the East Indies, produces shell and other lacs, that afford beautiful red dyes.
Larch	Larix alba	Europe, etc.	For tanning, inferior to oak.
Lichen dyes	Lecanora rocella, etc	Cool climates	Many genera and species give dyes; as cudbear, litmus, orchil, etc.
Litmus	Rocella tinctoria	Canaries, S. Europe, etc.	A lichen used to give a purple dye to silks. Used in chemistry as a test for alkalies and acids.
Logwood	Hæmatoxylon campechianum	Central America.	Used in dyeing red and black colors, shades of purple, etc. Called also campeachy wood.
Lombardy poplar	Populus dilatata		For tanning. Imparts a fragrant smell to the leather, similar to that of Russia leather.
Madder	Rubia tinctoria, etc	France	Employed to produce the celebrated Turkey red and other dyes. Affords garancine by the action of sulphuric acid.
Madder (Indian)	(See Munjeet.)		
Mangrove bark	Rhizophora mangle	Tropics	The bark is very astringent. Used for tanning.
Mimosa	Mimosa	Warm climates	The bark of an Australian species may be used in tanning.
Munjeet	Rubia cordifolia	N. India	Used for the same purposes as the European madder. Also affords garancine.
Myrobalans	Terminalia (various).	India	The fruit husk possesses an astringent principle. Used by tanners.
Nicaragua wood	(See Peach-wood.)		
Nutgalls	(See Galls.)		
Oak bark	Quercus (various).	Europe, etc.	The bark is employed in tanning and dyeing. It is stripped in spring; dried, ground, and steeped to extract the tannin.
Orchil, or Archil	(See Litmus.)	Europe	Is properly litmus in an early state of preparation, when it possesses a purple color.
Peach-wood, or Nicaragua wood	Cæsalpinia brasiliensis	S. America	Used as a material for red dyes.
Pearlash, or Potash	Various plants	Russia, America.	Procured by burning many woods and plants, and lixiviating the mass. Used for scouring wool and for cleansing generally; also in soap.

Common Name.	Botanical Name of the Genus or Species of the Plant used or producing the Article.	Native Place, or where chiefly grown	Qualities, Uses, etc.
Persian berries	(See Buckthorn.)		Afford a yellow dye.
Pomegranate bark	Punica granatum	Europe, etc.	Used in dyeing. Especially to give morocco leather a yellow dye.
Quercitron	Quercus tinctoria	N. America	A valuable yellow dye is obtained from the bark of the tree.
Safflower	Carthamus tinctorius	India, China, S. Europe, etc.	The flowers afford a yellow and red dye. Used in dyeing silks various shades of rose-pink, and in making carmine-rouge.
Saffron	Crocus sativus	S. Europe, etc	Used as a yellow coloring material. Obtained from the stigmas or tops of the flowers.
Sanders-wood (red). Santal-wood Saunders-wood	Pterocarpus santalinus	India	The wood affords a reddish-brown color, as a dye for woolen goods, also red and scarlet with certain mordants.
Sap-green	(See Buckthorn.)		
Sappan-wood	Cæsalpinia sappan	India and Ceylon	A wood much used as a red dye-stuff.
Spanish berries	(See Buckthorn.)		
Sumac, or Sumach	Rhus cortinus Rhus coriaria	S. Europe	The powdered leaves and young branches are used in tanning and dyeing orange, yellow, and black.
Tannin			A principle obtained from galls, oak-bark, etc. Used in tanning. It has the power of solidifying the gelatine of animal substances, as skins, and thus converting them into leather.
Terra japonica	Uncaria gambil	Malay Islands	Also called gambir. Used largely in tanning and dyeing.
Turkey berries	(See Buckthorn.)		
Turmeric	Curcuma longa	India, etc.	The powdered root (also called Indian saffron) affords a yellow dye. Is used in chemistry as a test for free alkalies.
Valonia	Quercus ægilops	Greece, Asia Minor	The acorns and cups of this species of oak are used in dyeing and tanning. Leather prepared by this substance is harder and less permeable to water than that made with oak-bark.
Weld	Reseda luteola	Britain, etc	The leaf and stems yield a yellow dye.
Willow bark	Salix alba	Europe, etc	Remarkable for its astringent taste. Leathers made from kid and lamb skins owe their agreeable smell to this bark, with which they are tanned.
Woad	Isatis tinctoria	Britain	Used to dye blue colors. Now superseded by indigo.
Wongshy	Gentiana (?)	Batavia	Yellow dye-stuff obtained from the seed-vessels of the plant.
Yellow berries	(See Buckthorn.)		

Tan-nom'e-ter. A hydrometer for determining the proportion of tannin in tanning liquor.

Tan-pit. A sunken vat, in which skins are steeping in tanning liquor.

Tan'ty. (*Weaving.*) The Hindoo loom, consisting of bamboo beams for the warp and cloth, a pair of heddles moved by loops, in which the big toes are inserted, a needle which answers as a shuttle, and a lay.

Tan-vat. A pit or tank in which tanning of hides is accomplished. See TANNING-APPARATUS.

Tap. 1. (*Machinery.*) A tapering, longitudinally grooved screw of hardened steel, having a square head, so that it may be turned by a wrench. It is used for cutting an internal screw, as that of a nut. See SCREW-TAP, Fig. 4754.

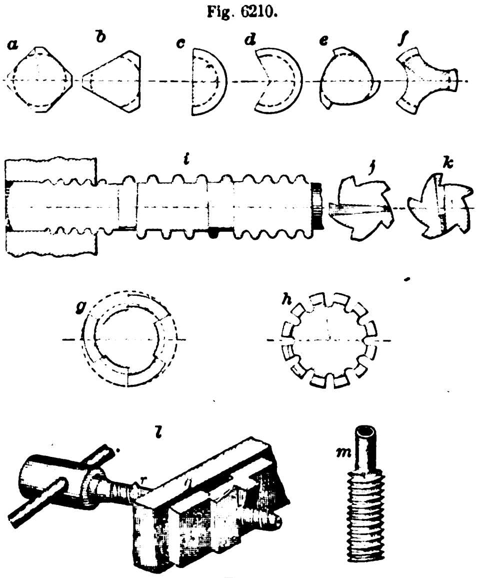
The most primitive kind of tap (Fig. 6210, *a*) is formed by filing four planes upon the screw: this gives very obtuse cutting edges. In *b*, three planes only are filed away, giving an angle more favorable for cutting. These sections are used for very small taps. The half-round tap *c* gives the most favorable cutting angle, and has been recommended as cutting a clean thread with comparatively small labor; the form *d* has also been employed. Taps with three or five cutting edges *e f* are more common; it is usual to form them with elliptical grooves, which permit the shavings to escape readily, and are easily wiped out.

In Bodmer's tap *g*, the cutting edges of the teeth are made prominent, their faces inclining backward at an angle of 3° from a true circular curve, so as to reduce the friction of the tool.

For cutting screw-dies and tools and other thin articles, the tap *h* has a larger number of grooves, and a greater proportion of its face is left standing to give it a sufficient bearing on the metal.

Taps with removable cutters have been used. *i j k* is Jones's tap. Tapering holes are made in the body of the tap to receive the cutters, which are caused to project slightly beyond the general surface by a slip of paper placed within the mortise. Sometimes they are made parallel and protruded by a set-screw. *l* shows a wood screw-cutting tap of this kind. It has a square helical groove, which fits two plates on the guide *p* through which the tap passes, and which is secured to the wood *q* to be tapped; the cutter *r* is inserted in a radial mortise. *m* is a hollow tap for the same purpose; a hole is made at the termination of the thread, and chamfered so as to form a

Fig. 6210.



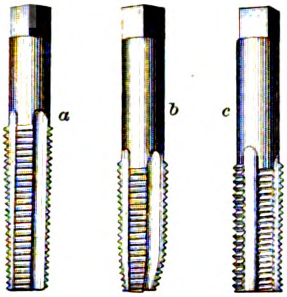
Taps.

cutting edge, the shavings passing into the central hollow of the tap.

Master taps are used for cutting the dies employed in cutting screw-threads. In some cases, for deep threads, two pairs of dies are employed, but generally one pair is cut by a tap one depth larger than the screw.

The process of screw-cutting was greatly improved by Maudslay, who introduced the practice of having three cutting edges, and using three taps, the entering taper tap, the middle tap, and the plug tap, by which shallow or *dead* holes in cast-iron can be safely tapped with full threads.

Fig. 6211.

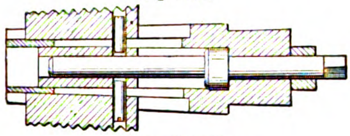


Taps.

a, taper-tap.
b, plug-tap.
c, bottoming-tap.

Fig. 6212 is an expanding-tap, the cutter being inserted in inclined dovetailed grooves in the sides of the stock. They are connected by screws to a plug sliding in a hole bored in the axis of the stock, and which serves to draw them up or down on the inclines to increase or decrease the diameter.

Fig. 6212.



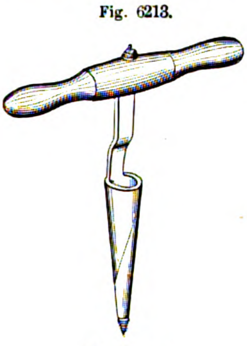
Expanding-Tap.

2. A faucet.
3. The heel of a boot, made up of *lifts*.

Tap-bor'er. A tapering boring-instrument for making spigot or bung holes in casks.

Fig. 6213 has a sharpened, salient, spiral edge, and a gimlet-point.
Fig. 6214 is the half of a hollow cone, with a sharpened edge and gimlet-point.
Fig. 6215 has a ring shank for a handle.

Fig. 6213.



Tap-Borer.

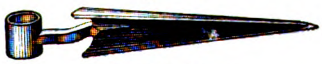
Fig. 6214.

Tap-Borer.

Tape. 1. (*Fabric.*) A narrow linen or cotton fabric, twilled or plain, white or colored.

2. (*Printing.*) *a.* One of the traveling-bands which hold and conduct the sheet of paper in a power-press. The *nippers* take the sheet from the feed-board, and the *fly*, taking it from the tapes, delivers it on to the heap.

Fig. 6215.



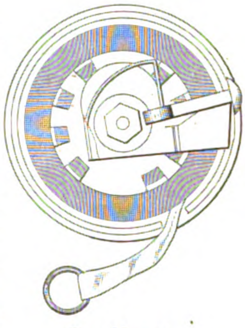
Ring Tap-Borer.

b. A similar band in a paper-folding machine.

Tape-car'ri-er. A tool-holder, like a frame-saw, in which a corundum tape is mounted to be used in cutting or filing.

Tape-fuse. A long, flexible, ribbon-shaped fuse, containing a composition which burns with great rapidity. By means of a fuse of this kind, a charge of powder may be exploded at the distance of several hundred yards, and apparently almost simultaneously with the communication of fire to the other end.

Fig. 6216.



Tape-Measure.

Tape-line. A measuring-tape winding into a case.

Tape-meas'ure. A ribbon of tape or other material winding upon an axis inside a case.

They are made of *linen* or *steel*, from 10 to 100 feet long, and divided into feet, inches, and subdivisions of an inch.

The linen tape-measures of the best quality are interwoven with fine brass wire, to prevent stretching.

The example is so arranged that pressure on the plug will hold the tape at any desired point.

Tape-pri'mer. A narrow strip of flexible material, usually paper, containing small charges of fulminating composition at short and equal intervals apart, and covered with a water-proof composition, as the Maynard primer. It was never much favored in the service, and has been superseded by the plan of placing the fulminate within the cartridge.

The tape-primer required a peculiar lock, having a recess for containing the tape and mechanism for advancing each primer successively to the nipple.

Ta'per. A small wax-candle. Usually having a long wick with such a covering of wax as to allow the taper to be coiled.

Wax tapers are made by drawing a string through a pan of melted wax at a speed regulated according to the thickness desired.

Ta'per-file. A file which is rectangular in section, and whose thickness and width gradually decrease toward the *point*.

The faces are not quite flat in the direction of their length, but are somewhat rounded; technically known as *bellied*.

A flat file, without a belly, is known as a *parallel* file.

Ta'per-vise. One whose cheeks are arranged to grasp objects whose sides are not parallel. See VISE.

Tap'es-try. (*Fabric.*) A kind of woven hangings of wool or silk, frequently raised and enriched with gold and silver, representing figures of men, animals, historical subjects, etc. The term is of somewhat indefinite meaning, and the purpose equally indeterminate. It was originally intended for hangings, to hide the wall, or make a screen or curtain. Ovid mentions human figures as worked on the curtains of theaters.

For an account of ancient tapestry, see Smith's "Dictionary of Greek and Roman Antiquities," article "Tapes."

Tapestry is described in the Book of Exodus.

"Plato, the comic poet, namesake of the philosopher, says: —

'There the well-dressed guests recline
On couches rich with ivory feet;
And on their purple cushions dine,
Which rich Sardinian carpets meet.'

For the art of weaving embroidered cloths was in great perfection in his time; Acesas and Helicon, natives of Cyprus, being exceedingly eminent for their skill in it, being weavers of very high reputation." — ATHENÆUS (A. D. 220).

The tapestry of Pollux, τάπητες, was woven shaggy: the *amphitapetia* was shaggy on both sides; the *tapetia* only on one side; the *ephestris* was shorn.

Tapestry-hangings are said to have been invented by the Pergamenians. Attalus III. bequeathed his kingdom to the Romans, and thence, it is said, hangings were introduced into Italy. The Greeks and Latins had embroidered hangings. These hid the bad carpentry or stone walls. The Anglo-Saxons had wall-hangings of silk, embroidered with needlework or plain. Tapestry was common in England to the time of Elizabeth.

Tapestry was made in France at a very early date. The oldest and most celebrated specimen in existence is the Bayeux tapestry, containing embroideries representing the conquest of England by William the Conqueror, and supposed to have been worked under the supervision of his queen, Matilda. Tapestry was first made by the loom in Flanders. The manufactory at Fontainebleau was established by Francis I. in the sixteenth century; that at Gobelin's was enlarged under Louis XIV.

The French ascribe the invention to the Saracens, and formerly called the workmen who were employed in its manufacture *sarazins*.

The manufacture was introduced into England by Sheldon, in the reign of Henry VIII. It was encouraged by his successors. Hampton Court Palace yet displays their tapestry on its walls.

These hangings were a very ornamental accession to the bare walls of the buildings of some centuries since. Arras, Brussels, Antwerp, and Valenciennes excelled in the manufacture, but the best known at the present day is the factory at the Gobelin's, near Paris. It is named after Giles Gobelin, a French dyer, of the reign of Francis I., and was established by Henry IV. about 1606, and much enlarged by the renowned Colbert in 1666. It is said to have been conducted by Flemish artists.

Hand tapestry is embroidered by the needle, woolen or silken threads being worked into the meshes of a fabric.

Basse lisse is woven upon a loom. The warp is horizontal, and is stretched above the pattern to be copied. The weft is inserted by a *flute*, which partakes of the characters of a needle and a shuttle. A treadle arrangement depresses some of the threads and forms a parted shed. The face of the work, being downward, cannot be inspected until it is removed from the loom; this inconvenience, probably, led to the substitution of the *haut lisse*, in which a vertical warp is stretched between a warp beam and a cloth beam. The pattern is placed at the back of the warp, through the threads of which it may be seen, and the outlines are copied upon the warp. The weft and pattern are then worked in with needles corresponding in number to the kinds and colors of threads used.

Tap'es-try Car'pet. 1. A two-ply carpet in which the warp is first printed and then woven.

2. The patent tapestry rugs have a velvet pile surface with a thick weft shoot of cotton, flax, or other material.

3. Tapestry Brussels carpet, called *moquette*, of a fine quality. *Wilton* carpet.

4. Mosaic tapestry; the cut wool is fixed to the ground by caoutchouc.

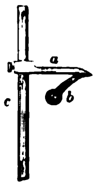
The Persian and Turkish modes of using carpet are the most ancient, the sizes being comparatively small, and placed about a room rather for individual convenience than as a general covering. The terms *tapestry* and *carpet*, or the originals thus translated, are in a little confusion. The ideas are now distinct, but when both were made by hand and in smaller pieces, the differences were rather of position than character. The rugs covered the *triclinia*, or were laid upon the floor, as appears in the representations in Pompeii, and later in the altar-cloths of the choirs in cathedrals and abbeys.

It is recorded that Sinchius, Bishop of Toledo, in 1255, covered his floor with tapestry, — an example followed by Eleanor of Castile, wife of Edward I.

Bedside carpets occur in 1301 on the Continent of Europe; and in the fifteenth century a carpet is shown around a throne, and a bedside rug with a handsome pattern, the remainder of the floor having a checkered matting of two colors.

Tap-hole. An opening at the base of a smelting-furnace for drawing off the molten metal. It is stopped by a plug of refractory clay (*bot*), which is removed in the act of tapping.

Fig. 6217.



Tappet.

Tap'lings. The whang-leather straps which connect the *souple* and *hand-staff*.

Tap'net. A rush basket in which figs are imported.

Tap'pet. (*Machinery.*) *a.* A projecting arm *a* which is touched by a cam *b*, or other moving object, in order to impart an intermittent reciprocation to the rod *c*. Specially used as a valve-motion in steam-engines.

b. A similar device on the stem of a stamp in an ore-battery. It is struck by a cam, lifting the stamp, which falls as the cam slides from under the tappet, its shoe striking the ore in the mortar.

Tap'pet-mo'tion. (*Steam Engineering.*) The apparatus for working the valves of some forms of condensing-engines. The valve-rods have levers attached, which are moved by projecting *tappets* on a rod connected to the beam.

Tap'pet-wheel. (*Machinery.*) A wheel having spurs on its periphery, adapted to trip a lever, trip-hammer, fulling-mallet, etc., or to raise the stamps of an ore-mill.

Tap'ping. 1. Screw threading a hole.

2. (*Founding.*) The jarring of a pattern in its bed in the sand to give it *clearance*. With small castings this is done by sticking a skewer into the pattern and *tapping* it with the *slicker* or *trowel*; with larger castings more energetic means are employed, but in the same way.

3. Boring a hole in a pipe, cask, etc., to insert a plug, connect a branch-pipe, or introduce a faucet, as the case may be.

4. Boring maples for *sugar-water*, as it is called in the Western, or *sap*, in the Eastern States.

Tap'ping-ap'pa-ra'tus. 1. For threading screws. See SCREW-TAP; TAP; TAPPING-MACHINE, 1.

2. For opening the flow-hole of a furnace. See TAPPING-BAR.

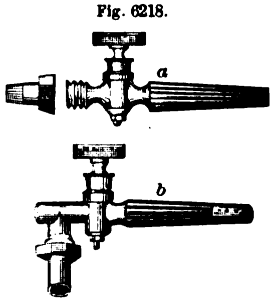
3. For cutting the bark and alburnum of the maple. See TAPPING-GOUGE; AUGER.

4. For boring holes in mains or pipes. See TAPPING-MACHINE, 2; TAPPING-DRILL.

5. For inserting a faucet in a cask. See TAP-BORER; TAP-COCK.

Tap'ping-bar. (*Founding.*) A round bar with a sharp point, used for letting out the metal from the furnace into the ladles. Two such are generally used; the first a light bar with a chisel edge to clean away the unburned clay from the tap-hole.

Fig. 6218.



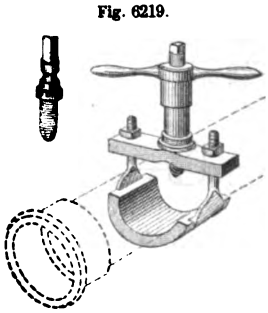
Tapping-Cocks.

Tap'ping-cock. A cock having a taper stem, enabling it to be fixed firmly in an opening by driving.

a, straight-nose tapping-cock.
b, bent-nose tapping-cock.

Tap'ping-drill. One for boring holes in water mains and pipes. A strap goes below the pipe, and has screw-bolts which hold the cross-piece, and also the tube in which the drill-stem works.

Fig. 6219.



Tapping-Drill.

Tap'ping-gouge. A gouge used in tapping the sugar-maple, and in making the spiles to conduct the sap to the buckets.

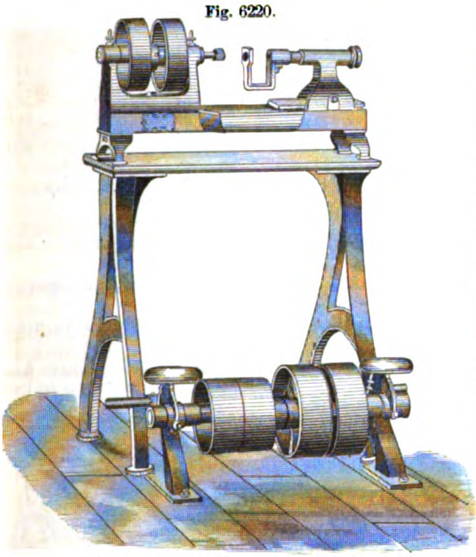
In the West the liquid is called *sugar-water*; in the East, *sap*.

Tapping with the gouge is not now so common; boring with the auger and inserting an elder or a turned spile is the usual plan.

Tap'ping-ma-chine'. 1. (*Metal-working.*) A machine for tapping out internal screw-threads.

In that illustrated, the taps are held in a chuck fixed in the rotary mandrel of the stationary head, and may project as far as desired. The work is held in a clamp on the sliding-head, which is advanced toward the tap. An arrangement is provided for gaging the penetration of the tap when the hole is not to pass through the work, and the motion is reversed in the act of drawing back the work.

Fig. 6220.

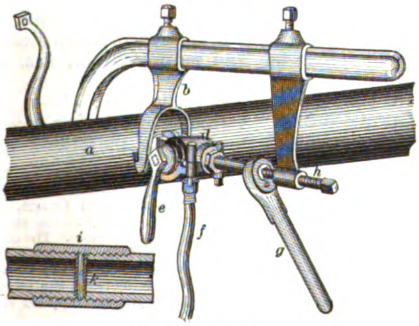


Brown and Sharpe Tapping-Machine.

2. A machine for tapping water-mains.

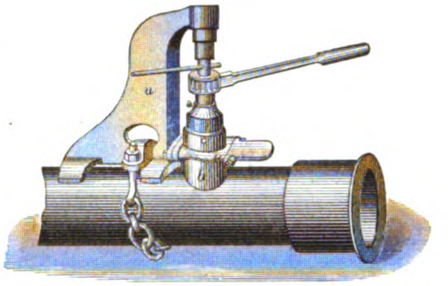
a is the main, against which the device is held by the movable arm *b*. The drill passes through the two-part drill-holder *d*. At the end nearest the pipe is a detachable washer in a socket, having a concave face, which is clamped against a packing-gasket to make a water-tight joint. The handle *e* operates a cock within, through which the drill passes, and which closes the opening when the drill is removed. The connecting-pipe is then substituted for the drill, the cock opened, and the connection made. The hose *f* conducts away the chips. The drill is operated by the ratchet-lever *g* and fed by the screw *h*. *i* is an arrangement for dispensing with the cock usually employed in making connections, and which is afterward left in the earth. A glass plate *k* is interposed between the ends of two sections of pipe, and crushed by screwing the sections together. The pieces are washed out by the flow of water.

Fig. 6221.



Tapping-Machine.

Fig. 6222.



Gas-Main Tapping-Machine.

The apparatus (Fig. 6222) is for tapping gas-mains without causing escape of gas. The curved standard *a* is lashed to the pipe, the drill-stock works through a hollow foot *b*, which is cushioned to render it gas-tight, and is provided with a sliding-valve arrangement, which is closed when the drill is lifted, and kept so until the end of the service-pipe is to be inserted.

Machines for tapping gas and water pipes and mains. Patents: —

Tap'ping-tool. A tool for tapping maple-trees to obtain the resulting sap (New England), or sugar-water (the West), which exudes from the alburnum principally. Tapping is done by a gouge and mallet, by an axe, or by an auger.

Tap-plate. A steel plate furnished with a number of holes which are wormed and notched, to adapt it for cutting threads on blanks.

Fig. 6223.

Tap-Plate.

Tap-wrench. A two-handled lever for rotating a tap used in forming an interior screw-thread. The shank of the tap is held between a fixed and a movable die, which are approached by a screw, and are adapted to hold shanks of various sizes. See DIE-STOCK.

Fig. 6224.

Tap-Wrench.

Tar. A dark-colored resinous substance obtained by distillation from the pine or from coal.

There are many oils resulting from the distillation of coal-tar; some of the light ones being used to produce local insensibility to pain, such as the freezing of the gum in dental operations. One of these light oils, benzol, exhibits in a remarkable degree the number and value of the coal-tar productions. Fifty years ago, in 1825, Faraday discovered, while experimenting on coal-tar, the substance now known as benzol. Twenty years after, a French chemist found that when benzol was treated with nitric acid, a substance called nitro-benzol resulted, having the odor of bitter almonds, and now used for giving almond soap its odor.

About the same time a Dutch chemist discovered a beautiful blue color while experimenting on indigo, and shortly after a blue solution was obtained in alcohol from nitro-benzol. It was soon proved that the two blue colors were of exactly the same constitution, and they were called aniline. They were regarded as curiosities, but no practical use was made of them, as there were many kinds of blue dyes, and much cheaper than aniline. But in 1856 an English chemist, Perkins, while searching for a cheap method of preparing quinine, from nitro-benzol, obtained a beautiful solution of *mauve* color. This was found to be such an effective dye that numerous experiments were made on this substance, and the result is considerably over three hundred dyes of all the beautiful colors of the spectrum, red, orange,

yellow, green, blue, indigo, and violet; first came the *mauvine* and *rose aniline* in 1856, then the *aniline red* in 1859, then the *aniline blue* in 1860, then the *aniline green* in 1863; after that the violets of methylic and ethylic *rosaline*, and *aniline black*.

In 1870, *alizarine*, the coloring principle of madder, was produced from one of the coal-tar products.

Dr. Hofmann, of the University of Berlin, furnishes, in "Percy's Metallurgy," the following list of the compounds generated by the destructive distillation of coal, the new atomic weights being used.

Hydrogen	H	Sextene (caproylene)	C_6H_{12}
Water	H_2O	Septene (œnanthylene)	C_7H_{14}
Carbonic oxide	CO	Ethine (acetylene)	C_2H_2
Carbonic acid	CO_2	Benzol	C_6H_6
Sulphurous acid	SO_2	Toluol	C_7H_8
Hydrosulphuric acid (sulphuretted hydrogen)	H_2S	Xylol	C_8H_{10}
Bisulphide of carbon	CS_2	Cumol	C_9H_{12}
Hydrocyanic acid	HCN	Cymol	$C_{10}H_{14}$
Hydrosulphocyanic acid	$HCNS$	Naphthaline	$C_{10}H_8$
Acetic acid	$C_2H_4O_2$	Anthracene	$C_{14}H_{10}$
Carbolic acid (phenol)	C_6H_6O	Phenanthrene	$C_{14}H_{10}$
Cresylic acid (cresol)	C_7H_8O	Fluorene	$C_{13}H_1$
Phlorylic acid (phlorol)	$C_8H_{10}O$	Pyrene	$C_{16}H_{10}$
Rosolic acid	$C_{20}H_{10}O_3$(?)	Crysene	$C_{18}H_{12}$
Hydrocarbons.		*Basic Nitrogen Compounds.*	
Methane (marsh gas)	CH_4	Ammonia	H_3N
Sextane (propyl)	C_6H_{14}	Aniline	C_3H_7N
Octane (butyl)	C_6H_{18}	Pyrodine	C_5H_5N
Decane (amyl)	$C_{10}H_{32}$	Picoline	C_6H_7N
Duodecane (caproyl)	$C_{12}H_{26}$	Lutidine	C_7H_9N
Paraffine	$C_{10}H_{2n}+_2$(?)	Collidine	$C_8H_{11}N$
Ethene (olefiant gas)	C_2H_4	Parvoline	$C_9H_{13}N$
Tertene (propylene)	C_3H_6	Corindine	$C_{10}H_{15}N$
		Rubidine	$C_{11}H_{17}N$
		Viridine	$C_{12}H_9N$
		Chinoline / Leucoline	C_9H_7N
		Lepidine	$C_{10}H_9N$
		Cryptidine	$C_{11}H_{11}N$
		Pyrrol	C_4H_5N

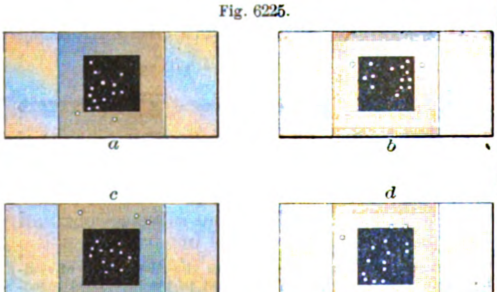
Tarring and feathering was a punishment of offending Crusaders (HOVEDON, "Temp. Richard I."). A bishop of Hulverstadt stripped, oiled, pitched, and feathered a number of monks and nuns.

Tar-board. (*Paper.*) A strong quality of mill-board made from junk and old tarred rope.

Tar′get. 1. A butt or mark in archery or rifle-shooting.

Fig. 6225 illustrates shots made by three of the contestants at the recent shooting-match at Creedmoor between the American and Irish teams; each team was composed of 6 men, and

Fig. 6225.



Target (Creedmoor).

had 15 shots at the distances of 800, 900, and 1,000 yards, making 270 in all for 6 men.

a, H. Fulton, American, 58; 800 yards.
b, J. B. Hamilton, Irish, 58; 800 yards.
c, J. K. Milner, Irish, 57; 800 yards.
d, H. Fulton, American, 57; 1,000 yards.
In a possible 60.

The sizes of the targets of the National Rifle Association at Creedmoor are as follows: —

	Up to 300 yds.	300 to 600 yds.	600 to 1,000 yds.
Size	6 × 2 feet	6 × 6 feet	6 × 12 feet.
Bull's-eye	8 × 8 inches	2 × 2 feet	3 × 3 feet.
Center	2 × 2 feet	4 × 4 feet	6 × 6 feet.

Bull's-eyes count	4.
Centers count	3.
Outers count	2.

See RIFLE.

The following is the complete score of the shooting at Dollymount, Ireland; the targets are shown in Plate LXVIII.

THE AMERICAN TEAM.

	800 yds.	900 yds.	1,000 yds.	Total.
Col. H. A. Gildersleeve	56	56	52	164
G. W. Yale	57	52	51	160
Major Henry Fulton	58	57	46	161
R. C. Coleman	56	48	52	156
Col. John Bodine	52	59	51	162
Gen. T. S. Dakin	58	55	51	164
Total	337	327	303	967

THE IRISH TEAM.

	800 yds.	900 yds.	1,000 yds.	Total.
Wilson	58	50	55	163
Hamilton	56	54	51	161
McKenna	52	44	53	149
Milner	55	37	41	133
Johnson	58	54	50	162
Pollock	59	53	49	161
Total	338	292	299	929

Total for American team	967
Total for Irish team	929
Americans over their opponents	38

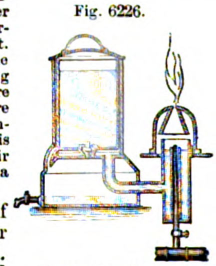
2. The *sight*, sliding on a leveling-staff. Also called a *vane*. See Fig. 2913.

Tar′la-tan. (*Fabric.*) A showy, transparent muslin dress-goods.

Tar-lamp. A lamp for burning tar for purposes of illumination.

The tar is contained in the cylindrical case, and flows from thence by a pipe to the burner, at whose summit it is ignited. The supply-apparatus is on the fountain-lamp principle, and a chamber below the reservoir catches any overflow, which is drawn off by a faucet. A jet of air is introduced through the center of the annular burner, having a pressure of $1\frac{1}{2}$ pounds to the square inch. This is admitted at pleasure by a faucet below. Without the central blast, a small lambent flame is obtained; when the compressed air is admitted, the tar burns with a vivid white light.

Fig. 6226.



Beale's Tar-Lamp.

Tar-pau′lin. A cloth of stout canvas, coated with tar or other water-proof compound. Employed on shipboard and ashore for covering hatches, boats, hammocks, etc., and protecting articles generally from the weather.

A tarpaulin, or thick unpainted canvas, sometimes called a *paulin*, forms part of the equipment for each carriage of a field-battery of artillery.

Tar′rass. A volcanic earth used in making cement. See POZZUOLANA.

Tarred Line. (*Nautical.*) Cord which has been tarred, in contradistinction to *white* line.

Tarred Links. Used for lighting up forts, trenches, etc. They are made of old rope, well beaten, to soften it, and are covered with a composition of pitch, tar, and mutton-tallow, similar to that used for pitched fascines.

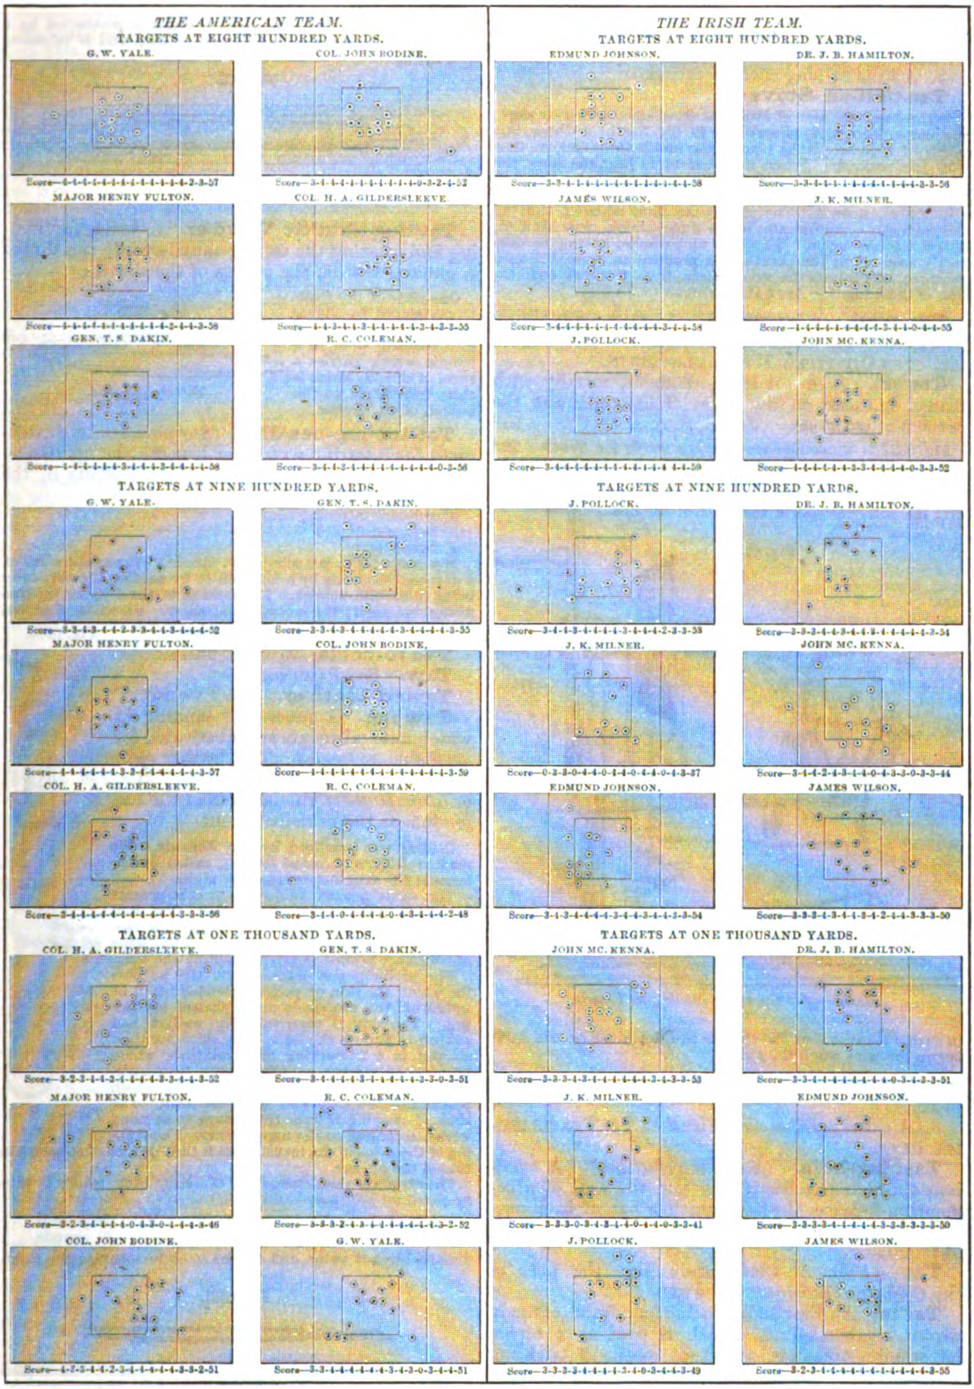
Tar′ris. POZZUOLANA (which see).

Tar′sia-work. A species of inlaying in wood, much practiced in Italy during the Middle Ages, especially for wall-paneling.

Wood in its natural colors was employed in the earlier specimens, but afterward, when more complicated figures, birds, flowers, etc., were introduced, the various pieces were stained; the colors, however, generally lacked permanence. The art was revived some years since in France, and M. Boucherie introduced a method of permanently tinting the wood to a considerable depth. Shades are produced by immersing the pieces in hot sand; the design is built up on paper, and applied in the manner of veneer.

Tar′tan. 1. (*Fabric.*) Woolen cloth, cross-barred with stripes of various colors, forming *panes*, and constituting the peculiar patterns which formerly distinguished the different Scottish Highland clans.

2. (*Nautical.*) A small vessel with one mast and



THE TARGETS AT THE INTERNATIONAL RIFLE-MATCH.

Diagrams showing the Shots made by each contestant of the American and Irish Rifle-Teams at Dollymount, Ireland, June 29, 1875.

PLATE LXVIII.

See page 2498.

a bowsprit, the mainsail being spread by a lateen yard. Used in the Mediterranean.

3. A kind of long covered carriage.

Tar-ta'ri-an Stove.

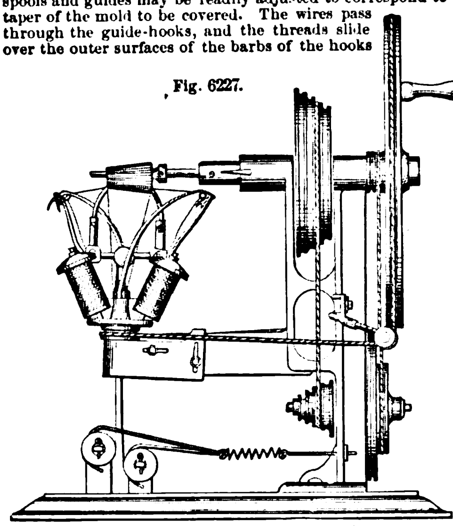
"The *kang*, the sort of large flat stove upon which we slept, was not entirely made of stone, as in the North of China, but partly of movable planks placed one beside the other, so that they join perfectly. When it is desired to heat the *kang*, the planks are taken away, and a quantity of dry and pulverized horse-dung is spread over the interior, and some lighted charcoal thrown upon it. The planks are then replaced, and the fire gradually communicates to the dung, which, once kindled, does not go out again. The heat and smoke, having no outlet [?], soon warm the planks, and produce an agreeable temperature, which lasts the whole night, from the slow combustion of the dung." — ABBÉ HUC, *Travels in Tartary*.

Tar-well. (*Gas-works.*) A tank containing water, through which gas is passed to extract the tar. See DIP-PIPE; HYDRAULIC MAIN.

Tas'sel. 1. A pendent ornament, usually with fringe, and used on the edges of hangings and the corners of cushions.

Fig. 6227 is a machine for covering molds for tassels. The spools and guides may be readily adjusted to correspond to the taper of the mold to be covered. The wires pass through the guide-hooks, and the threads slide over the outer surfaces of the barbs of the hooks

Fig. 6227.



Machine for Covering Molds for Tassels.

in such a manner that the threads are deposited on the wires before the same reach the mold.

2. (*Architecture.*) A board beneath the mantel-piece.

3. A *teasel; Dipsacus fullonum.* See TEASELING-MACHINE.

Tast'ing-hole. (*Steel-manufacture.*) A small hole through the bar-trough and the wall of a cementing-furnace, through which a bar of iron may be withdrawn to examine the condition and degree of progress.

Tat. (*Fabric.*) Cloth made from the fiber of the *Cochorus olitorius.* See JUTE.

Tat'ta. An East Indian name for a frame of finely woven bamboo-splints, which is used as a screen for window-openings, and kept moist by trickling water, so as to cool the air passing through it into the apartment. An *alcarazza.*

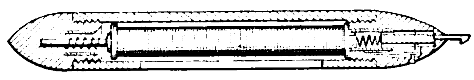
Tat'ting. A kind of lace edging, consisting of a set of loops strung upon a thread, on which they are afterward pulled up to form a loop-edging.

Tat'ting-shut'tle. A small shuttle used in *tatting.*

Fig. 6228 has a sheathed spool with a spring at each end. A tatting-hook at one end of the shuttle may be protruded or sheathed at pleasure.

The shuttle (Fig. 6229) has a pin *b* which is protracted by a thumb-piece to pass a thread through a loop, and is retracted by a spring.

Fig. 6228.

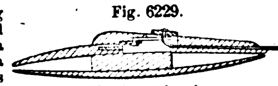


Tatting-Shuttle.

Tat'ting-shut'tle Wind'er. A device for holding and rotating the tatting-shuttle while the thread is guided between the prongs of the shuttle.

One plate of the shuttle is clamped by sliding sleeves on a bar attached to a rotating shaft in a handle which carries a spool of thread, which is thus transferred to the bobbin of the shuttle.

Fig. 6229.



Tatting-Shuttle.

Tat-too'ing-nee'dle. (*Surgical.*) An instrument for inserting a pigment beneath the epidermis. Used professionally for coloring white spots in the cornea.

a, ordinary tattooing-needle.
b, Baader's.
c, Agnew's.

Moses alludes to tattooing (Lev. xix. 28). It was the mark of a devotee, was made by a hot iron or by needles, the punctures being filled with powder. The emblem of the deity or the profession was used; the moon, cross, arrow. Branding of slaves, deserters, and even of recruits, was practiced.

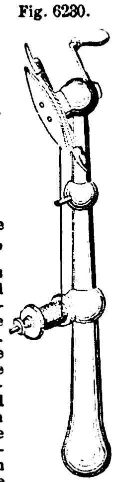
Tau'ro-col'la. Glue of bull's-hide.

Taw. See TAWING.

Tawed Leath'er. See TAWING.

Taw'ing. A process of tanning in which mineral agents are substituted for vegetable extracts. The leather produced is known as *Hungarian, white,* or *alum leather;* the latter from the use of alum as the principal agent.

Fig. 6230.



Tatting-Shuttle Winder.

Tawing was practiced by the Romans. We read in Isidore of *calcei* (shoes), called *alutæ*, because the skin was softened by alum.

The skins usually subjected to this process are those of the goat, sheep, deer, dog, and some other skins of small size, such as the raccoon, ground hog (woodchuck), fox, etc., some of which are tanned as pelts, retaining the hair.

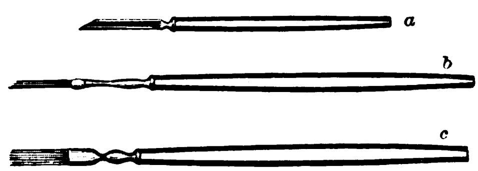
The preliminaries depend upon the purpose for which the skin or pelt is intended; if it be unhaired, the process is accomplished by liming. The skin is then carefully washed and rubbed to remove the lime. The skins are then steeped in a fermenting bran mixture, whose proportions are two pounds of bran to the gallon of water. This develops acetic acid, which neutralizes the lime and swells the skin. The time of steeping is from three days to as many weeks, according to the temperature. The sinking of the skins in the menstruum is the evidence of the completion of the process.

The skins are then steeped in the alum bath, which is thus prepared for 100 sheep-skins: —

Alum	20 pounds
Salt	4½ pounds

dissolved in hot water, and diluted so as to saturate the skins.

Fig. 6231.



Tiemann's Tattooing-Needles.

The skins are tramped in the bath, or subjected to the tumbling operation in a closed revolving cylinder with interior slats.

The skins are then put into a paste made by adding to the alum bath

Wheaten flour	20 pounds
Yolks of	50 eggs

well mixed. The skins are separately treated with this compound, and then left in it for a night. They are then drawn, suspended on poles, and left to dry, being occasionally stretched.

They are then worked on the softening iron to remove unevenness, develop whiteness, and stretch uniformly. The process is completed by stretching on hooks, rubbing with the stretching-iron occasionally, as the drying proceeds.

The skins may be surfaced with pumice, and glossed with a smoothing-iron.

When the *pelt* is to be dyed, the wool or hair is colored previous to the alum bath.

The coloring of the *skin* is by a tinctorial mixture applied to the grain side while damp, and rubbed in by an iron.

Split horse-hides are made into *tawed*, *white*, or *alum leather*, and are the material for leather aprons used by the mechanics of various arts, the pioneers of the army in full dress, for thongs of whips, and for other purposes.

In Hungary and other countries of Europe, alum-tanned leather, said to be equal to bark-tanned, is used to a considerable extent for harness. The process, it is said, may be completed in 24 hours. Heavy ox or cow hides fresh from the slaughter-house are first well washed in salt and water to remove the blood, and then laid on the beam, flesh side up, and well scraped. The hide is then placed on a smaller beam, and the hair removed with a sharp knife, after which it is placed in a tanning solution of salt and alum pulverized; the hide is well sprinkled with this and rolled up, and, as the liquid oozes out, it is heated and poured over the hide; this process is continued for 24 hours, when the leather is ready to take the grease; using a cold solution produces a firmer and less porous leather, but takes more time, — three or four days, — small quantities of alum being added to the solution each day. After scraping, the leather is colored with logwood and a small proportion of copperas: it is then rubbed with iron-black and dried. It is finally well rubbed in the direction of its length, and smeared with a mixture of equal parts of hog's lard, tallow, and train oil on the flesh side, tallow only being used on the grain side.

Taz'za. An ornamental vase with a spreading, flat top.

T-band'age. (*Surgical.*) A bandage shaped like the letter T, consisting of a strip of linen attached at right angles to another strip. When two such strips are so attached it is a double T. Used in supporting dressings in diseases of the perinæum, groin, etc.

Tea-boil'er Cock. A cock having a T-headed thumb-piece, by turning which its valve is opened or closed.

Teache. (*Sugar.*) The smallest evaporating-pan and the one nearest the furnace front. *Tache.* See TACHE.

Teach'ing-ma-chine'. A machine invented by Alfred Long of London for purposes of instruction in languages and music.

It consists of a series of cubes inclosed in a box with a glass side; on these cubes are written the words (or notes, in case of music) which it is intended the child shall learn, and then, by turning the handle of the machine, the words appear in various arrangements, and are read off each time, or translated as they appear, by the pupils.

Tea'gle. A corruption of *tackle.* A name applied in England to an apparatus for hoisting operatives and material to the upper stories of factories. See HOISTING-MACHINE; MAN-ENGINE.

Tea'ket-tle. An ordinary piece of stove furniture for boiling water for infusing tea, etc.

Team-boat. (*Vessel.*) A ferry-boat whose paddles are worked by horses on board.

Team'ing. 1. (*Steel-manufacture.*) The operation of pouring the molten cast-steel from the crucible into the ingot-mold.

2. (*Civil Engineering.*) The operation of transporting earth from the cutting to the embankment.

3. A certain mode of manufacturing work, which is given out to a boss, who hires a gang or team to do it, and is responsible to the owner of the stock.

In the shoe business, for instance, each man has his part to perform. One *lasts*, another puts on the *outer soles*, another finishes *bottoms*, and still others put on *heels* and finish *edges*, and thus the boot or shoe goes through all these different processes until it is completed, packed in boxes, and returned to the manufacturer. After reaching this point they are rigidly examined, the final "finishing-touches" put on, "cased" up, and marked.

Team-shov'el. An earth-scraper. A scoop drawn by horses or oxen, managed by means of handles, and used in removing earth. See EARTH-SCRAPER; SCRAPER.

Tea'pot. A vessel in which tea is infused.

The first notice of tea among the "Western barbarians" is perhaps the account given by Herodotus, Book IV. xxi., xxiii.: —

"Beyond the Tanais the region of Scythia terminates, and the first of the nations we meet with are the Sauromatæ, who inhabit a space of fifteen days' journey. . . Beyond these are the Budini, and beyond them a desert of eight days' journey. [Then follows an orderly account of several countries occupied by other nations, then a stony tract, and eventually a people] living at the foot of some lofty mountains [Himalaya]. They live chiefly on the *produce of a tree* which is called the *ponticus:* it is as large as a fig-tree, and has a kernel not unlike a bean. When it is ripe they press it through a cloth; it produces a *thick black liquor* which they call *aschy:* this they *drink, mixing it with milk;* the grosser parts, which remain, they form into balls [brick-tea] and eat."

The worthy chronicler was mistaken as to one point: it was a leaf and not a fruit. Even then he was much nearer to the mark than one of the large whiskey-distillers of Cincinnati, who observed to a lady in the hearing of the author, "Sponges, madam; I believe they grow on trees."

The annals of China place the use of the leaf at a very remote date. It was introduced into Japan in the ninth century A. D., but was not brought to Europe till some seven centuries later. It was about the middle of the seventeenth century (1664) that the East India Company presented to the queen of England a package of two pounds of tea, then valued at forty shillings a pound. About the same time some Russian ambassadors returned to Moscow, bringing some carefully packed green tea, which was esteemed a great delicacy. The overland tea is still the best.

An advertisement in the "Mercurius Politicus," September 30, 1658, is as follows: —

"That excellent and by all physitians approved *China* drink, called by Chineans Tcha, by other nations *tay*, alias *tee*, is sold at the 'Sultana Head' Coffee-house, London."

"I did send for a cup of tee, a China drink, of which I had never drunk before." — PEPYS, 1660.

In 1667 the British East India Company gave their agents an order for "teas of the best kind to the amount of 100 dollars." In 1678 they imported 4,713 pounds, a quantity which appears to have glutted the market for several years. In 1721 the annual import had reached 1,000,000 pounds.

Tea was used in China long before it was cultivated, several varieties of the bush growing wild.

Among the first notices by foreigners of its use — excepting the remarkable one by Herodotus, the father of history, as he has been termed, and his character for truth and veracity becomes more and more established — is the account given by two Mohammedan travelers of the ninth century, translated from the Arabic by Renaudot, "Ancient Accounts": —

"The emperor also reserves to himself the revenues which arise from the salt-mines, and from a certain herb which they drink with hot-water, and of which great quantities are sold in all the cities, to amount to great sums. They call it *sah* (or *tcha*), and it is a shrub more bushy than the pomegranate tree, and of a more taking smell, but it has a kind of bitterness with it. Their way is to boil water, which they pour over the leaf, and this drink cures all kinds of diseases." El Wahab elsewhere describes the infusion as "drunk out of beautiful cups molded of a rare earth, and made almost as transparent as glass."

"These Mohammedan travelers found a country in which letters were cultivated by high and low. There were schools in every town for teaching the poor to write and read, and the masters were paid at the public charge. There was a large literature of printed books. The governmental officers were selected from the literary graduates, and had been for three centuries" (sixth century A. D.). — PROF. SEWALL.

They had also dials, and clocks, moved by weights.

This was the era of Alfred the Great, the most versatile monarch and greatest man of history. It was also the brilliant epoch of the Moorish occupation of Spain, then the gem of Europe. About this time took place the separation of the Greek and Roman churches, and the temporal sovereignty of the latter was assuming its great proportions.

The *brick-tea* or *tile-tea* of China is used universally over Northern Asia and Chinese Tartary. Tea is used as a beverage and also as an ingredient in stews and soups.

"Brick-tea boiled with salt."

"We seated ourselves on a red carpet, and there was soon brought from a neighboring tent, which served as a kitchen, tea with milk, rolls fried in butter [doughnuts], cheese, dried grapes, and sweetmeats."

"Payments in Tartary are made in brick-tea, whether the

article be a horse, a house, or any other commodity. Five bricks of tea represent an ounce of silver." — ABBÉ HUC, Journey in Tartary, 1844-1846.

Another traveler writes: "On the Thibet side of the Himalaya mountains a tribe of wandering traders, called the Hunnias, travel over great distances, living upon brick-tea, which is brought from China, and consists of the coarsest leaves, twigs, and seeds of the tea, pressed by weights into lumps, and rendered more adhesive by a slight admixture of the serum of sheep's blood. Upon this they perform long journeys."

At Kiachta, in 1862, the imports of tea from China amounted in value to 7,748,816 silver roubles, equal in value to $ 5,812,000, as follows: —

Tea	6,851,445 roubles.
Brick-tea	897,371 roubles.

Fig. 6232, from Hooker's "Himalayan Journal," illustrates a brick of tea, two forms of teapot, and a teacup, used by the Thibetans. A tobacco-pipe, two pouches, flint and steel (which

Fig. 6232.

Teapots and Brick-Tea (Thibetan Himalaya).

might readily be mistaken for a knife), and those Oriental substitutes for the knife and fork, the chopsticks, are also shown.

A nourishing mess is prepared from this brick-tea, which is extensively used throughout the colder regions of Asia, by churning up a handful of the leaves with salt, butter, and soda, and boiling the compound, which is served up scalding hot.

Tea is produced in greater or less quantity and perfection in that part of Asia extending from westward of Nepaul to and including the Japanese islands on the east, and embracing in its greatest width more than 20° of latitude, say from 18° to 38° on the continent, and extending to beyond the 40th parallel in Japan. The great center of production, however, is an oval area in the East, lying on each side of the parallel of 30°, extending back some five hundred miles from the coast, its greatest width being somewhat less. Shanghae is on the extreme northeast boundary of this district, where it is terminated by the coast. Attempts have been made, it is said, recently, with considerable success, to introduce the culture of the plant into Ceylon. It has also been cultivated with some success in Northern India.

About 1844, Dr. Junius Smith, of South Carolina, attempted the culture of tea in that State. The plants throve, but the product could not compete in price with that grown by cheap labor in China. In Brazil, the shrub is found to thrive even more luxuriantly than in China, attaining the proportions of a small tree, but the leaf lacks the delicate aroma which distinguishes it on its native soil, becoming harsh and coarse-flavored Within a few years past it has been naturalized in California, where the climate and soil appear propitious.

Though indigenous in China, the native growth there is not much depended on for a supply. On the contrary, the plant is most carefully cultivated, and affords one chief employment to the people of that vast empire. The plant is grown in almost every variety of soil, but that best adapted to it is a light loam, more or less stony, abounding in vegetable mold, and moist but not wet. The seeds are gathered in October, and kept in sand till the following spring, when they are sown, either in rows in the field where they are to grow, or else in beds, from which they are transplanted; if the latter, they are put out the second year in rows three or four feet apart. In growing, they look not unlike a field of currant-bushes with us. They are hardy, yet if the weather is very cold they need protection; if dry, the cultivators resort to irrigation. The gathering of the leaves sometimes commences the third year, though often not till the fourth. There are three or four harvests, — the first, of leaf buds, early in April, though many prefer to forego this, and allow the leaves to grow. If gathered, these buds make the choicest variety of black tea, known as Pekoe. But new leaves soon appear, and a second gathering occurs the last of April, or early in May, which is the principal harvest, and affords a fine tea as the product. A third gathering occurs early in July, which furnishes leaves of an inferior quality; and sometimes there is a fourth gathering in August or September, which furnishes leaves still coarser and poorer. The plants rarely last more than eight or ten years, when they are dug up and replaced with a new stock. In gathering, the leaves are stripped off with much care, and carried to a building where they are assorted and dried.

The drying process varies as to the kind of tea to be produced, for our varieties of green and black tea are not so much the product of different species or regions as results from different ways of curing the same leaf.

The green teas are cured almost as soon as the leaves are brought from the field, being allowed to remain not more than an hour or two thinly spread upon trays, to dry off any superfluous moisture, before they are put into the roasting-pans. These latter have been in the mean time heated by a brisk fire, and into them are thrown a few of the leaves, which are allowed to remain four or five minutes, rapidly shaken and stirred, when they are thrown out upon a table and rolled with the hands. Afterward they are again thrown into a pan, heated by a slow, steady fire, and allowed to remain an hour or an hour and a half, being kept all the time in motion by the hands of the workmen. Sometimes they are thrown upon a table to be rolled a second time. This completes the chief part of the operation, though afterward, when a considerable quantity has thus been finished, it goes through a farther process of winnowing and sifting to separate impurities, and assorting into different varieties, and reheating also, to be sure that the drying is complete.

Teas for home consumption are never colored. Those for export to Europe and America are made more pleasing to the eye, if not to the palate, by the addition of Prussian blue, China clay, turmeric, and a white powder usually composed of kaolin, soapstone, or sulphate of lime. Black-lead and indigo are also employed for coloring and glazing. Rice or paddy husks mixed with fragments of the tea-leaf, and tea-dust mixed with sand and rice-water, known as "Lie tea," are other factitious products designed to "cheer but not inebriate" the outside barbarian.

The *maté*, or Paraguayan tea, is a holly (*Ilex paraguaiensis*), and is gathered in the woods during the whole year. It is kiln-dried, and then powdered in mortars. In use, a quantity of the leaf is placed in a bowl, steeped awhile in cold water, and then boiling water poured upon it. It is imbibed through a tube to avoid drinking the particles of leaf and stem.

The *yaupon* of the Carolinas, called by the South Carolina Indians the *cassina*, is also an *Ilex* (*I. cassine* or *vomitoria*), and has been used from time immemorial by the Southern Indians, the leaf being a valued article of exchange between the Indians of the coast — where it grows — and the tribes of the interior. It is a stimulant, and acts, according to quantity and the condition of the person, as a diuretic or emetic. It formed the "black drink" of the Indian ceremonials. See Lawton's "Travels in Carolina," London, 1709, pages 90, 91. Also Porcher's "Resources of the Southern Fields and Forests," Charleston, 1869, pages 431-433.

It is also used as a substitute for imported tea by the poorer inhabitants of North Carolina in the vicinity of the sounds, and to a small extent forms an article of domestic export.

A list of vegetable substances prepared by infusion for medicinal or stimulating purposes might be extended to an indefinite length. A few of these, in which the mouth acts the part of a teapot, the saliva serving to extract the stimulating principle, form the ordinary solace of no inconsiderable portion of the human race. To say nothing of tobacco, the chewing of which is pretty much confined to the natives of this country, though approaching cosmopolitan universality perhaps among sailors, we have the *betel* of the East Indies, the use of which is very general over a considerable part of the world's surface, and particularly among the Malayan races.

This is prepared from the leaves of several species of pepper, as *Chavica betle*, *Chavica siraboa*, plucked green and spread over with quick-lime (*chunam*), generally prepared from oyster-shells, and wrapped around scrapings of the areca nut (*Areca catechu*). Though too pungent for a European taste, and, it is said, frequently rendering its users toothless by the age of twenty-five, the Malays of all ages generally keep their betel-boxes in requisition from morning till night. It imparts a red color to the saliva and blackens the lips and teeth. Those species of plants of the genus *Chavica*, a division of the pepper family, which yield it, are extensively cultivated. They are climbers, and are trained on poles, trellises, or the stems of palms.

The coca, in general use among the Indians who inhabit the elevated plains among the Andes, is a stimulating narcotic, consisting of the dried leaves of *Erythroxylon coca*, in combination with a peculiar alkaline substance called *clipta*. Provided with a sufficient supply of this drug, an Indian will make an arduous journey of several days' duration without food. Its habitual use is said to be attended with effects analogous to those of opium. The plant is largely grown in the province of La Paz, in Bolivia, forming an important source of wealth to the inhabitants.

A German authority, Von Bibra, in his Preface to "Die narkotischen Genuss-Mittel und der Mensch" (Man and the Use of Narcotics), assumes the following: "Coffee leaves, in the form of infusions, are used by 2,000,000 of human beings; Paraguay tea is consumed by 10,000,000; coca by as many; betel is chewed by 100,000,000; chicory, either pure or mixed with coffee, by 40,000,000; cacao, either as chocolate or in some other form, by 50,000,000; 300,000,000 eat or smoke hashish; 400,000,000 use opium; Chinese tea is drunk by 500,000,000; coffee by 100,000,000. All known peoples of the earth are addicted to the use of tobacco, chiefly in the form of smoking; otherwise as snuffing or chewing."

Alcoholic stimulants are not included in his estimate.

Tear′ing-ma-chine′. A machine for disintegrating woven fabric to make fiber for reworking. It usually consists of a cylinder with sharp-pointed teeth that seize the fabric close to the feeding-rollers, and tear and deliver it into a receptacle.

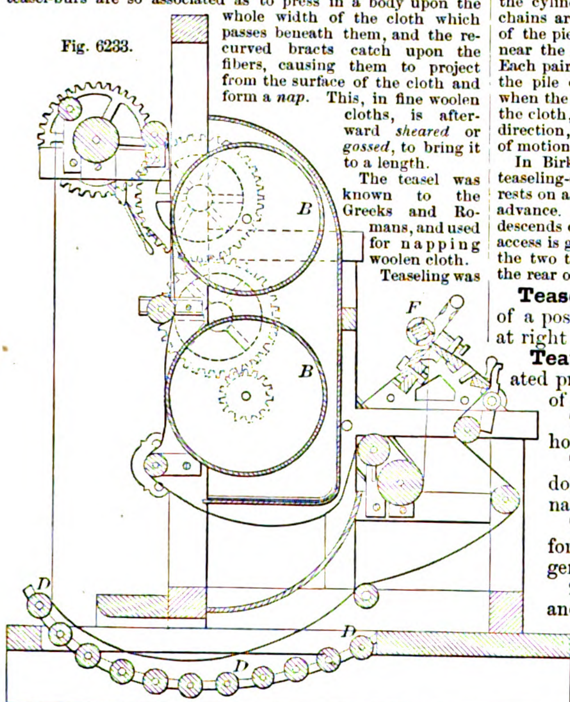
Tears. The vitreous drops from the melting of the walls of a furnace.

Teas′el-ing-ma-chine′. (*Woolen Manufacture.*) A machine in which woolen cloth is teaseled to raise a nap upon it, the ends of the fibers being exposed and laid in one direction, which forms the grain of the cloth.

The teasel (*Dipsacus fullonum*) has large burs with stiff, hooked awns, which are used in raising a nap on cloth. The teasel-burs are so associated as to press in a body upon the whole width of the cloth which passes beneath them, and the recurved bracts catch upon the fibers, causing them to project from the surface of the cloth and form a *nap*. This, in fine woolen cloths, is afterward *sheared* or *gossed*, to bring it to a length.

The teasel was known to the Greeks and Romans, and used for napping woolen cloth. Teaseling was formerly done by hand; a number of teasel-heads being fixed in a small wooden frame with cross handles. The surface of the cloth was worked first in the direction of the warp and then in that of the weft, the cloth being damped. The teasel-heads were cleaned by children with small combs, and when the teasels became damp they were laid aside to dry.

Fig. 6233.

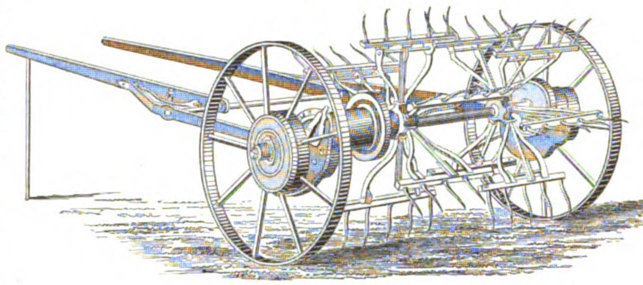


Teaseling-Machine for Finishing Woolen Cloth.

In the *gig-mill* the teasels are arranged in long frames attached to a hollow rotating cylinder, and the cloth by means of rollers is moved in a direction opposite to that of the cylinder, superseding the hand method. See GIG-MILL.

Oldland's teaseling-machine, English patent, 1830, consists of a horizontal, revolving *teasel-frame*, furnished on its under side with teasels, wire-cards, brushes, or other materials used in dressing, or raising the pile of the cloth. The revolving teasels are put in motion by a band on the spindle; and as the cloth is brought under the teasels by conducting rollers, it is pressed up against them by supporters covered with elastic material. There are two teasel-frames in the breadth of the goods, and each of these has a motion from the middle of the goods to the selvage and back again, so that the operation on the cloth is not rectilinear, but by the end motion of the cloth the lines of action continually cross each other at fine angles.

Fig. 6234.



English Hay-Tedder.

Ferrabee's teaseling-machine, English patent, 1830, employs two series of teasels, each attached to an endless chain, which passes around two cylinders, by which it is put in motion, the pile being raised from the middle sloping to the sides. Two of the cylinders which support and give motion to the teasel-chains are placed with their axes extending along the middle of the piece of cloth, and the other two cylinders are placed near the selvages of the cloth with their axes parallel thereto. Each pair of cylinders is made to turn in a direction to raise the pile of the cloth from the middle toward the selvages, when the cloth is at rest; but when an end motion is given to the cloth, the line of action of the teasels assumes an angular direction, whose obliquity is determined by the respective rates of motion of the teasels and the cloth.

In Birkenshaw's machine (Fig. 6233), the axes of the two teaseling-cylinders *B B* are in one vertical plane. The cloth rests on a series of rollers *D D D*, allowing but not forcing its advance. The cloth, after passing over the upper feed-rollers, descends on a series of rollers and goes under a bridge *F*, where access is gained to it by the attendant as it runs in contact with the two teaseling-cylinders. A shearing-cylinder is placed in the rear of the lower teaseling-cylinder.

Tease-ten′on. (*Joinery.*) One on the summit of a post, to receive two beams meeting each other at right angles.

Teat. (*Mechanics.*) A small, rounded, perforated projection, otherwise called a *nipple*, as that of a gun.

Tea-urn. A metallic, vase-shaped vessel to hold hot water for replenishing the teapot.

Teaze-hole. (*Glass.*) (Fr. *tizard*, "fire-door.") The fuel-opening in the glass-furnace.

Ted′der. 1. A rope, strap, cord, or lariat, for fastening an animal by the head to a manger, post, or stake. See TETHER.

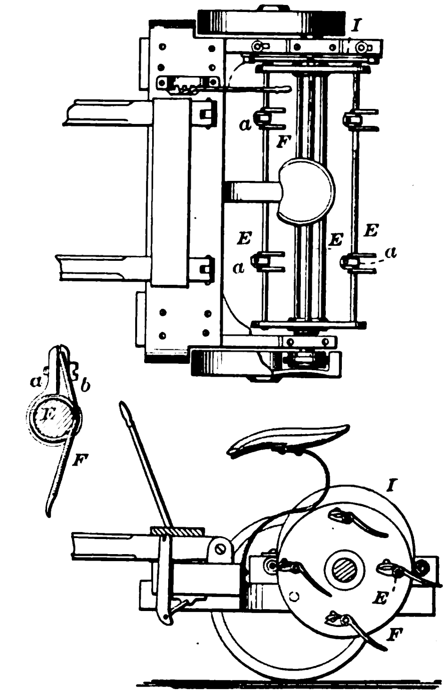
2. (*Agriculture.*) A machine for stirring and spreading hay, to expedite its being dried by the sun and air. See HAY-TEDDER.

The English hay-tedder (Fig. 6234) has two separately rotating cylinders, and is so arranged that the action of the barrels may be easily reversed, so that after the grass has been strewn in the usual way, by reversing the motion, throwing it backward, it is laid very lightly and loosely, permitting more free access of air for drying.

Tedders are classed as *Reels*, *Kickers*, and *Endless* belts, according to their mode of action.

In Fig. 6235, the bars *E* carrying the tedder teeth *F* are connected by cranks to a revolving ring *I* which is confined between two rollers, and so arranged as to cause the teeth to point in the same direction during their entire revolution with the tedder-frame. Screw-clamps *a b* secure the teeth upon the tedder-bars.

Fig. 6235.



Hay-Tedder.

Tedge. The *ingate* or aperture in a mold through which the molten metal is poured. The metal hardened therein is a *sprue*, or *waster*.

Tee. A T-shaped pipe-coupling, adapted for a stem-pipe and two branches.

Tee-ir'on. A rod with a cross-bar at the end, for withdrawing the lower valve-box of a pump.

Teem'ing-punch. One for *starting* or driving a bolt out of a hole. A *drift*.

Teest. A stake or small anvil used by sheet-iron workers. See STAKE.

Teeth. The plural of tooth.

It signifies a row of wires, prongs, or projecting pieces, which have various forms and duties in different tools, implements, and machines, as, —

The teeth of a comb, rake, saw, file, etc.

The wires of a carding-machine or curry-card.

The cog of a gear-wheel.

The tine of a fork. See TOOTH.

Specifically: The lower zone of facets of a *rose-cut* diamond, forming a truncated, pyramidal base for the *crown*, or projecting portion. See DIAMOND.

Teg'u-la. A roofing-tile.

Tein'o-scope. A name given by Sir David Brewster to the prism-telescope.

If a prism be placed horizontally with the refracting edge downward, so that the visual rays from an object enter and emerge from it at equal angles, the object will appear of its natural size; if the refracting edge be turned toward the object, this will appear to be elongated or magnified vertically. A similar prism placed vertically magnifies the object in the direction of its width; and a combination of the two gives an image enlarged in both directions, but fringed with the prismatic colors. This may be corrected by making the prisms of a glass which only transmits one color; by viewing the fringed image through a piece of glass of this kind; or, what is better for most purposes, by using a second pair of similar prisms placed in reversed directions to the first.

Professor Amici, of Modena, used a combination of four rectangular prisms, having their refracting angles different and connected in pairs; the pair nearest the edge are vertical, and the second pair horizontal, so as to produce equal refraction in each direction, the magnifying power being about three times. This plan is well adapted for ordinary glasses.

Tel-a-mo'nes. (*Architecture.*) Male figures serving as columns or pilasters. Somewhat similar are *Atlantes, Persians, Caryatides*, etc.

Tel'e-graph. In a general sense, the word *telegraph* includes all modes of communicating intelligence to a distance. The modes may be classified as, —

1. Visible.
2. Audible.
3. Tangible.

1. Of the first are: —

a. Semaphores; moving or posturing arms (*Chappe's; Pasley's; Popham's*).

b. Arrangement of disks, triangles (*Edgeworth's*), lanterns, arbitrary characters (*Hook's*).

c. Waving flags or torches (*Polybius*) by day or night.

d. Various flags disposed on signal halyards (*Marine Code*).

e. Colored lights.

f. Rockets varying in number or variety.

g. Intermittent flashes of light, from a mirror (*heliotrope*), or a lantern.

h. Puffs of smoke, according to a code.

i. A moving pointer acting by electric impulse (*Wheatstone and Cooke's telegraph*).

j. An adjustable column of liquid (*Percival's hydraulic telegraph*).

k. The printing (*House, Hughes*), dotting, and marking a traveling ribbon (*Morse*), chemical paper (*Bain*), and autographic (*Caselli, Bonelli* telegraphs, which imprint or impress visible characters on paper.

l. The electric telegraph, read by the passage of sparks to a conductor (*Bain*).

2. Of the *audible* may be enumerated: —

a. The clicking (*Morse apparatus*) and its imitations.

b. A bell actuated by electric connections (*Bell*). (*The telegraphic sounder.*)

c. Mechanical, noisy devices; horns, gongs, drums, trumpets, whistles, clappers; some actuated by machinery, as alarms, especially for marine *fog-alarms*. See SIREN.

d. Firing of guns; varied as to intervals or rapidity.

3. Among the *tangible* may be stated: —

a. The Morse instrument read by the pulsations of the armature.

b. An electric telegraph read by the shock transmitted.

The subject of telegraphs is considered under various special titles, and detailed description of each at this place would involve repetition.

A brief summary of the principle and general

method of operation of the electro-magnetic telegraph may not be out of place here. The parts common to all the various forms are :—

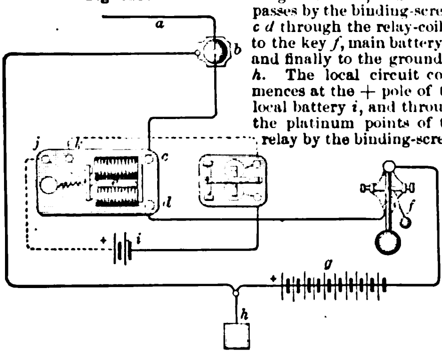
1, a *battery* for generating the electricity ; 2, a *wire* for conducting the current ; 3, a *transmitting instrument*, by which the circuit is made and broken to cause the intermittent impulses which make the signals ; 4, a *receiving instrument*, having a needle or armature which vibrates under the influence of the pulsations of the current.

Various forms of constant battery are used ; one is required at each station for transmission, a pole of each being connected by the wire with the opposite pole of the other ; the other poles are connected with the earth, which completes the circuit. When so arranged, the batteries are said to be reversed. When connection is made between the line wire and the battery at the transmitting station by means of key, lever, or other contrivance, the current flowing through the electro-magnetic coil at this station passes through the wire to another coil at the receiving station, by which it is intensified, regaining a portion of the force which it had lost by the resistance of the wire, and acquires sufficient power to operate the indicating or recording device, having done which it is conducted away to the earth. A current may thus be transmitted to any distance by having *relay* magnets at proper intervals to restore the strength of the current when it becomes enfeebled. The receiving apparatus at any or all intermediate stations may be included in the circuit, so that the dispatch will be repeated at those points, or it may be thrown out of the circuit, so that it will be received only at the extreme end of the line.

When the transmitting apparatus is out of connection with the battery, the current passing from the pole of one battery to the opposite pole of the other is conducted away to the earth. In some forms of telegraph, however, as the fire alarm, the circuit is continuous through the signaling instrument, the signals being made only when this circuit is broken.

Fig. 6236 shows the arrangement of wires, batteries, and instruments for one of the terminal stations of a line. The line-wire *a* first enters the lightning-arrester *b*, and thence passes by the binding-screws *c d* through the relay-coils *e* to the key *f*, main battery *g*, and finally to the ground at *h*. The local circuit commences at the + pole of the local battery *i*, and through the platinum points of the relay by the binding-screws

Fig. 6236.

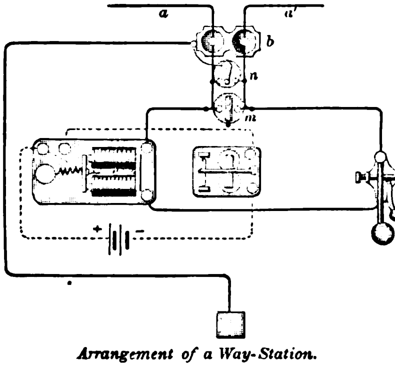


Arrangement of a Terminal Station.

j k, thence through the register or sounder coils *l*, and back to the other pole of the battery.

Fig. 6237 is a plan of the instruments and connections at a way-station. The line-wire *a* passes through the lightning-arrester *b* to the relay *e*, key *f*, back to the lightning-arrester, and thence to the next station. The local circuit is arranged similarly to the preceding. *m* is a *cut-out*, which may be turned so as to directly connect the wires leading into and out of the office, allowing the line-current to pass without going through the office. The *ground-switch n* is used to connect the line with the earth on either side of the instruments at pleasure. It is only used in case of accidents or interruptions on the lines.

Fig. 6237



Arrangement of a Way-Station.

Various as are the forms of telegraphs, and the appliances used in their working, they may be divided into a few general classes, dependent on the manner in which their indications are made.

1. The *indicator* or *needle* telegraph, in which the signals are read from the deflections of a needle to the right or left of a median line ; such is Wheatstone and Cooke's. The submarine telegraph, where the reflecting galvanometer of Thomson is employed, is a variety of this class.

2. The *disk*, *dial*, or "step-by-step" telegraph, having the letters of the alphabet arranged near the periphery of a disk, which is rotated *step* by *step* until each letter of a word is brought opposite an index. The magneto-electric telegraph of this kind is very convenient for local purposes in cities, requiring no battery and no skill in manipulation.

3. The *recording* telegraph, in which dots and dashes, representing the various letters and numbers, are marked by appropriate mechanism upon a strip of paper, as in the original Morse telegraph.

The *electro-chemical* telegraph of Bain and others belongs to this class.

4. The *printing*-telegraph, by which the letters are printed in ink upon a strip of paper, each from its appropriate key at the other end of the line. Such are those of Hughes, House, and others.

5. The *autographic* telegraph, which makes an exact facsimile of the message sent upon a prepared sheet of paper, as those of Caselli and Bonelli. This is a peculiar modification of the electro-chemical telegraph.

6. The *automatic* telegraph was invented by Wheatstone in 1858.

In the modern automatic telegraphic process, telegrams, by a device founded on the idea of the Jacquard loom, may now be committed to a roll of paper, punched with holes instead of letters, and dispatched automatically. The punched roll delivers its message to the instrument without attendance, and the message is printed at the other end of the line at the same time. The advantage claimed for this system is a gain of time, and the liberty to send messages when the line is in the most favorable condition without the assistance of the operator.

A larger number and greater variety of ideas can be conveyed with greater exactness in fewer words in the English language than in any other. Its advantage over French or German, for instance, is said to be from 25 to 33 per cent.

The telegraphs of the world are estimated (Hawkshaw) at 400,000 miles, at $500 per mile = $200,000,000.

The wire is now in all cases, except those of submarine cables, and sometimes in cities, conveyed upon poles. In this country any kind of available wood is used, and in passing through forests the wire is frequently attached to living trees. The poles seldom undergo any treatment for the purpose of preserving them. In England more pains is taken. The timber generally employed is larch treated with sulphate of copper, or red fir creosoted by the Bethel process. When not sulphated or creosoted, they are well seasoned and then painted, the but-ends being slightly charred to a foot above the ground line and tarred. Each pole is provided with an earth-wire or conductor for conveying electricity escaping from the wires in wet weather to the earth. These sometimes project above the tops of the poles, and serve as lightning-arresters.

The poles are also stayed by wire ropes connected to rods inserted in the ground, and in exposed positions double stays are employed.

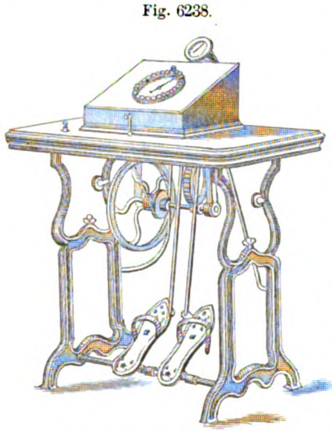
On railway lines the Varley double-cone brown-ware insulator is employed, and on canals and highways the single-cone white-ware or porcelain insulator. The wires are attached to the insulators at every post. What is known as the Britannia joint is exclusively employed for uniting the lengths of wire. This is made by bending the ends of the two wires, placing them side by side for a distance of three inches, binding them together with No. 19 wire, and soldering them.

The *domestic* or *district* telegraph is designed to connect stores, private dwellings, or other houses in cities with a central station, where there is an observer to attend to the messages received. The transmitting instrument is attached to the wall at a convenient place in the house, and connected by a wire leading to the roof, with a wire leading to the station ; it is provided with three knobs or levers, one for sounding an alarm of fire, another for summoning a policeman, and a third for indicating that a messenger is wanted. On either of these signals being transmitted, the requirement is at once indicated and attended to at the central office.

Fig. 6238 is a magneto-electric dial-telegraph adapted for railroads and private business purposes. The electricity is generated by working the treadles which rotate the armatures of the magnets. When the crank at the front of the machine is in upright position, as shown, the alarm from a distant station may be received : it is turned to the right when desired to transmit a message ; in either diagonal position the circuit is

broken, and when turned to the left the circuit is through the indicator only.

Fig. 6238.



Magneto-Electric Dial-Telegraph.

The automatic-alarm telegraph is constructed for "thieves" and for "fire." In one case, the shutters, windows, and doors are so connected with an alarm in an office or the bed-room as to spring an alarm if any of the said objects are tampered with.

In the other case, thermostats are placed at all necessary points, and when at any of these the heat of the room or passage rises a degree or two above the point for which it is set, an electric contact is made and the alarm is sprung.

The following patents of Watkins may be consulted: March 10, 1863; May 10, 1870; January 31, 1871 (six patents); March 28, 1871; October 27, 1874.

The system of *fire-alarm telegraphs*, now so general in large American cities, is referred to on page 849, and the devices on page 1913, REGISTER; page 1918, REPEATER.

One important application of the telegraph is for determining differences of longitude. For this science is largely indebted to Dr. Locke, of Cincinnati, by whom it was successfully practiced as far back as 1848. Cambridge Observatory, Mass., has thus been brought into direct communication with San Francisco by connecting the wire with the pendulum of a clock at Cambridge, so that the main circuit is broken and instantly closed at each oscillation; the moment at which the circuit is broken is noted by the observer at San Francisco, by a clock regulated to local time there, which, being compared with the local time at Cambridge, gives the difference of longitude between the two places. Many other stations, both in Europe and America, have been connected, and their longitudes determined in this way.

The moments of breaking and closing the circuit are practically the same at both places, the velocity with which the current traverses the wire being comparable only to that of light, though Professor O. M. Mitchell determined that a minute though appreciable interval of time elapsed during its passage between two widely separated stations.

The telegraph was first used for military purposes during the Crimean war, 1854-55. Its application for this purpose was greatly extended during our recent civil war, and has now become systematized in the armies of Europe.

In the French army the whole apparatus is carried in a covered carriage, divided into two compartments, one for an office, and the other containing a reel of wire. In the office is a table for supporting the instrument, two accumulators, one for the batteries, and the other for the signal-bells, and a seat for two persons. The reel is supported on its axis in the rear compartment, so that the wire unwinds as the carriage proceeds; it contains 3 kilometres (nearly 2 miles) of wire, and extra reel carriages are provided, each carrying 21 kilometres (over 13 miles) of wire on 7 reels. The wire is composed of 4 copper threads twisted together, and protected by an insulating coating of fiber and india-rubber, so that when laid on the ground it will sustain the passage of vehicles without injury. Poles are used in special cases. Each telegraph-carriage is in charge of a sergeant, two corporals, and twelve men divided into three squads, the first of which goes ahead with the sergeant, traces the line, cuts a trench for the wire, or makes the poles; the second has charge of the reels, and makes the necessary splices, and the third lays the wire or fixes it on the poles. In mountainous countries mules are substituted for the carriage; one carries a small tent, a tripod table, stake, the battery, and tools; another two reels of wire; a third draws a barrow which serves as a reel-frame, which is guided by two men, who carry it in difficult places. See TELEGRAPH-CARRIAGE.

Tel'e-graph'ic A-larm'. (*Telegraphy.*) A sounder operated by electro-telegraphic means.

There are many forms: —

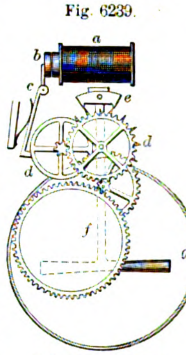
The alarm which runs down, a detent being withdrawn from the escapement. See ACOUSTIC TELEGRAPH, page 11.

The clicking-instrument, operated by successive impulses. This has grown into the ordinary telegraph, which is read by sound.

See also TELEPHONE.

Although Franklin, in 1748, fired spirits by means of a spark transmitted across the Schuylkill, the first distinct plan for a telegraphic alarm to call the attention of an operator or correspondent was by Schweigger, about 1811. He proposed a pistol, charged with a mixture of oxygen and hydrogen gases, to be fired by a spark derived from the long electric wire proceeding from the distant station.

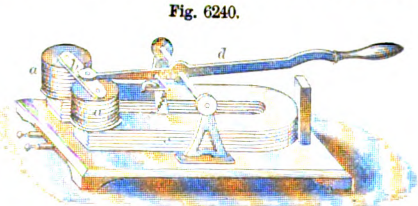
Fig. 6239.



Telegraphic Alarm.

Fig. 6239 is an alarm with an escapement. *a* is an electro-magnet; *b* an armature of soft iron, which is attracted as often and as long as the voltaic current circulates through the coil, but is prevented from coming in actual contact therewith by means of two copper studs tipped with ivory. The armature is mounted on the short arm of a lever *c*, which is normally pressed by a spring so as to engage a stop on the wheel *d*, preventing it from moving. When a current passes through the coil, the armature, being attracted, releases the lever from the stop, and clock-work mechanism operating through the scape-wheel *d* upon the pallets *e* causes the hammer *f* to vibrate, striking each side of the bell *g* alternately.

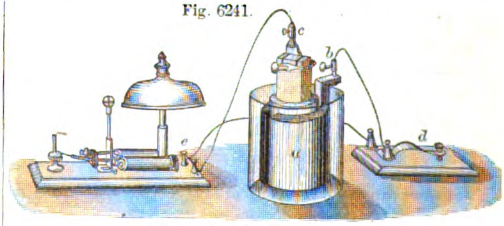
Fig. 6240.



Magneto-Electric Telegraphic Alarm.

In Fig. 6240, the hammer is rung without the intervention of an escapement, by means of a current of magneto-electricity. The cores of two coils *a a* are connected by a bar *b*, and serve as keeper to the horseshoe magnet *c*. On depressing the lever *d*, these are raised from the poles of the magnet, creating a current which passes through the coils and along the line to the bell.

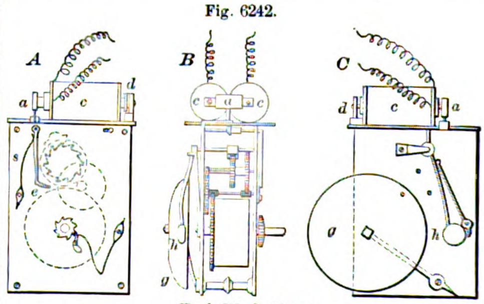
Fig. 6241.



Connection for Bell-Alarm.

Fig. 6241 exhibits the connections for a bell-alarm *a* is the battery; *b*, the zinc-pole; *c*, the carbon-pole; *d*, the key; *e f*,

Fig. 6242.



Clock-Work Alarm.

the binding screws of the bell-magnet. When the key is depressed, the battery current is thrown upon the bell. The three elements of the circuit may of course be separated by any distance within that through which the battery is able to transmit its current. A sounder or register may be substituted for the bell.

In the alarm, of which a side view is shown at *B*, and front and back views at *A C*, Fig. 6242, two electro-magnets *c c*, having their coils connected and wound in similar directions, are joined at one end by a piece *d* of soft iron. At the other end is pivoted a soft iron armature *a*, placed at such a distance as to be strongly attracted by the electro-magnet when the circuit is completed through its coils, and is connected with a detent *e*, which ordinarily engages a fly, but is released when the armature is attracted by the closing of the circuit, allowing a train of clock-work, impelled by a spring or weight to operate, and through the medium of a scape-wheel and pallets, causing the hammer *h* to strike the bell *g*. When the current ceases to flow, the armature is retracted by the spring *s*, again locking the mechanism.

Tel'e-graph–ca'ble. (*Electricity.*) The essential features of a submarine telegraph-cable are a wire or wires for conducting and a protecting compound. To these are added sheathing, to protect against abrasion or other injury, and sometimes material to increase the tensional strength of the cable. With these conditions to meet, there have been numerous patents in the United States and in England, but the patents of the latter country are in such a chaotic condition that it is almost impossible to give an intelligent idea of them. The same invention is the subject-matter of numerous patents, and the futility of many of the devices is only exceeded by the utter looseness with which they have been lapped and piled upon each other.

The inventions concern particularly, —

1. The arrangement of the coated wires in clusters with protecting envelope.
2. Wrapping or enveloping in light material to give buoyancy to the cable, and prevent the parting of the wire when laying it in deep water.
3. Modes of connecting and splicing the ends of sections or lengths of wire.
4. Machinery for constructing the cable; that is, putting on its insulating and preserving covering while the wire is paid off from a reel, or reels.
5. Materials for insulating and modes of applying the materials.
6. Coating and preservative materials over the insulated wire, or clusters of wires.
7. Means and modes of storing.
8. Machines for paying out, registering, and laying.
9. Modes of recovering, under-running, and mending.
10. Transmitting and receiving instruments.

The wires are of copper, frequently tinned, and generally coated with gutta-percha, but preferably with india-rubber. The details are very varied in different establishments, and for different kinds of cable.

In 1839, Dr O'Shaughnessy constructed a telegraph-line 21 miles long near Calcutta, embracing 7,000 feet of submerged wire; this was covered with cotton thread saturated with pitch and tar.

Professor Morse is said to have laid a wire between New York and Governor's Island in 1842.

In March, 1845, Brooman, in England, patented the method now universally employed for preparing gutta-percha; and in September of the same year Bewley patented a machine for making tubing, hose, etc., on the principle of Tatham's American machine for making lead pipe, patented in 1841.

In 1846, Mr. James Reynolds, of New York, invented a machine for covering iron wire with india-rubber, and in 1848, by the aid of this machine, covered a wire with gutta-percha, which was laid between New York and Jersey City.

Telegraphs of wire coated in this way were extensively introduced into Prussia in 1847-48, and in the latter year a gutta-percha covered wire was laid across the Rhine at Cologne by Dr. Siemens.

The first submarine cable ever laid in the open sea was laid between Dover, England, and Cape Grinez, France, in 1850. It was a single strand of wire, 27 miles in length, covered with gutta-percha, unprotected by any outside coating, and worked only one day. The next cable was also laid between Dover and Calais, in 1851. This cable was covered with iron wire, contained 4 conducting wires, was 27 miles in length and weighed 6 tons per mile. It was a permanent success. The next long cable was laid in 1853, between Dover and Ostend, a distance of 80 miles, contained 6 conducting wires, and weighed 5¼ tons per mile. In 1853 a cable of 1 conducting wire was laid between England and Holland, 120 miles, weighing 1¼ tons per mile. This cable worked for 12 years. From 1853 to 1858, 37 cables were laid down, having a total length of 3,700 miles; of which 16 are still working, 13 worked for periods varying from a week to five years, and the remaining 8 were total failures.

An unsuccessful attempt to lay a telegraph-cable between Ireland and Newfoundland was made by the "Niagara" and "Agamemnon" in 1857. In the succeeding year these vessels joined their cables in mid-ocean, and successfully completed the work. On the 16th of August, a message and reply were transmitted between Queen Victoria and President Buchanan. After 23 days, 400 messages having been transmitted, it was found to have lost its conducting power.

The name of Cyrus W. Field is indissolubly associated with the subatlantic cable enterprise.

The cable of 1858 consisted of a

Conductor. A copper strand of 7 wires, 6 laid around 1; weight, 107 lbs. per nautical mile.

Insulator. Gutta-percha laid on in 3 coverings; weight, 261 lbs. per nautical mile.

Outer Coat. 18 strands of charcoal iron wire, each strand made of 7 wires, twisted 6 around 1, laid equally around the core, which had previously been padded with a serving of tarred hemp.

Breaking Strain. 3 tons 5 cwt.; capable of bearing its own weight in a trifle less than 5 miles depth of water.

In 1865, it was attempted to lay a second cable. The operation was intrusted to the monster steamer "Great Eastern," which commenced the work of laying the cable on the 23d of July. After a considerable length had been paid out it parted, and the broken parts could not be recovered. This cable was much stronger than that of 1858, being made up as follows: —

Conductor. A copper strand of 7 wires, 6 laid around 1; weight, 300 lbs. per nautical mile; embedded in Chatterton's compound.

Insulator. Gutta-percha and Chatterton's compound; weight, 400 lbs. per nautical mile.

Outer Coat. 10 solid wires, drawn from homogeneous iron, each wire surrounded with tarred manilla rope, and the whole laid spirally around the core, which had previously been padded with a serving of tarred jute-yarn.

Breaking Strain. 7 tons 15 cwt.; capable of bearing its own weight in 11 miles depth of water.

Length. 2,300 nautical miles; actually laid, 1,896½ miles.

In 1866 a second attempt was made by the "Great Eastern," resulting in perfect success. She also succeeded in grappling the end of the cable laid the preceding year, and splicing it, so that there were now two lines of transatlantic telegraph. The cable employed on this occasion was similar to that of the year before, but of somewhat greater strength, 8 tons 2 cwt., its length 2,730 nautical miles, of which 1,868¼ miles were laid down, part of the remainder being employed in splicing the cable of 1865.

The distance in each case between the two points connected was about 1,600 nautical miles; the depth of water nowhere exceeding 2.7 miles.

The weight of the second laid (British) Atlantic cable was 2,740 cwt. In laying it while the "Great Eastern" was going at the rate of six knots an hour, the cable passes out at an angle of 6½° only, so that the inclined plane between the ship and the bottom was 17 miles long. The motion of the vessel in rolling, etc., had little effect; the greatest strain never exceeded one tenth of the breaking strength.

The paying-out mechanism consisted of six grooved wheels fitted with brakes; the cable was pressed into the grooves by six riding wheels, also provided with brakes, and kept down by levers and weights on their shafts; these served to keep the cable tight on the paying-out drum, 6 feet 1 inch in diameter, and 1 foot broad; four turns of the cable were taken around this, and it thence passed over a dynamometer wheel, which deflected it by a lever loaded with weights, and finally over a grooved wheel overhanging the stern of the ship. The apparatus subsequently used was similar to this.

The fifth Atlantic cable, between the coast of Ireland and Newfoundland, was laid by the "Great Eastern," assisted by three other steamships, each fitted with laying and picking-up machinery. The work was begun on the 16th June, 1873, and on the 27th the "Great Eastern" reached Heart's Content, Newfoundland, having payed out 1,700 miles of cable in 11 days.

This cable was made at the works of Siemens Brothers, near London, and is composed of a thick central wire, which is passed through a peculiar composition, and afterward surrounded by eleven smaller wires, the whole being cemented together by the composition. It is then coated with gutta-percha, and served with manilla fiber to the diameter of ¾ of an inch; the whole is then covered with ten iron wires spun on, each wire being previously wrapped with hemp, and afterward passed through two tanks, by which it is coated with tar, and finally coiled away in large tanks until wanted for use.

The following is a list of oceanic cables laid throughout the world up to the close of 1874. Those marked thus * are not working at the present time.

OCEAN TELEGRAPH CABLES OF THE WORLD.

Date.	From	Length in Miles.	Greatest Depth in Fathoms.
1850	*Dover, England, to Calais, France	25	30
1851	Dover, England, to Calais, France	25	30

1874	Valentia to Newfoundland	1,900	

United States vessels have lately been employed in taking soundings for the Pacific cable.

When this line of telegraph is laid, its length between the terminal points, namely, San Francisco and Yokohama, will be 5,573 nautical miles. The cable will, however, be divided into three sections, — from San Francisco to Honolulu, 2,093 miles; from Honolulu to Midway Island, 1,220; and from Midway Island to Yokohama, 2,260 miles.

a, Fig. 6243, is the Ohio River cable. It is composed of an interior wire of No. 10 Swedish iron, surrounded by three coats of gutta-percha and three of Osnaburg, the whole inclosed in No. 10 longitudinal wires, and lashed with one of similar size.

b is the Hudson River cable. It has three No. 10 conducting wires, each insulated by a gutta-percha covering inclosed in the same material, and is wrapped with tarred yarn.

c is an improvement on this, the wires being separated by solid gutta-percha incorporated in one mass with that which envelops all three. This is covered with tarred hempen twine.

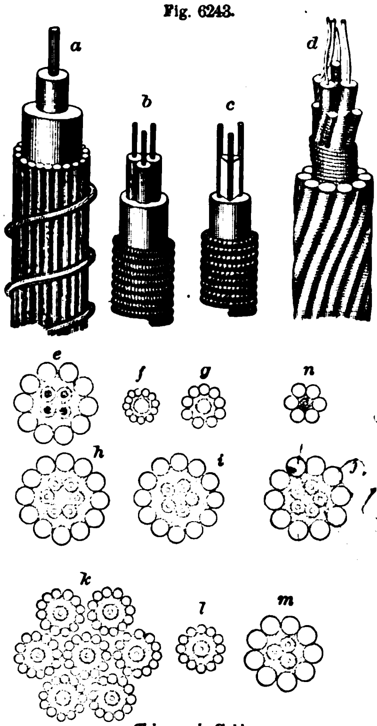
d e is the Dover and Calais cable, the first of importance laid in Europe, composed of four interior copper wires surrounded by gutta-percha covered with spun yarn. Ten galvanized wires were then twisted around the whole. Its length was 25 miles.

The next in order of time was the Holyhead and Howith cable, connecting England and Ireland. This had but one conducting wire. The shore ends were larger than those laid in deep water; *f* and *g* show the relative sizes. The distance between the two connected points is 60 miles; 10 additional miles of cable were constructed to meet contingencies.

h is the cable which it was attempted to lay down between Portpatrick and Donaghadee, Scotland and Ireland, in 1851. Owing to a gale, it was cut when 16 miles had been paid out. It was subsequently recovered in 1854, the depth of water being 150 fathoms, and found in good preservation.

i and *j* are the cables connecting Dover and Ostend, and Portpatrick and Donaghadee. These two cables are precisely similar in size and general construction, each having six wires; some improvements, however, have been introduced into the latter.

Fig. 6243.



Telegraph-Cables.

k is the shore end of the cable between Orfordness and the Hague. Each cable is composed of a single wire, the whole being brought together near the shore and twisted into one.

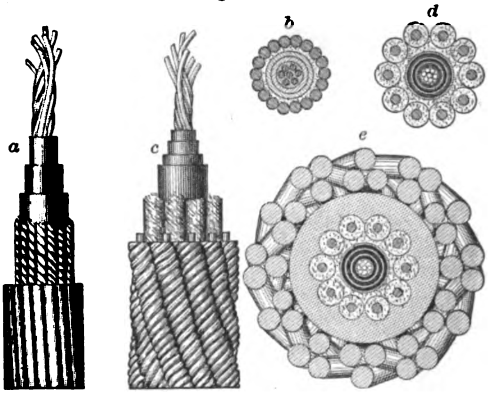
l, the cable between Prince Edward's Island and New Brunswick.

m, that across the Great Belt, in Denmark.

n, that across the Mississippi at New Orleans, on the Balise line.

The Malta and Alexandria cable (*a b*, Fig. 6244) is composed of seven copper conducting wires, over which are three layers of gutta-percha and one of tarred yarn, the whole inclosed by eighteen iron wires. The diameter of the deep-sea portion is .85 inch.

Fig. 6244.



Malta and Alexandria Cable.

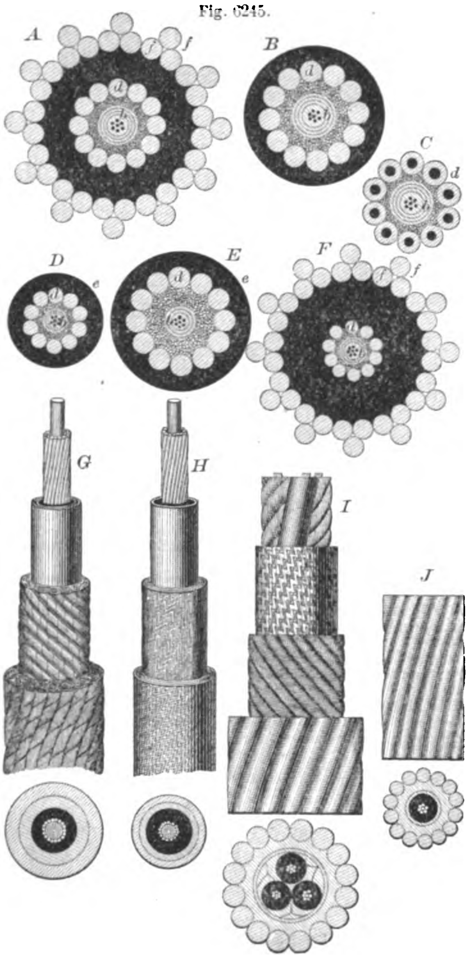
c d, the last four cables laid down between Ireland and Newfoundland. The seven wires of the core are each 0.048 of an inch in diameter, that of the whole strand being 0.144 of an inch, weighing 300 pounds to the mile.

The conductor is insulated by four layers of gutta-percha, alternating with thin layers of Chatterton's compound, the total diameter of the core being .464 inch. The sheathing consists of ten steel wires, 0.095 inch in diameter, each surrounded by five strands of tarred manilla hemp, and wrapped spirally round a covering of tarred jute yarn which surrounds the core. The weight in air is 4,000 pounds; in water, 1,568 pounds to the nautical mile.

e is a section on the same scale of the shore end of this cable.

The French Atlantic cable was laid by the "Great Eastern" in 1869. It is made in sections varying somewhat in size and mode of manufacture. The illustrations (Fig. 6245) are from "Engineering," and are one half (linear) the exact size.

Fig. 6245.



Submarine Telegraph-Cables.

A is a section of the shore ends of the cable between Brest and St. Pierre.

B, the intermediate portion connecting the shore ends to the main portion.

C, the main cable of the Brest and St. Pierre section.

D, the main cable of the St. Pierre and United States section.

E, the intermediate portion of the St. Pierre and United States section.

F, the shore end of the said western section.

The Brest and St. Pierre section weighs 400 pounds per nautical mile.

The western section 107 pounds per nautical mile.

In each case the copper conductor in the center consists of seven wires, six laid around one.

In each of them, —

b is an insulation of alternate layers of gutta-percha and Chatterton's compound, covered by a coating of tanned jute yarn of varying thicknesses in the different figures.

d, galvanized homogeneous iron wires bound with manilla hemp steeped in tar.

e, Clark's compound, consisting of mineral pitch and silica.

f, galvanized iron wire.

G H I J illustrate cables made by the Bishop Gutta-Percha Company, of New York.

In *G*, the center is an annealed steel wire surrounded by spirally laid copper wires; gutta-percha, $\frac{9}{16}$ inch thick, is laid on in three successive coatings; manilla yarn in a short spiral lay; manilla yarn in a long spiral lay. The annealed steel wire weighs 330 pounds per mile; copper wires, 475; gutta-percha insulation, 475; manilla yarn coating, 750 pounds; total, 2,012 pounds per mile.

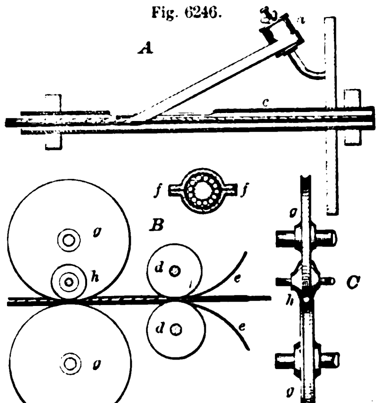
H is made in the same manner, except that instead of the manilla yarn two coatings of woven flax banding well saturated with tar are laid on spirally one over the other. Over this are put two coatings of Bishop's patent compound. This cable weighs 1,513 pounds to the mile.

I is a three-conductor cable, each strand being composed of nineteen copper wires twisted and insulated by gutta-percha $\frac{1}{8}$ inch in thickness, covered by woven banding and hemp tarred; the whole is surrounded by 16 No. 3 galvanized iron wires laid on spirally. This cable weighs 15,100 pounds to the mile.

J, a single-conductor cable, composed of nineteen copper wires similarly insulated and covered, and protected by 14 No. 7 galvanized iron wires laid on spirally. Its weight per mile is 5,850 pounds.

When rubber is employed for coating cables, an apparatus like that shown in Fig. 6246 is used. The rubber in very thin strips is wound upon a reel *a*, rotatable on a spindle. The

Fig. 6246.



Telegraph-Cable Apparatus.

wire is drawn through a slotted tube *c*, the rotation of which winds the strip upon the wire.

A second coating is put on by the apparatus *B C*. Here the wire having received the first coat is drawn by the rollers *d d* between two thin strips of rubber *e e*, the edges of which are compressed together, forming a flange on each side, as shown at *f f*. This is removed by passing it through two grooved rollers *g g*, the lower one of which acts against the two cutting edges of a disk *h*. A third coat is laid on by a similar machine.

A. F. Jaloureau of Paris has patented in the United States a method of forming telegraphic cables by the application of successive layers of bitumen, separated and maintained by spiral bands of bitumenized paper, and consolidated by coils of bitumenized twine or yarn, the whole protected, when necessary, by an outer covering of metallic wire.

In the machine for effecting this (Fig. 6247), the central wire core from the drum *A* is drawn longitudinally through the axis of a wheel carrying two bobbins *G*, by which the interior layer of wrapping-twine is applied, then over a boiler containing heated bitumen, which is applied to the twine by a roller on the longitudinal shaft of the machine; then alternately through the axes of wheels carrying bobbins *D D'*, etc., by which strips of paper are spirally wound on and over troughs of molten bitumen, which is applied by a roller as before.

A final covering of spirally laid twine is applied by bobbins on the wheel *C'*, which is coated with bitumen as the cable passes over another cistern. It is then drawn through a sand-tank *F*, and finally between pressure and tension rollers *G N O*, which extend and compact it. If desired, an outer layer of protecting wires is laid on by an additional wheel with bobbins similar to that employed in laying on the twine.

For raising a cable, grapnels with four prongs attached to a stout chain twenty or thirty fathoms long, connected to a long rope, are used for finding it and bringing it to the surface in the first instance; the end is then passed through a sheave, and conducted to a drum, rotated by the engine around which it is wound. In shallow waters, underrunning the cable is sometimes resorted to.

The drag-rope, in comparatively shallow water, is three or

four times the depth. For the Atlantic cable, the length of rope exceeded the depth by one fifth only.

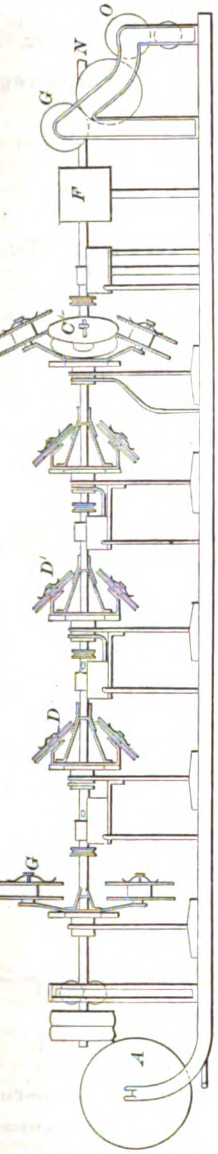


Fig. 6247.

The ship is run several miles to windward of the supposed position of the cable, and the drag being thrown out, she is allowed to drift broadside to, until by the increased strain shown by the dynamometer it is inferred that the cable has been hooked. The cable of 1865 was recovered in 1,900 fathoms of water; at this depth the strain on the dynamometer, due to the weight of the drag-rope, 2,300 fathoms in length, was $7\frac{1}{2}$ tons, increasing at times to $8\frac{1}{2}$ or 9 tons, according to the motion of the vessel; when the steady strain on the dynamometer exceeded this amount, it was assumed that the cable had been hooked; hauling

Machine for Manufacturing Telegraphic Cables.

in occupied five or six hours. When at the surface, the tension on the cable was nearly up to its breaking weight. It was grappled ten times, and several times raised a considerable distance, escaping from the grapnel, having been twice brought to the surface before the splicing was effectually accomplished.

Fig. 6248 illustrates the manner in which messages are transmitted through the Atlantic telegraph. *a* is the sending-battery; *b b'*, earth-plates; in this case, wires leading into the ocean. The current passes from the battery to the transmitting-lever *c*, and thence through the cable *d* to the point *e* at the receiving-station; here it divides, the greater portion passing through the galvanometer to the condenser *g*, an arrangement of mica plates and tin-foil acting as a Leyden jar. The remainder is conducted through the resistance-coil *h* to the earth-plate *b'*. This continues until the condenser is charged and the galvanometer-needle is no longer deflected. By depressing the lever *c*, its end is brought in contact with the earth-wire; a portion of the electricity stored up in *g* is transmitted back through the cable, taking the galvanometer in its way, and deflecting the needle, which carries a mirror, serving to indicate the letters. See REFLECTING-GALVANOMETER.

The transmission of electricity through a submarine cable is found to be a gradual rather than an instantaneous process. When a signal is made at one end of either of the Atlantic cables, no

Fig. 6248.

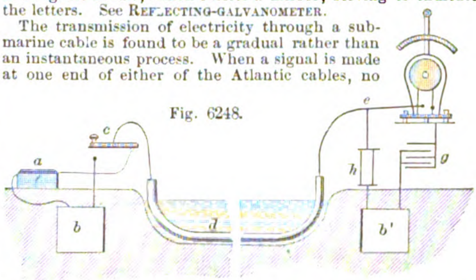

Diagram to Represent the Working of the Submarine Telegraph.

effect is experienced at the other for about .2 of a second; after .4 of a second, the current received attains about 7 per cent of its maximum intensity; in one second, about half; and not until the expiration of three seconds does it attain its full strength. To enable the operator at the receiving-station to translate the vibrations thus produced into the letters of the alphabet is the office of Sir William Thomson's REFLECTING-GALVANOMETER (which see).

Tel′e-graph-car′riage. A vehicle provided with the apparatus necessary for opening temporary communication with a permanent line. Fig. 6249 illustrates a form of carriage used by the postal department in England. This carries one of each of the different kinds of instruments employed, — six in number, — nearly 150 battery-cells, a proper quantity of telegraph-cable, and has accommodations for eight operators. It is used in military operations, at agricultural shows, races, etc., where no line of telegraph is immediately at hand.

The army-telegraph service is an important feature in most of the large European armies. A *field-telegraph*. See page 839; and notice under TELEGRAPH.

For account of a field-telegraph, see "Popular Science Review," Vol. XIII., London, 1874, pages 141 - 149.

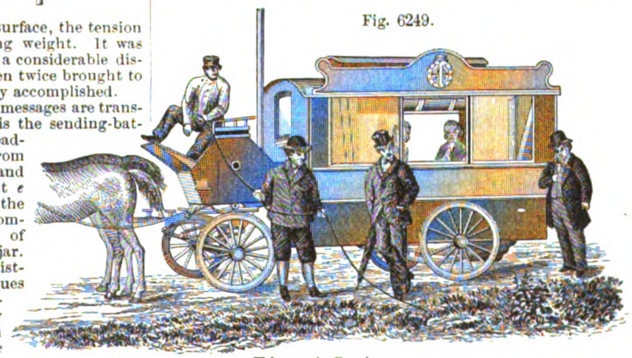
Tel′e-graph-clock. An arrangement by which time is signaled to a number of different apartments in a building or to several buildings.

This may be performed by electro-magnetic devices, or by simply mechanical means. For the former, see ELECTRO-MAGNETIC CLOCK, pages 785, 786.

Fig. 6250 is an example of the latter. A traveling pointer in each room moves over an index-path, which is the substitute for a clock-dial, being drawn by a wire connected to a weight, whose descent is controlled by a clock. Another system of wires connects the striking movement of the clock with the bell-hammer in each room, to strike the hours as they recur, in concert with the striking of the principal clock.

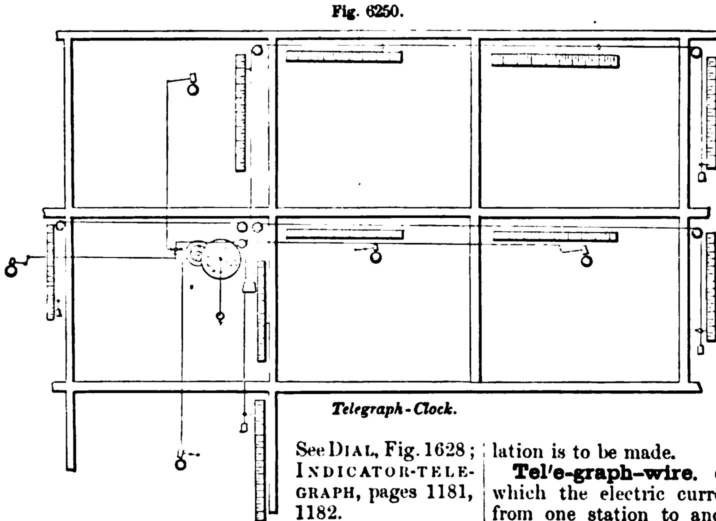
Tel′e-graph-di′al. A circle on which are arranged the letters of the alphabet, figures, etc., the hand or pointer being operated by electro-magnetic action.

Fig. 6249.



Telegraph-Carriage.

Fig. 6250.



Telegraph-Clock.

See DIAL, Fig. 1628; INDICATOR-TELEGRAPH, pages 1181, 1182.

Tel'e-graph'ic Key-board. The bank of keys of a printing-telegraph machine. See Fig. 3960, page 1802.

Tel'e-graph'ic Sig'nal. An alarm or visual indicator, usually set in motion by electro-magnetic means. See TELEGRAPHIC ALARM; SOUNDER.

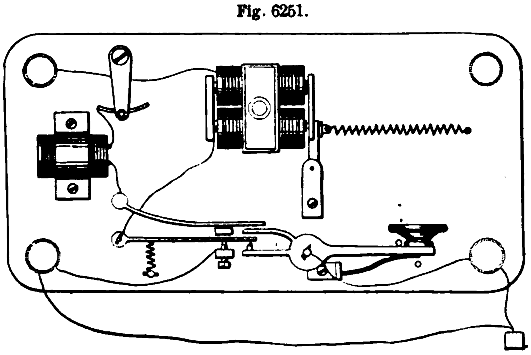
Tel'e-graph-in'di-cat'or. A pointer-telegraph. See INDICATOR, Fig. 2669, page 1181.

Tel'e-graph-in'stru-ment. A moving mechanical device used in the electric circuit. A *perforator*, *transmitter*, *receiver*, *relay*, *register*, or what not. See list under TELEGRAPH.

Tel'e-graph-key. (*Telegraph.*) The vibrating piece in a transmitting-instrument, which is touched by the finger to establish an electric circuit. See MORSE ALPHABET, *b*, Fig. 3225, page 1476.

Fig. 6251 shows a key in connection with Farmer's magnetic telegraph for sending messages simultaneously in opposite directions upon a single line of telegraph. Upon the receiving-magnet is a single set of coils, and the key makes two contacts at the down stroke, closing the branch circuit through the receiving-magnet, and the branch through the rheostat, both at once, and at the same time disconnecting the receiving-magnet from the direct ground, and connecting with the ground through the battery. The rheostat branch circuit is broken at the key at its upward stroke. See also Fig. 2744, page 1225.

Fig. 6251.



Farmer's Magnetic Telegraph.

Tel'e-graph-post. One for keeping the wires elevated above the ground and out of contact with surrounding objects, excepting the insulators on the posts.

Tel'e-graph-reel. A device on which the endless slip of paper is wound on a recording-telegraph. A common feature in telegraphs. See *i*, Fig. 3225, page 1476.

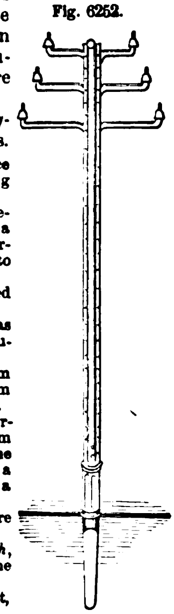
Tel'e-graph-reg'is-ter. (*Telegraphy.*) A recording-device at the receiving end of a circuit. See MORSE APPARATUS, Fig. 3225, page 1476; Figs. 4247, 4248, page 1913.

Tel'e-graph Tar'iff-in'di-cat'or. A means of ascertaining distance, approximately, by a graduated tape-line or rule sweeping from the central position, representing the office whence the calculation is to be made.

Tel'e-graph-wire. (*Telegraphy.*) The road by which the electric current passes from one station to another, the metallic communication between stations, also connecting instruments, battery, and ground. Wire and instruments form the *circuit*.

Wires are attached by *binding-screws* or *terminals* to instruments.

Fig. 6252.



Telegraph-Post.

A *loop* is a wire going out of an office and returning to the same and forming part of a main circuit.

Cross-wires is a metallic connection between two wires, owing to sagging or a blow. *Weather-cross* is a leakage of current from one wire to another, owing to defective insulation in damp weather.

A *return* wire is a *metallic circuit* used instead of the *earth*.

To *disconnect* is to take a wire off, so as to break the circuit, leaving the wire insulated.

To *loop* two wires is to disconnect them from their ordinary places and join them together, so as to form a metallic circuit.

To *cross-connect* wires is to interchange them, so that a current from one wire is shifted to another at one station and then back again at a farther station, to work around a faulty station.

To *put wires straight* is to restore the usual arrangement.

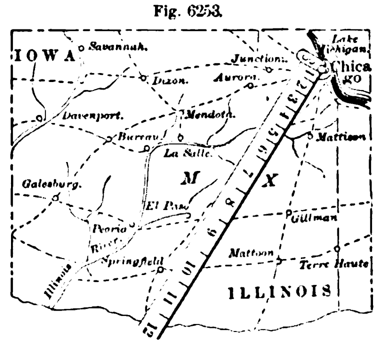
To *ground* a wire, or to *put to earth*, is to make a connection between the line-wire and the earth.

To *open* a wire is to disconnect it, so that no current can pass.

To *shackle* a wire is to cut it and place an insulator between the ends.

Bishop's process for insulating and protecting telegraph-

Fig. 6253.



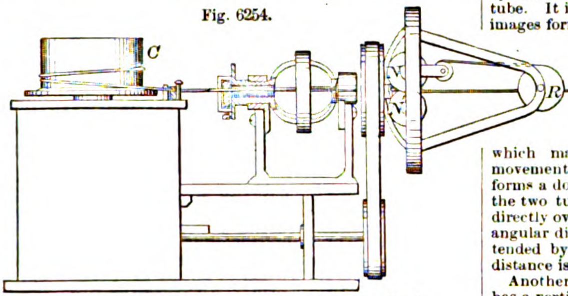
Telegraph Tariff-Indicator.

wire consists in wrapping the wire with a layer of jute, flax, or similar fiber, and applying an exterior coating, composed of asphaltum, 2½ lbs.; gutta-percha, ¼ lb; crude rosin, ¼ lb.; spirits of turpentine, ½ gall; boiled linseed oil, 1 gill; umber, 2 oz. Successive layers of the fiber and compound may be applied.

Moses G. Farmer's telegraph-wire is formed of a core of steel, which is first carefully tinned and then covered with copper, after which the compound wire is tinned, to prevent rusting. See also TELEGRAPH-CABLE.

Fig. 6254 is a machine for covering telegraph-wire with metal. The wire to be covered is drawn along by the rotation of the cylinder C to which it is attached, passing through the hollow axle of the overhung wheel K, to which motion is imparted by belt and pulley. The metallic covering ribbon is wound upon

Fig. 6254.



Machine for Covering Telegraph-Wire with Metal.

the spool R, and, being conducted over a small pulley, passes downward to the wire to which it is spirally applied by the two grooved rollers N N', connected to the wheel K, and revolving therewith. Previous to being wound upon the cylinder C, the compound wire is compelled to pass through a gage.

Tel'e-i-con'o-graph. A combination of the telescope and camera-lucida, invented by M. Revoil.

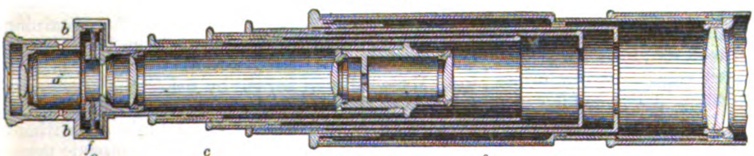
The principle involved is that of allowing the image transmitted by the object-glass of a telescope to pass through a prism connected with the eye-piece. The rays of light that would in the ordinary use of the telescope be transmitted direct to the eye are refracted by the prism, and thrown down upon a table placed below the eye-piece. The distance between the prism and the table determines the size of the image projected on the latter, and it is easy for the observer to trace on a paper placed on this sketching-table the actual outlines indicated by the refracted light. The telescope has both vertical and horizontal motion, and is so constructed that a connected drawing can be made of a larger area than can be included in the object-glass at one view; in fact, an entire panorama can be traced, if the relative positions of the axis of the telescope and the surface of the sketching-table are undisturbed.

Te-lem'e-ter. An instrument for determining the distance of an object whose linear dimensions are known, from its apparent length or hight, when viewed between two parallel wires of a telescope.

A graduated rod has long been used for this purpose in surveying; the number of divisions included between the two wires showing at once the distance in yards, feet, or other units between the rod and the telescopes.

In instruments of this kind used in military operations for ascertaining the distance of troops, the two wires are made to approach or recede from each other; standard distances, the hights of infantry and cavalry, are assumed as bases to which an indicating scale upon the telescope is graduated.

Fig. 6255.



Bardou's Telemeter.

Bardou's (Fig. 6255) consists of a telescope whose eye-tube a is surrounded by a broad flange b marked with a scale c for showing the distance in yards of infantry. An exterior ring f is graduated for showing the distance in yards of cavalry. By means of interior teeth b' on the flange b engaging pinions c c on the screw-pins d d', two wires are caused to approach or recede from each other; when these exactly coincide with the extremities of the object, the number beneath the index o, upon the scales b, indicates the distance if infantry be observed, or upon f if the object be cavalry. g g' are the field-lenses, and h is the object-glass.

Rochon's double-image telescope has within its tube a prism of Iceland spar (a mineral possessing the power of double refraction), which divides the pencil of rays into two pencils diverging from each other at a determinate angle. This prism is, by means of a rack and pinion, movable from end to end of the tube. It is moved back or forth until the edges of the two images formed by the prism are in exact contact, when an index on the slide indicates the distance according to a scale engraved on the outer surface of the tube.

The binocular marine-glass of M. Lorieux, of Paris, is designed to determine distances by the angle subtended by an object of known dimensions. It comprises two telescopes, the axes of which may be thrown out of parallelism by an angular movement around an axis joining the two eye-pieces. This forms a double image of the object, which appears single when the two tubes are parallel. One of these images will appear directly over the other; and when their edges are in contact, the angular distance between the two tubes is equal to that subtended by the object at the eye of the observer, whence the distance is readily inferred.

Another form of telemetric marine-glass by the same optician has a vertical plate on each side of the axis of the object-glass of the telescope. These are made to approach to or recede from each other by means of a right-handed screw on one side, and a left-handed screw on the other, the distance of the object being inferred from the distance apart of the two plates when their edges exactly coincide with the extremities of the object. In later constructions of this instrument, the edges of the plates are placed horizontally, as being generally more convenient.

The prism-telemeter consists of two prisms connected by a measuring-chain or tape-line, serving as a base for the triangle which determines the distance. The two observers face each other. The difference in the apparent direction of the object, as viewed by reflection in the prisms, indicates by a scale attached thereto the distance of the object.

The telemetrical telescope of Captain Gautier, of the French artillery, indicates the distance of an object by the angles formed by it at two different stations successively. The object is viewed by reflection from a prism which causes a known deviation, 3°, in its apparent direction, and from two opposite mirrors, all in the tube of the instrument.

An electric telemeter for ascertaining the distances of objects in motion has been invented by Captain Kocziczka, of the Austrian engineer corps.

Two points of observation at a known distance apart are connected by a telegraph-wire. At each station is a telescope, parallel to the axis of which, and turning with it, is a long thin needle. A second needle turns on a point representing the other station, and is connected with the wire therefrom. When an object is observed simultaneously at each station, the angle formed by the two needles — one following the motion of its own telescope, and the other that of the telescope at the other station, with which it is electrically connected — fixes the position of the object on a plat of the country placed on the table on which the instrument is mounted.

An instrument analogous to this was devised by the Archduke Leopold, to determine the proper time to explode a torpedo when an enemy's vessel passes over it. If a series of torpedoes be arranged in a straight line, one station is placed on the prolongation of this line, while the other commands a cross view of it. When a vessel passes over this line, the observer at the first station touches a key, which closes a circuit passing through both stations. The second observer, having his telescope, which is provided with a metallic arm that touches successively a series of terminals communicating with the conductors, will, at the same moment, by the movement of the telescope, bring this arm in contact with the insulated wire belonging to a torpedo, if the vessel passes directly over it, exploding the charge.

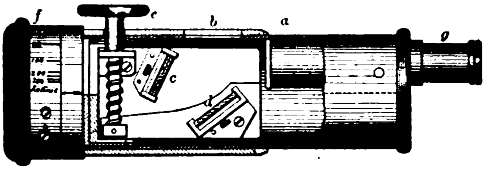
Balbreck's telemetric double-telescope consists of a square tube or box, pivoted on a ball and socket joined at the top of a tripod, and containing two mirrors turning on vertical pivots. These mirrors are partly silvered and partly transparent, and are provided with tangent screws, each carrying a divided circle with an index, by which the amount of movement may be read. Two telescopes enter

the tube at right angles from opposite directions; one at each end just beyond the mirrors. A rectangular glass prism is placed at the focus in the angle to change the direction of the rays. The distance between the centers of the mirrors is one metre. Openings are made in the sides of the box opposite the mirrors to admit light from the object to be observed.

In observing, the box is turned until the object seen by reflection is brought into coincidence with the central line of the telescope at the other end. Through the transparent part of this mirror the object will be seen by reflection, but not on the central line. It is brought into coincidence with this by means of the tangent screw. The box is now revolved 180°, and the object viewed through the other telescope, and adjustments made similar to those first described, the box being turned as before, bringing the second image again to coincide with the first. The divided circle of the first mirror will then show very nearly the true parallax; a correction is, however, necessary if very accurate results are desired.

The telemeter of Captain Gautier, of the French army (Fig. 6256), consists of a tube *a*, having an opening *b* at one side, and containing two mirrors set normally at an angle of 45°, one of

Fig. 6256.



Gautier's Telemeter.

which (*c*) is fixed, and the other (*d*) admits of slight movement by means of a thumb-screw *e*. A ring *f* turning on the axis of the instrument carries a prism, through which an object may be viewed by direct vision.

In measuring distances, the observer selects a distant and well-defined object nearly at right angles to that whose distance is to be determined, and having brought the zero or "infinity" line on the ring opposite an arrow-mark on the tube, he views the first object or "natural signal" by direct vision through the eye-tube *g*, looking over both the mirrors and through the prism. By turning the screw *e*, the image of the object whose distance is sought, and the rays from which, passing through the opening *b*, are reflected from *c* to *d*, and thence to the eye, is brought into coincidence with the natural signal. He then steps back a certain distance, say 20 yards, on the prolongation of the line passing through this first station and the natural signal. This distance, which serves as a base line, should not be less than $^1{}_{100}$ of that of the station from the object whose distance is sought. The reflected image will no longer coincide with the "natural signal" seen by direct vision through the prism. By turning the ring *f* the prism is revolved until its refraction again causes the two images to coincide. The ring is provided with a graduated scale containing a series of factors by which the length of the base must be multiplied in order to obtain the distance of the object. That factor which stands opposite the arrow on the tube is the proper multiplier.

These factors are derived by a simple calculation, from the trigonometrical properties of a triangle supposed to be right-angled at the second station. Should the first and second stations, however, not be precisely in line with the natural signal, a correction may be applied, depending on the amount of this angular variation; but this correction is so small, within the limits of angular measurement, as to be neglected in ordinary practice.

The ring may, on the same principle, by assuming one or more invariable base-lines, be so graduated as to give the distance directly in yards or metres. See also Wilson's United States patent, September 29, 1868, No. 82,669.

Tel'e-phone. An instrument for conveying signals by sound. It may consist of a steam-whistle, a fog-trumpet, or other audible alarm. The term, until lately, has been particularly applied to a signal adapted for nautical or railroad use, in which a body of compressed air is released from a narrow orifice and divided upon a sharp edge, in the manner of a steam-whistle.

The term is now acquiring a different signification.

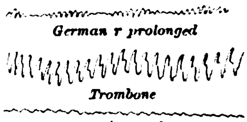
The subject of the number of vibrations per second, as constituting a given note, has been considered under MUSIC, PITCH, PIPE, etc.; and the mode of counting the vibrations under SIREN. The *vibroscope* is another instrument invented by Duhamel for the same purpose. See also METRONOME; TONOMETER.

Articulate sounds are accompanied by the expulsion of air from the mouth, which impulses vary in quantity, pressure, and in the degree of suddenness with which they commence and terminate.

An instrument which will record these impulses has been termed by its inventor, Léon Scott, a *phonautograph*, or *phonograph*, and by Mr. Barlow a *logograph;* the pressure of the air in speaking is directed against a membrane which vibrates and carries with it a delicate marker, which traces a line on a traveling ribbon. The excursions of the tracer are great or small from the base line, which represents the quiet membrane, according to the force of the impulse; and are prolonged according to the duration of the pressure, different articulate sounds varying greatly in their length as well as in intensity; farther, another great difference in them consists in the relative abruptness of the rising and falling inflections, which make curves of various shapes, of even or irregular shape. The smoothness or ruggedness of a sound has thus its own graphic character, independent both of its actual intensity and its length.

Barlow's *logograph*, described in the London "Popular Science Review," Vol. XIII. page 278, *et seq.*, consists of a small speaking-trumpet, having an ordinary mouth-piece connected to a tube, the other end of which is widened out and covered with a thin membrane of gold-beater's skin or gutta-percha. A spring presses slightly against the membrane, and has a light arm of aluminium, which carries the marker, consisting of a small sable brush inserted in a glass tube containing a colored liquid. An endless strip of paper is caused to traverse beneath the pencil, and is marked with an irregular curved line, the elevations and depressions of which correspond to the force, duration, and other characteristics of the vocal impulse. The lines thus traced exhibit remarkable uniformity when the same phrases are successively pronounced.

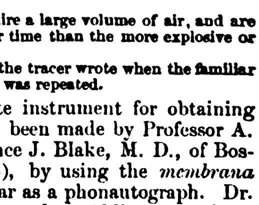
Fig. 6257.



Lines obtained by the Phonautograph.

Fig. 6257 shows curves obtained by Mr. Charles A. Morey by the interposition of a light lever between the membrane and the smoked glass, which is drawn along beneath the style, whose excursions are much magnified by the lever. The curves show respectively the tongue trill or German *r* prolonged, the mark produced by the sound of a trombone, and by the sound of *oo* in mood. See "American Journal of Science and Arts," August, 1874, pages 130, 131.

Fig. 6258.



Logographic Curves.

Fig. 6258 shows a tracing from the utterance of the word "incomprehensibility," with different degrees of effort. It will be noticed that while a certain variation occurs due to the energy, each sound preserves a specific character.

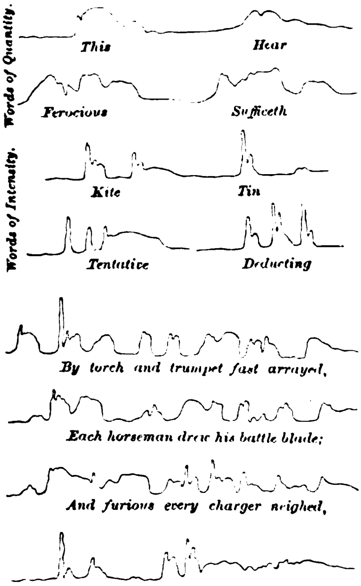
Fig. 6259 shows in the upper portion the effect of words of quantity which require a large volume of air, and are maintained a relatively longer time than the more explosive or intense kind.

The lower diagram is what the tracer wrote when the familiar stanza from "Hohenlinden" was repeated.

A much more delicate instrument for obtaining sonorous vibrations has been made by Professor A. Graham Bell and Clarence J. Blake, M. D., of Boston, Mass. (June, 1874), by using the *membrana tympani* of the human ear as a phonautograph. Dr. Blake's mode of exposing the middle ear without injuring the ossiculæ or the delicate tympanic membrane is described at length in the "Boston Medical and Surgical Journal," February 4, 1875, pages 121 – 123.

The *stapes* was removed, and a short style of hay substituted of about the same weight, so as to increase the amplitude of the vibrations and afford means of obtaining tracings upon smoked glass, as in the phonautograph experiments. The membrane is kept moist by a mixture of glycerine and water, and the speci-

Fig. 6259.



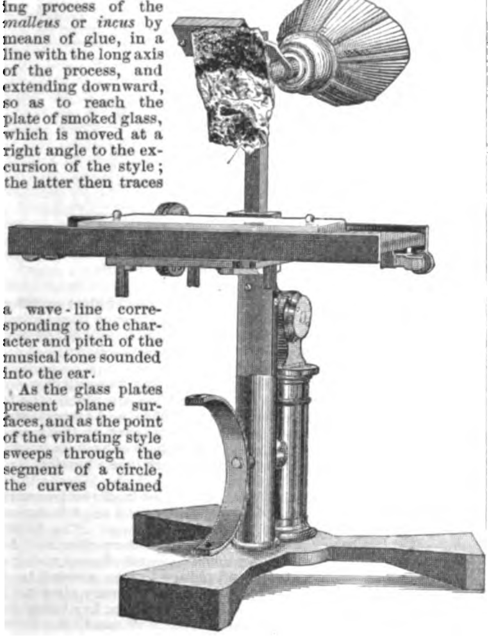
Logographic Curves.

men attached to a perpendicular bar sliding in an upright post, and moved by a ratchet-wheel. To the upright is attached, horizontally, a metallic stage six inches in length, upon which slides a carriage with a glass plate, and having a regular movement given to it by wheel and cord. A bell-shaped mouth-piece is inserted in the external auditory meatus and luted in position.

The vibrations of the membrane due to a musical tone sounded in the bell may be observed by means of a ray of light thrown upon small specula of foil attached to the *malleus*, *incus*, or to different portions of the *membrana tympani*, or may be recorded on smoked glass by a style fastened to the descending process of the *malleus* or *incus* by means of glue, in a line with the long axis of the process, and extending downward, so as to reach the plate of smoked glass, which is moved at a right angle to the excursion of the style; the latter then traces a wave-line corresponding to the character and pitch of the musical tone sounded into the ear.

As the glass plates present plane surfaces, and as the point of the vibrating style sweeps through the segment of a circle, the curves obtained are apt to be discontinuous, especially when the amplitude is great. To obviate this difficulty, a sheet of glass is employed having a *curved* surface, the concavity being presented to the style. The sheet of glass is a section of a cylinder whose semi-diameter is equivalent to the length of the style. In this way the point of the style never leaves the surface of the glass, and the curve resulting from its vibration is continuous. The carbon film is preserved by pouring collodion upon it; as soon as this is dry, the film may be floated off with water and placed upon a plane sheet of glass, or upon paper, and varnished in the ordinary way.

Fig. 6260.



The Membrane of the Tympanum used as a Phonautograph.

See the following works: "Use of the Membrana Tympani as a Phonautograph and Logograph, with Plates," Archive for Ophthalmology and Otology, 1876. "Use of the Membrana Tympani as a Phonautograph and Logograph," Boston Med. and Surg. Journal, Feb., 1875. "Mechanical Value of the Distribution of Weight in the Ossicula," Trans. Am. Otological Society, 1874.

Another step in the direction of the conveyance of sound consists in connecting a membrane in a mouth-trumpet by means of a fine cord with a similar membrane in a trumpet applied to the ear of a person at a considerable distance, say in another room. The sounds are audible, not merely as to pitch, but are recognizable as articulate sounds. The writer knew an officer who was with Nelson at Copenhagen, who was wounded so that his hearing was destroyed. He was in the habit of placing a music-box against his teeth, or holding in his teeth a string whose other end was shut tightly between the lid and the box. He said he *heard* very well.

The experiment of connecting distant sounding-boards, so that one is made to vibrate in unison with the other, is familiar; indeed, the synchronous vibration may be obtained even by the vibrations of the atmosphere, as when the sounds of a piano are repeated by those of a guitar which has been tuned in unison and stood up in the corner of the room. This is even more palpable when the guitar is laid upon the piano top.

"There is an experiment, first made by Wheatstone, where the music of a piano is transferred from its sound-board, through a thin wooden rod, across several silent rooms in succession, and poured out at a distance from the instrument. The strings of the piano vibrate, not singly, but ten at a time. Every string subdivides, yielding not one note, but a dozen. All these vibrations and subvibrations are crowded together into a bit of deal not more than a quarter of a square inch in cross section. Yet no note is lost. Each vibration asserts its individual rights; and all are, at last, shaken forth into the air by a second sound-board, against which the distant end of the rod presses. Thought ends in amazement when it seeks to realize the motions of that rod as the music flows through it." — Prof. Tyndall, in "Martineau and Materialism."

From the mechanical transmission of sounds by the air, string, or wooden rod, we pass by a decided step to devices by which vibrations are made to produce rapid contacts and breaks of an electric circuit, and thus become means of transmitting tones; and, conversely, to means of making rapid contacts, so as to set matter vibrating, and causing it to generate musical tones.

The knowledge that the pitch of tone depended upon the rapidity of vibration was well known to Pythagoras; the generation of sound by motion is familiar in the vibration of strings and wires in the Æolian harp, and the sound of the wind in a tube. The tuning-fork is so proportioned that it produces sounds of but one *pitch*, while its *timbre* depends on the quality of its material, and its *intensity* upon the amplitude of its vibrations.

Besides the tone generated by the agitation of the atmosphere, it was observed as long ago as 1785, by the Canon Gottoin de Coma, that an iron wire of at least 10 yards in length, when stretched in the open air, spontaneously gives forth a sound under the influence of certain variations in the state of the atmosphere, the effect being due to the transmission of atmospheric electricity. This transmission does not in fact occur in a continuous manner like that of a current, but rather by a series of discharges.

Mr. Beatson has proved that the discharge of a Leyden jar through an iron wire causes this wire to produce a sound if the discharge is first passed through a moist conductor, such as a wet string or animal tissue.

Professor Page in America, De la Rive in France, Gassiot in London, and Marrian in Birmingham, discovered that rods of iron placed in the interior of a helix through which a current of electricity is passed give out decided sounds at the moment when the circuit is made or broken.

Reis applied this discovery in his telephone. By causing the circuit to be made and broken very rapidly, a musical note was emitted by a rod placed in a helix traversed by the current.

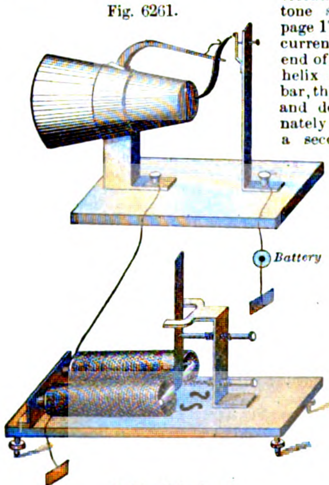
De la Rive found that exactly similar sounds were produced where the intermittent current was passed through the iron rod itself; and Professor Bell has produced similar effects by passing the current through retort carbon, plumbago, German-silver wire, and platinum wire.

In fact, the intermittent current occasions a molecular vibra-

tion in the conductor through which it is passed, whatever may be the material of which it is made, and this vibration may be rendered audible by coiling up the conducting-wire and applying it to the ear; as, for instance, an empty helix of copper wire, through which a discontinuous current is passed.

In the electro-magnetic telephone of Kirpath, the telephone sending-instrument consists of an open funnel in which the tone is sounded, and a diaphragm of thin elastic membrane, which is set in vibration by the tone, and which by its vibrations continually makes and breaks the electric circuit. The number of breaks in a second corresponds with the number of vibrations belonging to the tone sounded (see PIPE, page 1708); and since the current passes at the other end of the line through a helix around a soft iron bar, this bar is magnetized and demagnetized, alternately, as many times in a second as there are vibrations in the tone sounded at the sending-instrument At each demagnetization, a longitudinal shrinkage of the bar occurs, and a resulting sound; this is rendered more audible by placing the bar on a delicate sounding-board, which partakes of the vibrations synchronously with those of the original membrane, and reproduces the same sound.

Fig. 6261.

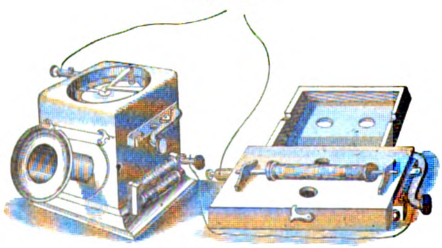


Reis's Telephone.

Fig 6261 shows one of Reis's telephones, used by Legat in his experiments upon *Telephonie*. The discontinuous current, produced by the oscillating lever which vibrates in concert with the membrane on the end of the trumpet, is passed through an electro-magnet (shown beneath), so as to occasion vibration in its armature, which is attached to a sounding-board.

Fig. 6262 principally differs from the other in its receiving-instrument. The intermittent current traverses a coil surround-

Fig. 6262.



Reis's Telephone.

ing a rod of iron, occasioning a molecular vibration in the iron. The resulting sound is rendered more intense by placing the rod and helix upon a sounding-board.

Another form of receiving-instrument is thus described by De la Rive: —

"The most brilliant sound is that which is obtained by stretching upon a sounding-board well-annealed wires, $^1/_{20}$ or $^2/_{20}$ of an inch in diameter and from 3 to 6 feet in length. They are placed in the axis of one or several bobbins, the wires of which are traversed by electric currents, and they produce an assemblage of sounds, the effect of which is surprising, and which greatly resembles that to which several church-bells give rise when vibrating harmonically in the distance"

De la Rive mentions one or two *rheotomes* or *circuit-breakers*, forms of apparatus employed by him in his experiments upon the production of sound telegraphically, for the purpose of making and breaking the circuit very rapidly.

Fig. 6263 is simply a toothed wheel so arranged as to make and break contact with a spring resting against the edge. By giving the wheel a movement upon its axis, we cause the plate to leap from one tooth to another; each leap produces a rupture in the circuit, which is closed again immediately afterward. The musical tone given out by the plate, when we have no other means of measuring it, gives us exactly the number of times that the circuit has been opened and closed, that is to say, interrupted, in a second.

Fig. 6264 is another form of rheotome used by De la Rive, consisting of four needles arranged upon a horizontal rod, so as to dip into mercury alternately when the axis is caused to revolve.

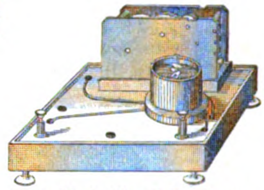
Fig. 6264.



De la Rive's Circuit-Breaker or Rheotome.

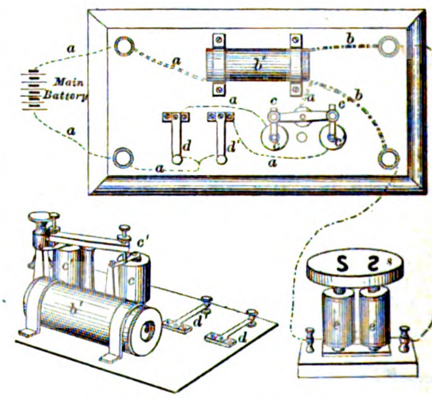
The two needles are inserted perpendicularly and parallel with each other, and so arranged that when they are immersed simutaneously in two capsules filled with mercury, and insulated from each other, the circuit is closed; and when they are not immersed, it is open A clock-work movement, or simply a winch moved by the hand, gives a rotatory movement to the axis; whence it follows that in a given time — a second, for example — the circuit may be closed or interrupted a great number of times.

Attention has long since been directed to the utilization for telegraphic purposes of the means afforded and effects elicited by the numerous observers and experimenters in this branch of acoustics.

It is well known that many distinct sounds pass through the air simultaneously without interference, and that the ear is capable of receiving several impressions at the same time, or is capable of directing its attention to one set alone, as when one listens to an alto alone of a quartette, oblivious at the time of the other voices, though not perhaps of the words of a friend seated by one's side.

Gray's electro-harmonic telegraph is founded upon the principle before stated, that an electro-magnet elongates under the action of the electric current, and contracts again when the cur-

Fig. 6265.



Gray's Electro-Harmonic Telegraph.

rent ceases. Consequently, a succession of impulses or interruptions will cause the magnet to vibrate, and if these vibrations be of sufficient frequency a musical tone will be produced, the pitch of which will depend upon the rapidity of the vibrations.

By interrupting an electric current at the transmitting end of a line with sufficient frequency to produce a musical tone by an instrument vibrated by said interruptions, and transmitting the impulses thus induced to an electro-magnet at the receiving end of the line, the latter will vibrate synchronously with the transmitting-instrument, and thus produce a musical tone or note of a corresponding pitch.

The instrument shown in Fig. 6265 consists of the transmitting-apparatus mounted on a base board, and a receiving-apparatus, shown in a position beneath the former The induction-coil b' has the usual primary and secondary circuits. An ordinary automatic electrotome c has a circuit-closing spring c' so adjusted as when in action to produce a given musical tone. A common telegraph-key d is placed in the primary circuit a a to make or break the battery connection. The key being depressed, and the electrotome consequently vibrated, the interruptions of the current will simultaneously produce in the

secondary circuit $b\,b$ of the induction-coil a series of induced currents or impulses corresponding in number with the vibrations of the electrotome; and as the receiving electro-magnet *e* is connected with this circuit, it will be caused to vibrate by successive elongations and contractions, thus producing a tone of corresponding pitch, the sound of which may be intensified by the use of a hollow cylinder *s* of metal, placed on the poles of the magnet.

When a single electrotome *c* is thrown into action, its corresponding tone will be reproduced on the sounder by the magnet When electrotomes $c\,c'$ of different pitch are successively operated by their respective keys $d\,d'$, their tones will be correspondingly reproduced by the receiver; and when two or more electrotomes are simultaneously sounded, the tone of each will still be reproduced without confusion on the sounder, so that by these means melodies or tunes may be transmitted.

Another system is founded upon the alternate making and breaking of a telegraphic circuit by means of the vibration of tuning-forks or musical reeds, as in Helmholtz's apparatus for the production and transmission of vocal sounds. If a given fork be made to interrupt an electric circuit by its vibrations, and the intermittent current thus produced be passed through a series of electro-magnets, each in connection with a fork of different pitch, and consequently different rate of vibration, only that fork will be thrown into vibration which is in unison with the first one. Practically the time required to do this is a small fraction of a second. The advantages of this method are numerous. Not only may many receiving-instruments at one station be operated, each by its own key, through a single wire, but many different stations in the same circuit may be operated, that one alone receiving the message which has an instrument with the requisite pitch, so as to vibrate in synchronism. Many signals may in this way be transmitted over the same wire at the same time, and many dispatches sent simultaneously to as many stations. All this may be done, too, without affecting the line for its ordinary use.

Three inventors have been and are working at this form of apparatus, — Elisha Gray and A G Bell of the United States, and La Cour of Denmark. See English patents Nos 1,740 and 2,646 of 1874; 947 and 974 of 1874 La Cour, 2,999 of 1874. Gray's United States patents, 166,094, 166,095, 166,096, of 1875; 175,971 of 1876 Bell's patents, 161,739 of 1875; 174,465 of 1876.

In Gray's electric telegraph for transmitting musical tones, the transmitting apparatus consists of a keyboard having a number of electro-magnets corresponding with the number of keys on the board, to which are attached vibrating tongues or reeds, tuned to a musical scale Any one of these tongues can be separately set in motion by depressing the key corresponding to it.

The closing of either of the keys completes the primary circuit from the battery through the electrotome connected with the key depressed, and the circuit-closing spring of said electrotome will immediately be thrown into rapid vibration, and a musical tone of a certain pitch will be given forth, while at each vibration the current in the primary circuit of the induction apparatus will be interrupted. By the usual intermediate means secondary induced currents are transmitted to the receiving station. Thus, for example, if the circuit-breaking spring of the electrotome vibrates one hundred and twenty-eight times per second, the tone given forth is that known as the *fundamental C*, while one hundred and twenty-eight terminal secondary currents will be induced in the secondary circuit of the induction apparatus, and transmitted through the animal tissue, — which may be the human body, — forming part of said circuit, to the resonant receiver, and will, from some cause not understood or explicable in the present stage of the art, vibrate the same synchronously with the transmitting electrotome, and thus give forth a musical tone of the same pitch.

This animal membrane must possess the specific characteristics of being a conductor of electricity; of being yielding and elastic; and of having a surface of greater electric resisting capacity than its interior.

These characteristics are found in the skin of the human body, as shown in Fig. 6268.

The operation of the key and its corresponding electrotome may be more readily understood by referring to Fig. 6266. In this, *a* is a steel reed tuned to vibrate at a definite rate corresponding to its position in the scale. One end is rigidly fixed to the post *b*, while the other end is left free, and is actuated by a local battery. The magnets *e* and *f* are arranged in the same local circuit, magnet *f* having a resistance of about thirty *ohms*, and magnet *e* about four *ohms*. When the reed *a* is not in vibration, the point *c* is in electrical contact with it, which throws a shunt wire entirely around the magnet *f*; thus, practically, the whole of the local current passes through magnet *e* at the instant of closing the key *c*. It is well known that when two electro-magnets are placed in the same circuit, the one which has the higher resistance (other things being equal) will develop the stronger magnetism, and that if the magnet of higher resistance be taken out of the circuit, the force of the other will be increased. When the key *c*, being depressed, closes the local circuit at *d*, the operation of the reed is as follows: The whole of the current from battery *l* passes through the magnet *e*, which attracts the reed say with a power of four. When the reed has moved toward *i* far enough to leave the point *g*, the shunt circuit is broken, and the current flows through both the magnets. Immediately, the power in *f* rises from zero to five, and that of *e* drops from four to one, and the reed is attracted toward *f* with an effective force of four, until contact is again established with the point *g*. The operation is repeated at a rate determined by the size and length of the reed which corresponds with the fundamental of the note it represents.

The main battery is connected as follows: One pole is connected to the ground; the other runs to the instrument, and, entering at binding-screw 4, runs to point *h* of key *c*; from key *c* to point *i*, which makes contact with the reed *a*; from reed *a* to binding-screw 1, and thence to line. It will be seen that when the key is at rest the batteries are open at the points *d* and *h*.

Fig. 6266.

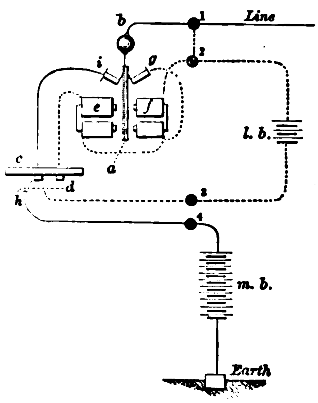


Diagram of Gray's Telephonic Transmitter and Circuits.

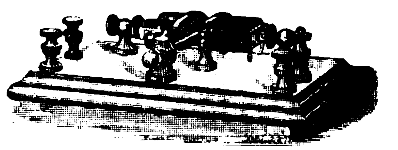
The diagram, Fig. 6266, shows but one key and connections, but all the keys in the instrument, whether one or more octaves, have corresponding reeds and actuating-magnets, the only difference being in the tuning of the reeds. There is but one main and one local battery used, and the connections to each key are run in branch circuits from the binding-screws, as shown in Fig 6266. But since all these branches are open at the key-points, neither of the batteries is closed unless a key is depressed.

If now the keys are manipulated, a tune may be played which is audible to the player. When any key is depressed, the local battery sets in vibration its corresponding reed, which sounds its own fundamental note according to the law of acoustics. So far, the instrument is an electrical organ with steel tongues, the motive power being electricity instead of air. The main battery has had no part whatever in its operation.

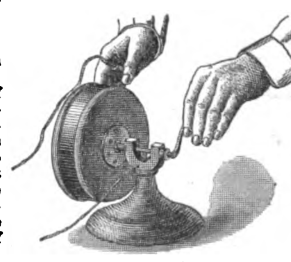
Fig. 6267.



Gray's Telephonic Transmitter, for Composite Tones.

If, however, the main circuit is closed by connecting the distant end to ground, and the point *i* is properly adjusted so that it makes and breaks contact with the reed at each vibration, a series of electrical impulses, or waves, will be sent through the line, corresponding in number per second to the fundamental of the reed, and corresponding synchronous electrical waves can be converted into audible vibrations at the distant end of the line, the note produced being of the same pitch as that of the sending reed.

Fig. 6268.



Gray's Telephonic Receiver.

There are various ways by which these electrical waves may be converted into audible material vibrations. One of them, shown in Fig. 6268, is a thin cylindrical sounding-box, made of wood, the face of which is covered with a cap made of thin metal, electrically connected to the metal stand by means of a wire.

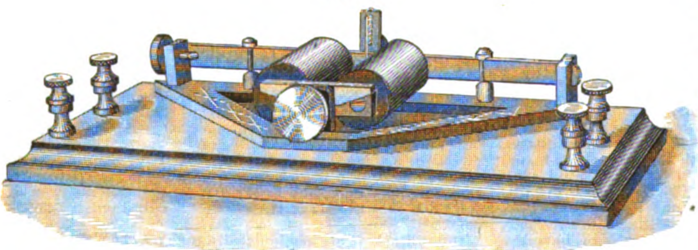
If the operator connects the cap, through the stand, to the ground, and, taking hold of the end of the line with one hand, presses his fingers against the cap, which he revolves by means

of the crank with the other hand, the tune that is being played at the other end of the line becomes distinctly audible, the intensity of the sound being determined by the rate of revolution of the plate. When the motion stops, the sound entirely ceases.

The animal tissue plays a prominent part, as previously stated. If, instead of the revolving plate and the animal tissue, an electro-magnet be placed in the circuit, or a number of them, and a tune be played at the transmitting end, the tune will be heard from all these receiving electro-magnets. These may be on the principle of that shown in Fig. 6265, consisting of a common electro-magnet having a bar of iron rigidly fixed at one pole, which extends across the other pole, but does not touch it by about 1/64 of an inch. In the middle of this armature a short post is fastened, and the whole mounted on a box made of thin pine, with openings for acoustic effects.

So far, consideration has been given to simple tones, but, as in the case of the string and rod referred to previously, a single wire has been found adequate to convey composite tones; a considerable number of tones of different pitch, either in harmony or discord, and the metallic plate or battery of magnets is adequate to translate them. In adapting this principle to a rapid telegraphic system, it becomes necessary to analyze the tones at the receiving end, so that the various messages in the different tones from as many transmitters worked by distinct operators, and all sent to line without any regard to each other, may be sorted at the receiving end by a corresponding number of receiving instruments, each of which shall sound its appropriate message in its own tone, ignoring all the others. The messages, say eight in number, and of as many varying tones, having been simultaneously sent to line, may be said — for the convenience of statement — to be carried as a composite tone to the receiving end, where they pass through a series of receivers, each one of which is in harmony with one of the transmitters. Each receiver sorts out its own message, and among them they may be said to absorb the whole of the vast number of complicated vibrations which have been sent pell-mell through the wire in the form of so many successive magnetizations and demagnetizations.

Fig. 6269.



Gray's Analyzer, or Receiving-Instrument.

Fig. 6269 is a perspective view of one form of a receiving instrument called an *analyzer*. It consists of an electro-magnet adapted to the resistance of the circuit where it is intended to be used, and of a steel ribbon strung in front of this magnet in a solid metal frame, and provided with a tuning-screw at one end, so as to readily give it the proper tension. The length and size of the ribbon depend upon the tone required. If this ribbon be tuned so that it will give a certain note when made to vibrate mechanically, and the note which corresponds to its fundamental is then transmitted through its magnet, it will respond and vibrate in unison with its transmitted note; but if another note be sent which varies at all from its fundamental, it will not respond. If a composite tone is sent, the ribbon will respond when its own note is being sent as a part of the composite tone, but as soon as its own tone is left out it will immediately stop. Thus it *analyzes* the tones which are passing over the line, and selects its own, allowing the others to pass to other instruments with which they are in accord.

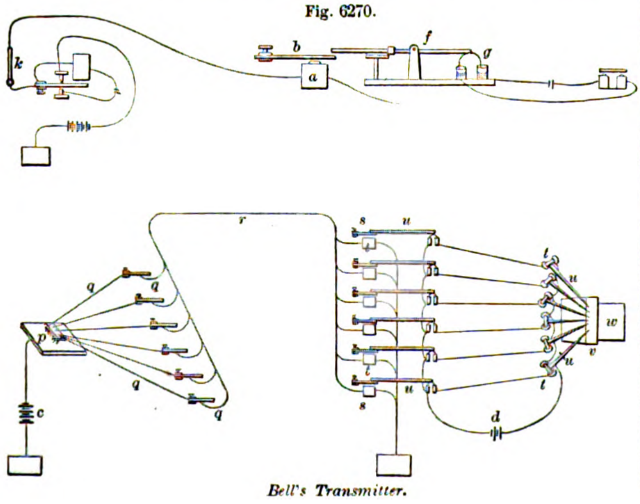
A successful experiment with this system was made at Milwaukee, Wis., on January 8, 1876. A loop was arranged by way of Horicon to Portage and back by way of Watertown, a distance of 200 miles. Over this single wire eight operators sent messages and signals in the same direction at the same time, without any one interfering with another. See for fuller description "Journal of the American Electrical Society," Vol. I. 1875. See also Gray's patent, No. 175,971, dated April 11, 1876.

The same principle has been applied to the transmitting and receiving apparatus of sounding, recording, and printing telegraphs. Bell's patent, No. 161,739, April 6, 1875, comprises a transmitter consisting of a local circuit containing an electro-magnet, with a steel spring armature tuned to a pitch corresponding with a similar armature *b* in the receiver *a*, and vibrating between two platinum points, one communicating with the main line, and the other with the local. The impulses are produced by a key *k*, and are transmitted through the main line to the receiving magnet *a*, the spring armature *b* of which tilts a light, pivoted, non-conducting lever, having at its other end a platinum bow *g* that dips into two cups of mercury and closes the circuit. The wooden lever *f* is balanced so as to vibrate much more slowly than the spring armature by which it is operated, and does not resume its normal position in contact with the latter until this has ceased to vibrate; that is, until the key *k* has been raised.

An autographic telegraph on this principle is composed of a number of these transmitters, the armature of each being connected by a wire with a metallic or conducting bristle mounted in a non-conducting base placed over a metallic plate *p*, with which the bristles are in contact.

The plate is in communication with the main battery *c*. The bristles are insulated from each other, and are placed as near together as possible. From the platinum point with which each transmitter comes in contact in making the circuit, wires *q q* lead to the line wire *r*. At the other end of the line is a series of receiving-instruments *s s* corresponding in number to and having armatures vibrating in consonance with those of the transmitters. Branch wires connect the receivers with the main line wire *r*. In connection with each receiver is a local circuit comprising an electro-magnet *t* and a vibratory lever *u*, one arm of which constitutes the armature of the magnet, and the other arm terminates in a stylus which normally rests upon an ink-ribbon *v* over the bed of the receiving-table *w*. The stylus-armed ends of the levers converge, so as to be in the same relative position, and about as near together as the metallic bristles at the transmitting end of the line. The message to be copied at the receiving end of the line is written or impressed with non-metallic ink on a sheet of metallic foil, and this sheet is placed on the metal plate under the bristles at the transmitting end.

Fig. 6270.



Bell's Transmitter.

The sheet of paper or other material on which the message is to be delivered is placed on the receiving-table *u*, under the stylus-armed levers, and both sheets are simultaneously drawn over their respective tables. So long as the bristles have metallic contact, intermittent electrical impulses from their respective transmitters pass along the line wire and operate the receivers, whose armatures *s s* are attracted, and dip into the mercurial cups, which are in a circuit worked by the battery *d*, lifting the recording ends of the levers away from the ink-ribbon. When, however, the writing comes under the bristles, each, as the metallic contact is interrupted by the interposition of the non-metallic ink, ceases to transmit the electrical impulses, and the circuit-

breaker of the corresponding receiver is raised out of contact with the mercury, the stylus end of the lever comes in contact with the ink-ribbon and causes a mark to be impressed upon the paper underneath. Springs may be employed to give this downward impulse to the levers when the circuit is thus broken. The effect of the alternate elevation and depression of the levers acting upon the ink-ribbon is to reproduce on the receiving-sheet a fac-simile of the writing or object drawn upon the metallic foil at the transmitting end.

Bell's patent, No 174,465, March 7, 1876, describes a method of operating telephonic apparatus by means of undulatory currents of electricity. Instead of making and breaking the circuit, he throws it into waves. He distinguishes three kinds of vibratory currents by which telephonic effects may be produced. 1. *Intermittent;* by making and breaking the circuit. 2. *Pulsatory;* by occasioning *sudden* changes in the intensity of a continuous current. 3. *Undulatory;* by causing *gradual* changes in the intensity of a continuous current. The specification describes the effect upon the current of transmitting a number of musical notes simultaneously by intermittent or pulsatory impulses, and by undulatory currents respectively, and also instances several modes of throwing the current into waves either with or without a battery.

Tel'e-scope. An instrument for magnifying distant objects, so as to make them appear comparatively near.

Gerbert of Auvergne, who taught astronomy in his school at Rheims, observed the stars through a tube, A. D. 1000 He derived it from his tutors at Cordova, and they, no doubt, from the Alexandrian savans. In both places, celestial observations were made through long tubes with object and ocular diopters at the respective ends. No lenses as yet.

Who was the first discoverer of the telescope cannot now be determined. Spectacles were known in the thirteenth century. Roger Bacon employs some expressions indicative of a knowledge of the effect of the combination of lenses. Dr. Dee mentions (1570) that "perspective-glasses" will enable a commander to ascertain the strength of an enemy's forces, referring apparently to an optical instrument then in use.

Baptista Porta said: "If you properly combine a concave and a convex lens, you will see distant and near objects larger and clearer."

Digges states that by an arrangement of mirrors and transparent glasses the image of a small object at a distance may be so augmented as to be brought apparently near to the observer. The matter is restated in a second edition of his works, published in 1591.

Toward the middle of the seventeenth century, Borelli, a Dutch mathematician, interested himself in determining the question of inventorship, and decided in favor of Jansen and Lippersheim, spectacle-makers of Middelburg, Holland, about 1590. Galileo, hearing of the principle of the new wonder, constructed one in 1609, magnifying four times, a second magnifying seven times, and then one magnifying thirty-two times.

It is only fair to give another account, for which we are indebted to Descartes, who lived at about the time when the invention was made public, and had a right to know whereof he affirmed. He says it was made by James Metius, and was due to a fortunate accident. James was a glass-cutter, and had a brother who was a professor of mathematics and a maker of mirrors and burning-glasses. James, it appears, was amusing himself by trying the effect of looking through two glasses, held in line and at a distance, by the respective hands. Fortunately he tried the experiment with a concave and convex glass, which gave the wonderful effect now so familiar. They were fitted in a wooden tube, and made the first telescope ever used in the world, says Descartes. The inventor was a suspicious character, and tried to keep the invention secret even on his death-bed. But his brother and some few others had seen it, and were able to follow the track, which they opened to the world, and which was followed by Galileo. Humboldt says: —

"The accidental discovery of the space-penetrating power of the telescope was first made in Holland, probably as early as the close of the year 1608. According to the latest documentary investigations, this great invention may be claimed by Hans Lippershey (or Laprey), a native of Wesel, and spectacle-maker at Middelburg; Jacob Adriansz, also called Metius, who is said to have made burning-glasses of ice; and Zacharias Jansen.

"Lippershey, on the 2d of October, 1608, offered to the States-General 'three instruments with which one can see to a distance.' On the 17th of the same month, Metius, in his offer to the States-General, states that 'through meditation and industry he had constructed such instruments for two years.' Zacharias Jansen, who, like Lippershey, was a spectacle-maker at Middelburg, together with his father, Hans Jansen, invented the compound microscope having a concave lens for its eye-glass, toward the end of the sixteenth century (probably about 1590), but discovered the telescope only in 1610

"When the news of the recent Dutch invention reached Venice, Galileo was accidentally present; he at once divined what were the essential conditions of the construction, and immediately completed a telescope at Padua for his own use He directed it first to the mountains of the moon, and showed the method of measuring their hights; attributing, like Leonardo da Vinci and Möstlin, the ashy-colored light of the moon to the light of the sun reflected back upon her from the earth. He examined with small magnifying powers the group of the Pleiades, the cluster of stars in Cancer, the Milky Way, and the group of stars in the head of Orion Then followed in quick succession the great discoveries of the four satellites of Jupiter, the two 'handles' of Saturn, — or his surrounding ring imperfectly seen, so that its true character was not at first recognized, — the solar spots, and the crescent form of Venus.

"As early as November, 1610, Galileo wrote to Kepler that 'Saturn consists of three heavenly bodies in contact with each other.' In this observation there was the germ of the discovery of Saturn's ring. Hevelius described, in 1656, the variations in the form of Saturn, the unequal opening of the 'handles,' and their occasional entire disappearance. But the merit of having explained scientifically all the phenomena of the ring of Saturn taken as one belongs to Huyghens (1655). Dominic Cassini first saw the black stripes in the ring (1684), and recognized its division into at least two concentric rings.

"The spots on the sun were first observed through telescopes by John Fabricius of East Friesland, and by Galileo either at Padua or Venice. Fabricius published his discovery in June, 1611, while Galileo did not make his generally known until May, 1612. Galileo noticed that the same spots sometimes returned, and was persuaded that they belonged to the sun itself. The difference in their dimensions when near the center of the sun's disk and on approaching his margin attracted his attention; though it does not appear, from his second letter to Welser, in August, 1612, that he had observed the inequality of the ashy-colored border at the two sides of the black nucleus, when approaching the limb of the sun. Fabricius, like Galileo, recognized the fact that the spots belonged to the sun itself, and also noticed that spots which he had observed disappeared and returned again, and these phenomena taught him the rotation of the sun, which had been conjectured by Kepler before the discovery of the spots. The cycle of admirable discoveries, which scarcely occupied two years, was completed by the observation of the phases of Venus. As early as 1610, Galileo noticed the sickle or crescent form of the planet, and, according to a practice much in vogue in those days, concealed the important discovery in an anagram.

"Huyghens, with an object-glass polished by himself, first discovered one of Saturn's satellites (the sixth) in March, 1655; and from a superstitious notion, entertained by some astronomers of the period, that the number of satellites could not exceed that of the primary planets, did not seek to discover any more of them. Four other of Saturn's moons were discovered by Dominic Cassini: the seventh, or outermost, which has great alternations of brightness, in 1671, the fifth in 1672, and the third and fourth in 1684, with an object-glass of Campani's having a focal length of 100 - 136 feet. The two innermost, or the first and second, were discovered in 1788 and 1789 by Herschel, with his colossal reflector. The second satellite offers the remarkable phenomenon of performing its revolution around the principal planet in less than one of our days.

"The telescopes which Galileo constructed himself, and others which he used for observing Jupiter's satellites, the phases of Venus, and the solar spots, magnified four, seven, and thirty-two times in linear dimensions, — never more.

"The 'Arenarius' of Archimedes says very distinctly that 'Aristarchus had confuted the astronomers who imagined the earth to be immovable in the center of the universe; that this center was occupied by the sun, which was immovable, like the other stars, while the earth revolved around it.'"

Turning the invention to immediate account, Galileo discovered the spots on the sun. On January 7, 1610, he discovered three of the moons of Jupiter, and the fourth shortly after. His discovery of the phases of Venus furnished another proof of the truth of the heliocentric theory. The papal persecution which followed Bruno, who was burnt in 1600, and Galileo, who was denounced in 1616, are familiar to readers. Galileo was visited by Milton while in prison, became blind, then deaf, and died a prisoner of the Inquisition, which followed him after death, denied his right to make a will, to be buried in consecrated ground, or to have a monument. The nineteenth century has attended to the latter duty.

The eye-glasses of the Galilean telescope were double-concave. Kepler first pointed out the possibility of making telescopes with two convex lenses. Scheiner, in 1650, reduced it to practice. De Rheita made one with three lenses; he also made a binocular telescope. The focal length of some of these telescopes was immense. Campani, in 1672, made one for Louis XIV., the focal length of whose object-lens was 136 feet. Auzont had one of 600 feet. Huyghens had one of 123 feet, which is still preserved by the Royal Society of London.

These were used without tubes. Huyghens adopted the plan of placing his object-glass in a short tube, having a ball-and-socket joint, at the top of a tall pole. To this tube was connected a string, so that the observer could bring its axis in line with that of another short tube containing the eye-glass. The great difficulty of managing these cumbrous instruments led to the invention of the reflecting-telescope.

The difficulty of the problem is thus stated by Whewell, in his "History of the Inductive Sciences": —

"If we endeavor to augment the optical power of this instrument, we run, according to the path we take, into various inconveniences, — distortion, confusion, want of light, or colored

images. Distortion and confusion are produced if we increase the magnifying power, retaining the length and the aperture of the object-glass. If we diminish the aperture, we suffer from loss of light. What remains, then, is to increase the focal length."

"Comes Mr Reeve with a twelve-foot glasse. Up to the top of the house, and then we endeavoured to see the moon, and Saturn, and Jupiter, but the heavens proved cloudy."—PEPYS'S *Diary*, 1668.

"The May-pole which stood close to the site of the church of St. Mary-le-strand was begged in 1717 by Sir Isaac Newton, and removed to Wanstead, where it was used in raising the largest telescope then known."—PENNANT'S *London*.

Telescopes are of two kinds, reflecting (or catoptric) and refracting (or dioptric). In the former, an image of the object to be viewed is produced by a concave reflector; in the latter, by a converging lens.

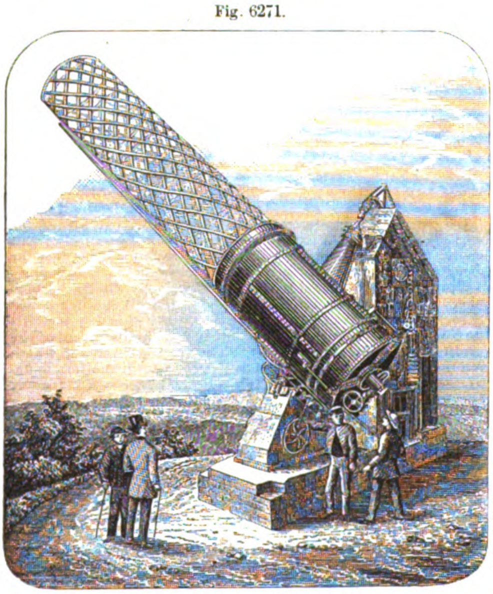
Reflecting telescopes are of four kinds.

The Gregorian telescope (*A*, Fig. 6272) was invented by James Gregory of Aberdeen in 1663. It has an annular metallic speculum and a smaller concave speculum placed in the axis of the tube, at a distance from the larger speculum greater than its focal length. The eye-piece is placed in a smaller tube at the extremity of the longer tube.

The Cassegrainian telescope (*B*, Fig. 6272), was invented by Cassegrain in 1672. It is similar to the Gregorian, except that the smaller speculum is convex instead of concave, and that it is placed in the tube at a distance from the larger speculum less than its focal length. A telescope of this kind, having a speculum of 4 feet diameter and 30 feet 6 inches focal length, was sent from England to Melbourne in 1868. The speculum weighed 3,500 pounds, and was composed of 32 parts copper and 14.77 tin.

Fig 6271 is a representation of the Melbourne telescope, which is really a very fine instrument. The tube is of open work, in order to avoid the air-currents, which with such powerful and delicate instruments are sometimes very annoying in large closed tubes. The mirror in this telescope is placed at the bottom of the tube, and a hole is pierced in the center, in which is placed the *ocular*, in this respect like the Gregorian and Cassegrainian. The hole does not make any practical difference in

Fig. 6271.

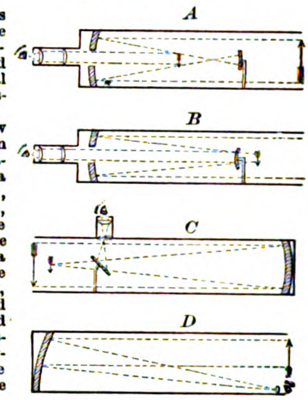


The Melbourne, Australia, Telescope.

the working of the mirror. The clock-work for driving the instrument is seen attached to it. The astronomer directs his *ocular* to a little plane mirror at the upper part of the tube, where the star image is reflected from the parabola.

The Newtonian telescope (*C*, Fig. 6272) was invented by Sir Isaac Newton in 1669. A large concave reflector is placed at one end of the tube. At a distance from the larger mirror less than its focal length is placed, at an angle of 45° to the optic axis of the telescope, a plane reflector, by which the rays proceeding from the object are turned to the side of the tube and viewed by an eye-piece whose axis is at right angles to the axis of the large tube. Foucault used a prism, which was an improvement, especially in making solar observations.

Fig. 6272.



Reflecting- Telescopes.

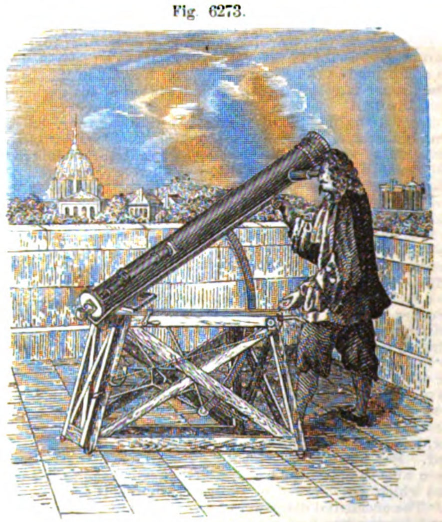
Fig 6273 represents the reflecting-telescope made by Sir Isaac Newton's own hands, and presented to the Royal Society, in whose possession it remains.

Fig. 6274 is the new reflecting-telescope in the national observatory of Paris. It has a parabolic glass mirror, weighing 1,300 pounds, at the bottom of the tube, from which the rays are reflected to a plane mirror in the head of the telescope, the image there formed being examined through a system of magnifying-glasses known as the *ocular*. The telescope is suspended on a movable axis, and has all the usual adjustments in altitude and azimuth with the automatic clock-work motion.

The platform on which the observer stands travels on the rails shown on the floor, and is omitted from the engraving. The weight of the movable portion of the telescope is 9 tons; its cost, $ 40,000.

In the Gregorian, Cassegrainian, and Newtonian instruments the central rays are lost. In the telescope (*D*, Fig. 6272) of Sir William Herschel, invented in the latter part of the last century, the large speculum is inclined to the axis of the tube, and

Fig. 6273.



Telescope of Sir Isaac Newton.

the image of the object observed is brought to the interior edge of the tube, where it is examined by the eye-piece instead of through the medium of the second reflector. By this instrument Sir William Herschel made his numerous and important discoveries.

Herschel's 7, 10, and 20 foot reflectors were made about 1779. He discovered Uranus, March 21, 1781. In 1779, he completed his 40 foot telescope, which was taken down in 1822.

The largest instrument of this class ever made was erected by Lord Rosse on his estate at Parsonstown, Ireland, in 1842.

The diameter of the speculum is 6 feet, having a reflecting surface of 4,071 square inches,—more than double that of Herschel's 40-foot telescope, with which he discovered the moons of Saturn and Uranus, and which had a polished surface of but 1,811 square inches.

A foundry was constructed for the special purpose of casting the speculum, which is composed of copper and tin combined in very nearly their atomic proportions, or 126.4 copper to 58.9 parts tin.

The metal was molten in cast-iron crucibles 2 feet in diame-

ter and 2½ feet deep; these were allowed to heat ten hours previous to the introduction of the metal, which required ten more hours to acquire sufficient fluidity for pouring. The bottom of the mold was formed of layers of hoop-iron turned to the required shape, and its sides of sand. When sufficiently cooled, the cast was removed to the annealing-oven, where it was allowed to remain for sixteen weeks previous to undergoing the grinding process. This was effected under water, by means of a cast-iron grinder having grooves cut lengthwise, transversely, and circularly in its face, emery being used to abrade the surface of the speculum and wear it to a truly circular form; this operation required six weeks.

The tube of this huge telescope, including the speculum-box, is 56 feet long, and is made of 1-inch deal boards hooped with iron. On the inside, at distances of 8 feet, are also iron rings 3 inches deep and 1 inch broad, for strengthening the sides. The diameter of the tube is 7 feet, and it is fixed to masonry in the ground by a universal joint, to allow it free movement in any required direction. At 12 feet distance on each side, walls are built 72 feet long and 56 feet high at their highest parts, the walls being 24 feet distant from each other, and lying exactly in the direction of the meridian. These allow the telescope a motion of but about 15 degrees on either side of the meridian, in an east and west direction; but in the opposite direction, that of the meridian, it may be lowered until nearly parallel with the horizon, when directed south, and so as to point to the north pole of the heavens in the other direction. Elevation or depression is effected by means of a chain and windlass, and the telescope being counterpoised in every direction, two men can perform these operations with great facility, though the total weight is about 15 tons, the speculum alone weighing 3 tons. The total cost of the instrument was not less than £12,000.

Specula for reflecting-telescopes are now made of silvered glass. Its use was first suggested by M. Foucault. Dr. Henry Draper of New York has been very successful in constructing specula of this kind; his process is described in the fourteenth volume of the "Smithsonian Contributions to Knowledge."

M. Secretan of Paris has constructed one for the observatory of Marseilles exceeding 2½ feet in diameter.

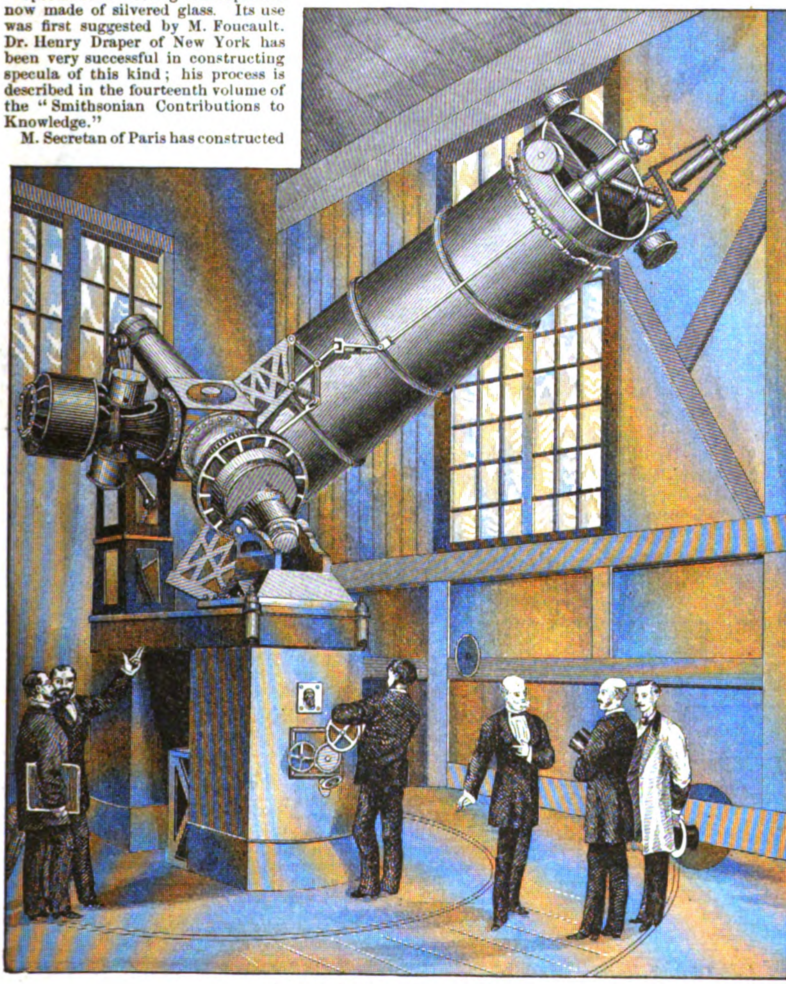
The advantages possessed by glass are that it weighs but from one half to one third as much as speculum metal, that it can be made much thinner, it is more easily wrought, and the loss of light by reflection from the silvered surface is comparatively trifling, while that from a metallic mirror amounts to from one third to one half; besides, should the silvering become tarnished, it can be removed by solution, and replaced without the necessity of regrinding the speculum.

The following remarks on the *apertures* and *powers* of telescopes, by Mr. Tomlinson, will be interesting:—

"The largest achromatic telescopes, such as those at Dorpat and Kensington, have each a clear opening of 13 inches, while that of Lord Rosse's reflector is 6 feet. Taking the diameter of the pupil of the eye at ⅛ inch, the former instruments admit 10,816 times and the latter 331,776 times the quantity of light which is received from any object by the unassisted eye. But as every speculum absorbs about half the light that it receives, the latter number must be reduced to 165,888. These numbers, then, show how much the area of any object may be magnified by these telescopes without rendering it less bright than it appears to be to the naked eye; and their square roots, 104 and 407, show their magnifying powers in such a case.

"We may also, from the size of the aperture of any other telescope, estimate what is called its absolute or penetrating power, which is independent of its length or internal arrangements, and depends solely on the size of the object-glass. The number obtained by the above rule shows how many times farther any object may be seen with the telescope than without it, supposing its brightness to remain the same at all distances as it does *in vacuo*.

Fig 6274.



Great Reflecting-Telescope of Paris.

"The *magnifying power* is totally independent of this, and can be made as great as we please, however small the telescope; but it is obvious that as long as the quantity of light admitted is the same, the more the image is enlarged the fainter it will be, its brightness being always proportional to the quotient of the absolute power divided by the magnifying power. If the latter exceed the former, as it does in astronomical telescopes, the object will be less bright than to the naked eye; but if the absolute exceed the magnifying power, the object will be seen brighter with the telescope than without it."

The telescope at the Washington Observatory, having double the aperture of either of the refractors referred to above, of course admits four times the quantity of light. In this respect it is, however, surpassed in a nearly fourfold ratio by the great reflector of Lord Rosse.

A refracting-telescope in its simplest form consists merely of a double convex lens (the object-glass), which forms an image of the object to be viewed, and a second and smaller double convex lens, called the

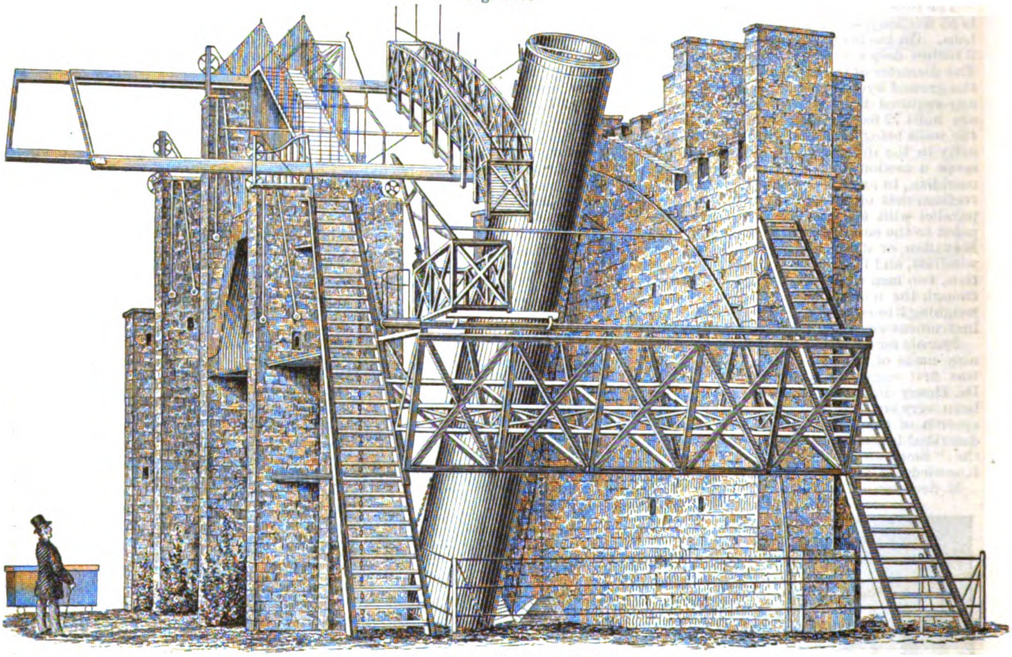
eye-piece, used as a simple microscope to examine the object formed by the first. For perfection of result, the object-glass is made double or triple, to neutralize certain optical inconveniences, called spherical and chromatic aberration, and the eye-glass is generally composed of two lenses suitably combined.

The telescope of Galileo (*A*, Fig. 6276) has a double convex object-glass and a double concave eye-glass. The common opera-glass is made on this principle. The eye-pieces of telescopes are the Ramsden, or *positive*, and the Huyghen, or *negative*.

The positive (*B*, Fig. 6276) has two plano-convex lenses, with the convex sides toward each other. The inner one is the field-glass, and the outer the eye-glass. Their focal lengths are equal. It is suited for micrometers and other instruments having wires in the focus of the object-glass.

The negative eye-piece (*C*, Fig. 6276) has two plano-concave lenses, the convex sides of both being turned toward the object-glass. The ratio of the focal lengths is usually 3 to 1, the latter representing the eye-glass. — G. Chambers. See Lens; Achromatic Lens.

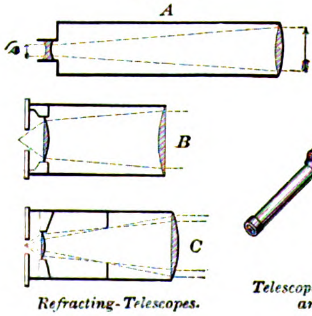
Fig. 6275.



Earl of Rosse's 6-foot Reflector.

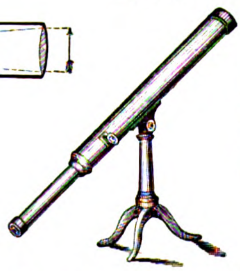
The equatorial telescope is so mounted that its vertical axis points toward the pole, having an inclination corresponding to the latitude, so that a single motion, one of rotation around that inclined axis, will cause the line of sight, the optical axis, to trace upon the sphere a circle corresponding to that in which any heavenly body appears to move. The circles increase or diminish as the telescope is moved upon its horizontal pivot, changing the angle between the line of sight and the inclined axis, just as the circles apparently described by the heavenly bodies increase or diminish according to their polar distance.

Fig. 6276.



Refracting-Telescopes.

Fig. 6277.

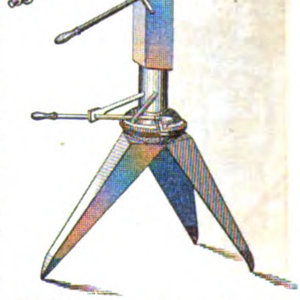


Telescope Mounted on a Pillar and Claw-Stand.

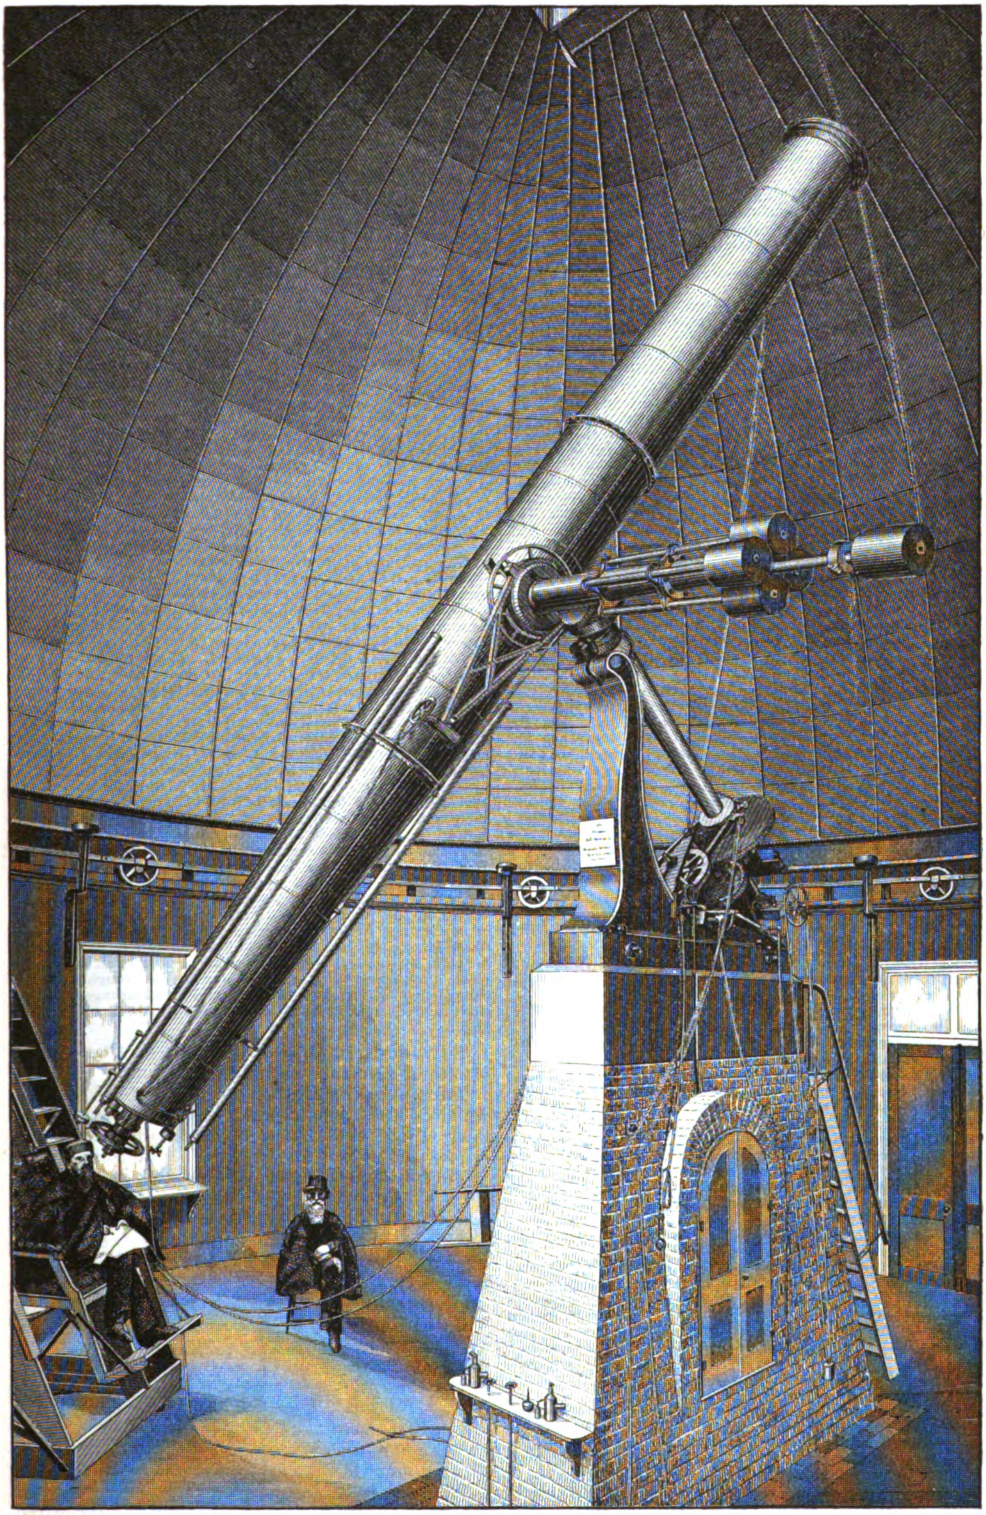
The equatorial of the Cincinnati Observatory was purchased in Munich by Professor O. M. Mitchell, the originator and director of the observatory. The object-glass has a diameter of nearly 12 inches. The death of this talented and Christian gentleman in the service of his country has been a great loss to science and to the social circle, where he was highly esteemed for his modesty and merit.

Large refractors are now universally mounted equatorially, and are made of dimensions which but a few years ago were deemed impracticable. The improvement in this respect is in a large degree due to the exertions of Mr. Alvan Clark, of Cambridgeport, Mass., who, like most other great improvers of the telescope, is a self-taught artist. It would seem that opticians, like poets, are born, not made. Mr. Clark's first object-glasses, strange to say, were made for England, but in 1862 he completed one having a clear aperture of 18½ inches for the Chicago Astronomical Society. This was followed by the great telescope of 26 inches aperture for the United States Naval Observatory

Fig. 6278.



Telescope with Motion in Altitude and Azimuth.



EQUATORIAL REFRACTING TELESCOPE AT WASHINGTON, D. C.

PLATE LXIX.

See page 2524.

at Washington, completed in November, 1873. Mr. Clark is confident of being able to produce an object-glass of 5 feet 6 inches clear aperture and 75 feet focal length.

The largest that had previously been made were those at the observatories of Cambridge, Mass., and Pulkowa, Russia, each having a clear aperture of 15 inches. These were large in comparison with the instruments that had previously been used, those at Dorpat and Kensington having but 13 inches aperture. In the United States, at that time, among the largest were those at

Cincinnati........12 inches aperture; 17 feet focal length.
West Point....... 9⅜ inches aperture; 14 feet focal length.
Washington...... 9⅝ inches aperture; 14 ft. 4½ in. focal length
Alleghany City...13 inches aperture.

The disks for Clark's lenses are made by Chance & Co., of Birmingham, England.

The crucibles are of clay, and are built up gradually in rings of about 2 inches in hight, the process requiring a whole year for its completion.

Optical glass of the best quality is then selected and crushed, and the fragments separated according to their specific gravity by a hydraulic separator, in the manner employed for treating ores. Those of uniform quality and size are selected and melted by the most intense heat of a Siemen's gas-furnace; the mass is then cooled very slowly, and the central portion sawn out. This may be reheated until sufficiently fluid, and molded to approximately the desired shape.

The disks are then tested, to ascertain if the glass is homogeneous and free from flaws. This is effected by throwing the light from a lamp through a lens on one side of the disk, and placing the eye in the focus of the lens at the other side. Any imperfections thus appear greatly magnified, and if not removable by grinding, cause the rejection of the piece, at least for a lens of the size for which it was intended. Polarized light also affords a very delicate test as to whether or not it has been equally annealed. The disk is ground upon concave plates of cast-iron of the proper curvature by pushing it back and forth, at the same time giving a slow rotary movement. Emery, with water, is used as an abradant, finer sizes being successively used.

The polishing is effected by coating the tool with a thin layer of pitch, which is pressed into the proper shape; this is covered with rouge and water, and the disk manipulated as in the grinding process. The pieces forming the lens are, when finished, put together and set on edge, facing a luminous point placed at a distance equal to twelve or fifteen times the focal distance of the lens; the appearance of this point through the lens is examined with an eye-piece of high power, or by the eye placed in the focus; the optician thus judges what parts have an excess or a deficiency of curvature. The polishing process is then repeated upon such portions as are too prominent; the lens is re-examined, and this process repeated until no departure from the proper curve at any point can be detected. This in the case of large lenses is a long and tedious operation, requiring many trials and repetitions of the process. The object-glass has but two pieces,—a plano-concave lens of flint and a double convex lens of crown glass.

The Washington equatorial (shown in Plate LXIX.) has a clear aperture of 26 inches and a focal length of 31 feet 6 inches, its total length being 32 feet 6 inches. The rough glass for the object-lens was received by Messrs. Clark in December, 1871, and was ground, polished, and finished in November, 1872. Another year was required to finish the tube and complete the other parts of the instrument.

The tube is of thin steel, in three pieces, and is mounted upon a pillar of brick supported by an arched foundation of bluestone, and capped by a block of sandstone weighing about two tons. The dome inclosing the instrument is 41 feet in diameter and 25 feet high. It rests upon a tower of equal diameter and 21 feet in hight. For lightness, and in order that the temperature may be maintained at that of the air outside, it is made of pine, covered with galvanized iron. It rests upon thirty-two iron rollers, running upon a circular track, and is rotated by a reaction-wheel driven by water from a main of the Washington aqueduct, and operating also the clock-work mechanism and the conical pendulum of the instrument.

The circles are each read by two microscopes reaching from the eye end of the telescope along its sides to the right-ascension circle, which is divided to seconds, the declination circle being divided to tenths of a minute of arc. The instrument has the usual number of eye-pieces and ring micrometer, a filar micrometer, an Airey double-image micrometer, a mica-scale micrometer, and a spectroscope. The disks for the object-glass cost $7,000; the whole instrument, about $48,000; and the building for its accommodation, about $14,000.

Next in size to this is a telescope constructed by Messrs. T. Cooke and Sons of York, England, for Mr. R. S. Newall, the contractor for the first Atlantic cable. This has an object-glass of 25 inches aperture and 29 feet focal length, and is represented as being a superior instrument.

Another English telescope, constructed by Rev. Mr. Craig in connection with Mr. Cravatt, F. R. S., has a 24-inch object-glass, with a focal length of 76 feet, the length of the tube being 85 feet. This was mounted on Wandsworth Common. The great focal length of this appears remarkable, the tendency of late having been to reduce this as far as possible in proportion to the aperture of the lens.

A telescope is now in course of construction in Dublin for the Austro-Hungarian government. Its object-glass will have an aperture of 27 inches, and its total length will be about 32 feet.

The ratio of focal lengths, mode of construction, powers, proportions, adjustments, and mounting are fully explained in many treatises on the subject. See Pearson, Loomis, Heather, Simms, etc., etc.

One of the most important applications of the telescope is to instruments for making observations upon the heavenly bodies, both to determine their positions and for ascertaining the latitude and longitude. By means of a very small telescope of low power attached to his sextant, the navigator is enabled to observe with far greater accuracy the contact of the sun's disk with the horizon, or the contact of the limbs of the sun and moon, than he could with the plain sight tube. In fact, the lunar method of finding the longitude would be of little value without the telescope, and the nicety and precision now attained in observations on land, both in astronomical observations and in triangulations for surveys, would be utterly impracticable.

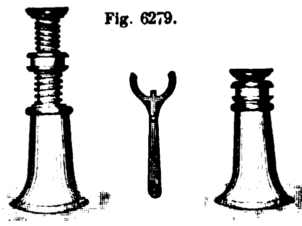
Sir John Herschel says: "The honor of this capital improvement" (the application of the telescope to the measurement of astronomical angles) "has been successfully vindicated by Derham to our young, talented, and unfortunate countryman, Gascoigne, from his correspondence with Crabtree and Horrockes, in his, Derham's, possession. The passages cited by Derham from these letters leave no doubt that, so early as 1640, Gascoigne had applied telescopes to his quadrants and sextants, *with threads in the common focus of the glasses*"; and had even carried the invention so far as to illuminate the field of views by artificial light, which he found "*very helpful when the moon appeareth not, or it is not otherwise light enough*." These inventions were freely communicated by him to Crabtree, and through him to his friend Horrockes, the pride and boast of British astronomy, both of whom expressed their unbounded admiration of this and many other of his delicate and admirable improvements in the art of observation. Gascoigne, however, perished at the age of twenty-three at the battle of Marston Moor; and the premature and sudden death of Horrockes, at a yet earlier age, will account for the temporary oblivion of the invention. It was revived or reinvented in 1667 by Picard and Auzout (Lalande, Astron.), after which its use became universal. Morin, even earlier than Gascoigne (in 1635), had proposed to substitute the telescope for plain sights; but it is the thread or wire stretched in the focus, with which the image of a star can be brought to exact coincidence, which gives the telescope its advantage in practice; and the idea of this does not seem to have occurred to Morin.

Tel'e-scop'ic Boil'er. (*Steam.*) One formed of several concentric cylindrical portions.

Tel'e-scop'ic Chim'ney. (*Nautical.*) One which is in sections slipping into each other, to be lowered in time of action, or, in certain river-steamers, in passing beneath bridges.

Tel'e-scop'ic Jack. A screw-jack in which the lifting head is raised by the action of two screws having reversed threads, one working within the other, and both sinking or telescoping within the base. By this differential arrangement greater power is obtained.

Fig. 6279.



Telescopic Jack.

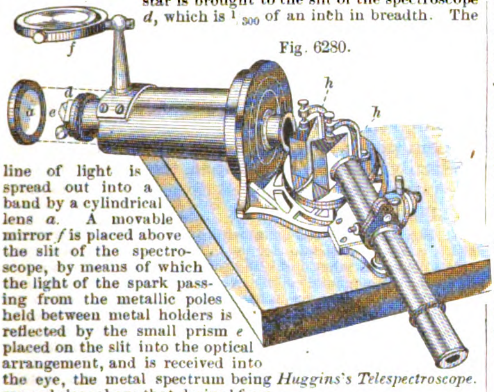
Tel'e-scop'ic Lens. A compound lens suited for the *eye* or *object-glass* of a telescope. Terrestrial telescopes, or spy-glasses, have two additional lenses, enabling an object to be seen in its natural instead

of an inverted position. See LENS; EYE-GLASS; OBJECT-GLASS; TELESCOPE; etc.

Tel′e-spec′tro-scope. An instrument for observing the light from the planets and fixed stars, for ascertaining their physical condition and the composition of their atmospheres.

At the end of the telescope is placed the spectroscope (Fig. 6280), which contains two prisms *h h*, while the image of the star is brought to the slit of the spectroscope *d*, which is $\frac{1}{300}$ of an inch in breadth. The

Fig. 6280.



line of light is spread out into a band by a cylindrical lens *a*. A movable mirror *f* is placed above the slit of the spectroscope, by means of which the light of the spark passing from the metallic poles held between metal holders is reflected by the small prism *e* placed on the slit into the optical arrangement, and is received into the eye, the metal spectrum being ranged close above that derived from the star, so that the coincidence or otherwise of the two sets of lines can be accurately observed.

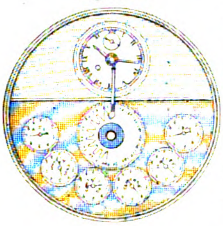
Huggins's Telespectroscope.

Tel′e-ster′e-o-scope. An instrument described by Helmholtz, 1857, for producing an appearance of relief in the objects of a landscape at moderate distances.

It consists of a frame on which are set at a convenient distance — say 4½ feet — apart two plane mirrors at an angle of 45°, which receive the rays of light from the objects; these are reflected to two central mirrors, forming an angle of 45° with the first, in which they are viewed by the eye. The effect produced is the same as if the eyes of the observer were at the same distance apart as the two larger mirrors. When objects at a great distance are viewed, they do not appear in strong relief, but rather as if detached from the general landscape. — *Annales de Chemie*, 3d series, Vol. LII. p. 118.

Tell′tale. 1. A device for counting, indicating, detecting, or verifying.

Fig. 6281.



Telltale.

2. (*Nautical.*) *a.* See TELLTALE-COMPASS.

b. An index in front of the wheel, or in the cabin, to show the position of the tiller.

3. (*Music.*) A movable piece attached to an organ to indicate when the wind is nearly exhausted.

4. (*Gas-making.*) A device attached to a station-meter to point out any irregularity in the production of gas.

It consists of a circular plate placed centrally in the dial-field and carrying a paper disk, and connected by gearing with the wheel which turns the hand belonging to one of the dials of the meter. Above it is a clock, to whose minute-hand is attached an arm carrying a pencil pushed against the paper disk by a spring. If the paper disk were stationary, the pencil would thus be caused to make a vertical stroke up and down each hour, but as the disk slowly turns with the dial-wheel, to which it is connected, the pencil traces a series of curves which are closer together or farther apart in proportion to the quantity of gas passing through the meter. If the quantity of gas produced has been uniform, the apexes of the curves will be equidistant from each other at the margin of the disk; if otherwise, their distances will vary, being nearer together when less than the usual quantity passes through the meter, and farther apart when the normal amount is exceeded.

5. (*Horology.*) A clock attachment for the purpose of causing a record to be made of the presence of a watchman at certain intervals. Arésa's is provided with a rotating paper dial, showing the hour and minute at which the watchman touched a projecting button having a point which punctures the paper dial.

Smith's has a rotating circular frame, fitted with springs and pins; the operative mechanism must be touched at certain definite intervals in order that these shall appear in their proper places when inspected in the morning.

A *telltale* clock is described in English patent No. 1,502 of 1856. See also WATCHMAN'S TIME-DETECTOR.

6. A turnstile having mechanism which indicates the number of passengers.

Tell′tale-com′pass. (*Nautical.*) A compass is suspended overhead in the cabin. The face of the card is downward, so that it is visible from below, and enables the captain to detect any error or irregularity in steering. See HANGING-COMPASS.

Tel-lu′ri-an. *Tellurion.* See TELLURIUM.

Tel-lu′ri-um. The preferable spelling, in consonance with *planetarium, lunarium. Encyc. Brit.*, XVII. 753.

An apparatus for the purpose of illustrating to the eye the real and apparent movements of the earth; exhibiting the ellipticity of the earth's orbit; the position of the sun (represented by a lamp in one of the foci of that ellipse); the inclination of the pole to the plane of the ecliptic, and the constancy of the pole during the entire yearly revolution; the apparent movement through the constellations of the zodiac; the phenomena of eclipses, day and night, sunrise and sunset, and the seasons; the varying declination of the sun; the equation of time; the motions and phases of the moon; and affording a model whereon to illustrate the theory of the tides, lunar disturbances, etc.

See No. 66,791, Campbell, July 26, 1867.

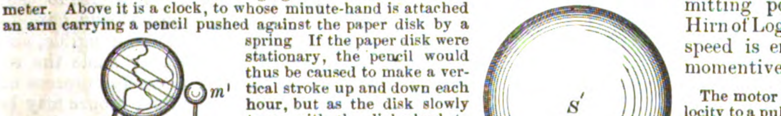
In Davis's tellurium (Fig 6282), a ball *S′* representing the sun is attached to an upright shaft rotated by a crank through the medium of intermediate gearing, and passing through a sleeve rotated by gearing driven by the same crank, and carrying a toothed disk *k* engaging a rod passing through a horizontal tubular arm attached to and at right angles to the sleeve. The rod has a series of wheels at its outer end, which impart a rotary motion to the ball representing the earth, placed on an arm inclined at an angle of 23° 28′ therewith, to the beveled disk *B′*, and to the moon *m′*; the bent stem on which the latter is mounted is connected with an eccentric ring, causing it to move in an elliptic orbit around the earth; it has also a friction-wheel, which, traveling around the inclined edge of the disk *B′*, produces an alternate ascent and descent of the moon, illustrating its changes of declination; the parts by which the moon is revolved are also so adjusted as to exhibit the retrogression of their nodes.

See also ORRERY, pages 1577, 1578; PLANETARIUM, page 1727.

Tel-o-dy-nam′ic Ca′ble. A means for transmitting power, originated by Hirn of Logelbach, in which high speed is employed to give the momentive effect of great mass.

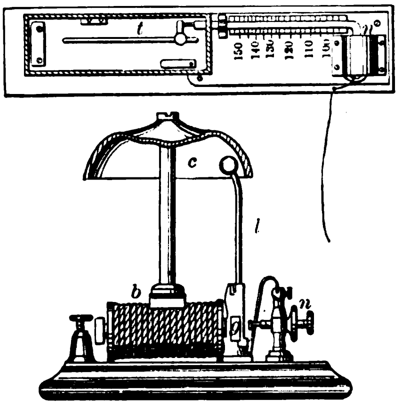
The motor is made to give a high velocity to a pulley-wheel, and this wheel is employed to carry a cable which passes over another pulley at the point where the power is to be applied for use. The cable may be lighter in proportion as the velocity with which it travels is greater. Theoretically, there is no limit to the reduction in size, if sufficient velocity be imparted to give the

Fig. 6282.



Tellurium.

Fig. 6283



Electro-Magnetic Temperature-Alarm.

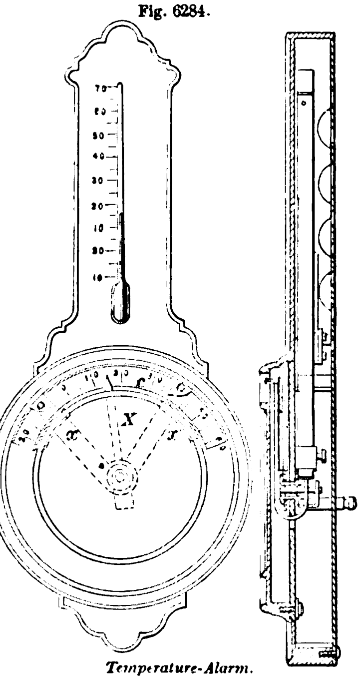
requisite momentum, but in practice this is governed by the velocity with which the pulleys may be safely run, and the strength required by the cable for overcoming the inertia of the pulleys, the friction on their axes, and the resistance of the air, and also the friction of the smaller pulleys on which it must be supported when the distance is considerable. The cable used is of wire, generally about .4 inch in diameter, and is supported at intervals of about 150 yards in grooved pulleys protected by gutta-percha The large transmitting and receiving pulleys at the ends are about 4 meters (13¼ feet) in diameter, making from 150 to 200 revolutions per minute; the cable consequently travels at the rate of 50 to 75 miles an hour. See WIRE-ROPE; WIRE-WAY.

This mode of transmitting power was first successfully employed about 1852, and has since been somewhat extensively introduced into France and other countries.

In the government powder-mills at Okhta, Russia, 274 horse-power, derived from turbines, is thus carried over 4,600 feet; at the mines of Fahlun, Sweden, over 100 horse-power is transmitted nearly 3½ miles. Some have been put up in this country. One at Lockport, N. Y., transmits 25 horse-power 700 feet over pulleys 5 feet in diameter.

The power lost by friction of the two great pulleys has been ascertained to be 2¼ per cent, by the smaller pulleys and rigidity

Fig. 6284.



Temperature-Alarm.

of the cable 1 per cent, for each 1,000 meters; to this must be added the resistance of the air. It was calculated by the inventor that all these together would entail a loss of 25 per cent in a length of six miles, leaving 75 horse-power available at that distance out of 100 originally applied; this is, however, thought to be an overestimate.

Tel'o-type. (*Telegraphy.*) A printed telegram.

Tem'o-in. (*Engineering.*) A pillar of earth left in an excavation to show how much earth has been removed.

Tem'per. 1. An alloy used by pewterers: tin, 2; copper, 1. See ALLOY.

2. The particular condition, as to hardness, of steel. See TEMPERING.

3. Milk of lime, or its equivalent, added to boiling sirup to clarify it.

Tem'per-a-ture-a-larm'. A device which automatically makes a signal when the temperature of the place where it is located exceeds or falls below a determinate point.

In Fig. 6283, one end of a wire, attached to a slider on the rod *t*, is set to a certain degree in the tube of the bent thermometer *n*, the other end being connected with one of the poles of an electro-magnetic coil *b*. A second wire, inserted into the bulb of the thermometer, leads to the other pole. When the mercury rises so as to touch the other end of the first wire, the circuit is completed, and the armature *g* of the electro-magnet, which turns on a spring axis, operates the rod *l*, sounding the bell *c*.

In Fig. 6284, the expansion and contraction of a metallic thermometer, through the medium of a segment rack and pinion, operate an index *X*, which, on coming in contact with a projection upon either of two arms x x', closes an electric circuit and operates an alarm. These arms are independently adjustable toward and from the central point of the index *c*, so as to permit various maxima and minima. See also THERMOSCOPE; THERMOSTAT; THERMOSTATIC ALARM; etc.

Tem'per-er. A machine in which articles are ground together, with the addition of a proper quantity of water, to intimately commingle them and develop the plasticity. Sand and lime thus tempered form mortar; clay thus tempered becomes fit for the potter's use. The machine used by Coignet in compounding his *béton* is called a *malaxator*.

Machines for compounding flour and water into dough are substantially similar, and are called *kneading-machines*. See pages 1230, 1231.

Tem'per-ing. (*Metal-working.*) The process of producing in a metal, particularly steel, that peculiar degree of hardness and elasticity which adapts it for any of the purposes to which it is to be applied.

The malleable metals generally increase in hardness by being hammered or rolled, and *hammer-hardening*, that is, hammering without the application of heat, is frequently employed for hardening some kinds of steel springs.

Steel, however, is for most purposes hardened by plunging it while hot into water, oil, or other liquid, to cool it suddenly.

One of the earliest notices of this art is a simile in the Odyssey, "As some smith plunges into cold water a loudly hissing axe, tempering it."

The notices of the early use of *bright iron* are given under the caption STEEL.

Bronze is tempered by a process reverse to that adopted with steel. Cooling bronze slowly hardens it. The sudden cooling makes it less frangible, and is adopted with gongs. Dr. Faraday made the remark many years since. By a careful process of alloying, tempering, and hammering, bronze may be made as hard as steel, and make excellent springs.

Pliny (A. D. 701) recommends *oil* for tempering steel; he states that *water* makes it brittle.

Metals, in general, suffer no apparent change when heated to redness and suddenly cooled. Pure malleable iron remains entirely unaffected, but when combined with proportions of carbon variable within certain limits, forming steel, it possesses this property of being hardened when suddenly cooled, and being again softened by reheating and slowly cooling to an eminent degree, giving it that pre-eminence which it enjoys over

all other metals for forming weapons, tools, and many other articles. This quality, which appears to be due to molecular changes in the metal caused by great changes of temperature, is to a certain extent participated in by cast-iron, which contains a much larger proportion of carbon, and may be superficially hardened by chilling: without, however, again being softened by a second application of heat.

Thin plates of steel may be hardened by placing them between two good conductors of heat, as a hammer and anvil. Thicker pieces become moderately hard when exposed to the air upon the anvil. If laid on cold cinders or other poor conductor, they become softer, and still more so if placed in hot cinders, or are otherwise very gradually cooled. By heating in closed boxes with charcoal, and very slowly cooling, the metal is reduced to its softest state; by using iron turnings or fine scale from the forge, lime, or other matter which will combine with the carbon, its surface may be reconverted into malleable iron, as is done in Perkins's process for transferring steel engravings. See BANK-NOTE ENGRAVING, page 228; ANNEALING, pages 111-114; STEEL-PLATE ENGRAVING.

Great diversity exists in opinion and in practice as to the best method to be adopted in each particular case. The following principles are, however, generally agreed on: —

The lowest available temperature should be employed in forging and tempering steel; the hammering should be applied equally throughout, and for cutting tools should be continued until they are nearly cold.

Coke or charcoal is much better for fuel than coal, the sulphur in which is apt to be injurious.

The scale should be removed from the face of the work to expose it more uniformly to the cooling medium.

Hardening a second time without rehammering should be avoided, and the less frequently the steel passes through the fire the better.

The smallest works are heated with the flame of the blowpipe, and are occasionally supported on charcoal. Larger works, which are yet too small to be conveniently exposed to the open fire, are protected by an iron tube or box, which is placed in the fire. A crucible or iron pot filled with lead and heated to redness is excellent for long, thin tools, such as artist's gravers. Sometimes a pan filled with charcoal dust and heated to redness on the fire is used.

Many articles are heated in the ordinary forge-fire. The bellows should be used sparingly, and the work should be allowed ample time to get hot, or *soak*, as it is termed. The piece should be uniformly heated by moving it about to expose all parts to the fire, and it is better that it should be rather underheated than over-heated, as the latter involves the risk of burning the metal, while in the former case the defect may be corrected by a second beating. Too little heat fails to produce hardness, and in the opinion of some has an opposite effect. It is consequently resorted to for lowering the temper, the steel in this case being dipped into water, suddenly withdrawn, held a few moments in the steam, again dipped, and similarly treated, and so on until cool.

Various liquids and compounds have been recommended for hardening. Plain water is that generally used, and that which has been long in use is preferred. The common opinion is that mercury gives the greatest degree of hardness: then cold salt water, or water mixed with astringent or acidifying matters; then plain water; and lastly, oily mixtures.

These last are generally used for springs and thin articles, and in some cases water covered with a film of oil is employed. A very high degree of hardness is said to be imparted to gravers, watchmaker's drills, and like small tools by plunging them while hot into a stick of sealing-wax, withdrawing them, and repeating the operation until they become too cool to penetrate. Steel pens are hardened in an oily mixture, and generally tempered in oil or an oily mixture, the boiling point of which is of the proper temperature to let the temper down, or in a dry oven, where a lesser heat may be imparted. Saws and springs are generally hardened in various compositions of oil, suet, wax, and other ingredients, which are partially wiped and afterward burnt or *blazed* off. Gunlock springs are sometimes fired in oil over a fire in an iron tray to let down the temper. Watch-springs are hardened in oil and *blazed* off; they are then stretched in a frame and polished, which appears to have destroyed the elasticity; this is, however, afterward restored by hammering. It is said that Damascus sword-blades are hardened by heating to a certain temperature, and then waving them in a draft of cold air.

Files, previous to being hardened, are drawn through beer-grounds, yeast, or other sticky matter, and then through common salt, mixed with cows' hoof previously roasted and pounded, which serves to protect the teeth against the direct action of the fire. This lessens the tendency to crank, and the fusion of the salt also indicates the proper heat for hardening. The temper of the tang is afterward *drawn* to render it less brittle.

Needles are tempered by exposure to heat on an iron plate over a fire. They are kept in motion by an iron shovel till the blue color appears, when they are instantly removed.

A convenient method of tempering small articles is by a flat bar of iron heated to redness at one end; these are placed on a part of the bar which is at the required heat until they assume the proper color. A number may thus be operated on at once, being gradually pushed forward from the cooler to the hotter parts of the bar.

The heat required for letting down the temper is judged of by the color of the film of oxide which forms upon the surface of the steel when it is reheated after hardening. For this purpose a portion at least of the metal must have a bright surface. This, as the metal becomes heated, assumes the following colors: 1, pale yellow, deepening into a straw yellow; 2, full yellow; 3, the color deepens to purple, copper, brownish purple; 4, deepens into violet; 5, indigo blue to dark blue; 6, lighter blue to sky blue; 7, the blue becomes greenish, producing shades of gray and sea green; 8, the steel reddens.

These colors form a sure guide for the workman, who has only to remove the article from the fire, when it assumes the desired color, and immerse it in cold water; this, however, is sometimes dispensed with.

The following tabular statement shows the colors and degrees of heat proper for tempering various articles of steel: —

1.	Very pale straw yellow	430°	Tools for metal.
2.	A shade darker of yellow	450°	
3.	Darker straw yellow	470°	Tools for wood, screw-taps, etc.
4	Still darker straw yellow	490°	
5.	Brown yellow	500°	Hatchets, chipping-chisels, and other percussive tools, saws, etc.
6.	Yellow, tinged slightly with purple	520°	
7.	Light purple	530°	
8.	Dark purple	550°	Springs.
9.	Dark blue	570°	
10.	Paler blue	590°	Too soft for the above purposes.
11.	Still paler blue	610°	
12.	Still paler blue, tinged with green	630°	

It has been proposed to employ in tempering, alloys composed of lead and tin in such proportions that the fusing-point of each alloy should correspond to the letting-down temperature proper to each class of articles to be tempered.

Garman and Seigfried's process of working and tempering steel consists in heating it to a cherry red in the forge, then covering it with salt; salt is also thrown into the fire, and the steel is worked until it is nearly brought to the finished form. The steel is then covered with a mixture of one part each by weight of salt, sulphate of copper, sal ammoniac, and sal soda, with ½ part of nitrate of potash, heated and hammered; being thus alternately treated with the composition, and heated and hammered until it assumes its finished form. It is then slowly heated to a cherry red and plunged into a bath composed of rain water, 1 gallon; alum, 1½ ounces; sulphate of copper, 1½ ounces; sal soda, 1½ ounces; nitrate of potash, 1½ ounces; salt, 6 ounces. These proportions may be slightly varied.

Large articles are very liable to crack if removed from the hardening bath before becoming cool, owing to the unequal contraction of the interior and exterior portions.

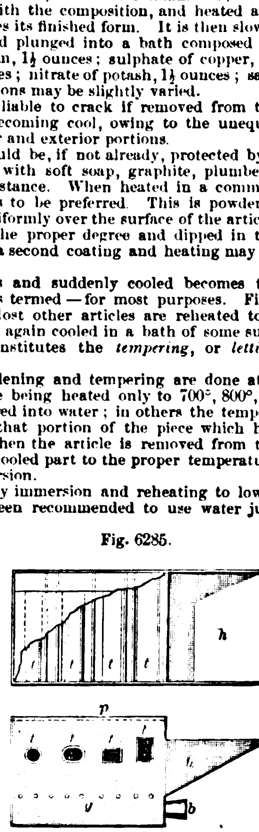
To avoid this they should be, if not already, protected by a coating of scale covered with soft soap, graphite, plumbers' size, or other suitable substance. When heated in a common fire, prussiate of potash is to be preferred. This is powdered and sprinkled or sifted uniformly over the surface of the article, which is then heated to the proper degree and dipped in the water; when extra large, a second coating and heating may be advisable.

Steel heated to redness and suddenly cooled becomes too hard — *glass hard*, as it is termed — for most purposes. Files are left in this state. Most other articles are reheated to a greater or less degree, and again cooled in a bath of some suitable substance. This constitutes the *tempering*, or *letting down* the temper.

In some cases the hardening and tempering are done at a single operation, the piece being heated only to 700°, 800°, or 900° Fah., and then plunged into water; in others the tempering heat is derived from that portion of the piece which has not been cooled, which, when the article is removed from the bath again, heats up the cooled part to the proper temperature for tempering by re-immersion.

Instead of hardening by immersion and reheating to lower the temper, it has also been recommended to use water just sufficiently hot to produce the desired temper at once. The proper heat varies according to the kind of steel and the size of the articles. For springs for the needle-gun a temperature of about 130° Fah. has been employed. For some kinds of steel, boiling water is used. Cooling in hot water is said to increase the tenacity and elasticity of steel containing 0.2 to 0.4 per cent carbon, without much affecting its hardness.

Fig. 6285.



Fellows's Tempering-Furnace.

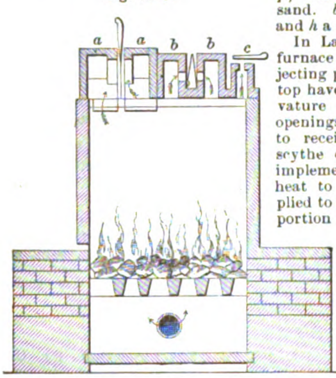
Tem'per-ing-fur'-nace. (*Metal-working.*) One specially

contrived for imparting an equal heat to the articles to be tempered.

Fellows's has a series of tubes *t* over the grate *g*, in which the articles are placed to heat for hardening. To lower the temper, they are placed on a plate *p*, which is covered with sand. *b* is the blast-pipe, and *h* a coal-receptacle.

In Layton's tempering-furnace (Fig. 6286), projecting portions *a a* of the top have a downward curvature and longitudinal openings, adapting them to receive the edge of a scythe or similar curved implement, enabling the heat to be uniformly applied to the blade; another portion *b b* has openings to which the heat is admitted through side apertures, and applied at particular spots in the blade, to rectify irregularities in the temper; at a third opening *c* the heat may be applied to the flat of the blade.

Fig. 6286.



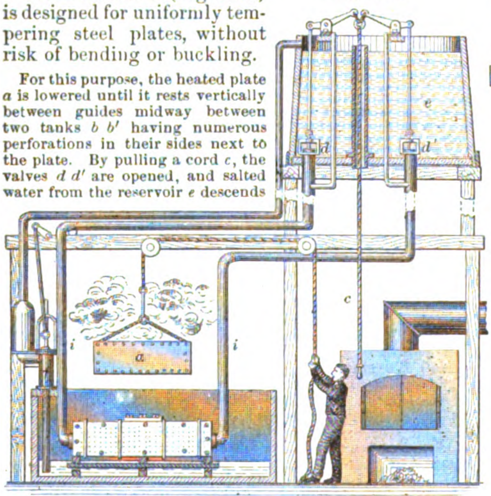
Layton's Tempering-Furnace.

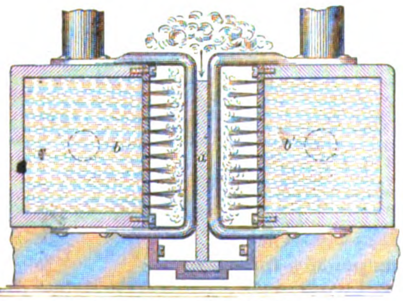
Tem′per-ing-ma-chine′. One for handling heavy steel plates during the operations in tempering.

Urban's machine (Fig. 6287) is designed for uniformly tempering steel plates, without risk of bending or buckling.

For this purpose, the heated plate *a* is lowered until it rests vertically between guides midway between two tanks *b b′* having numerous perforations in their sides next to the plate. By pulling a cord *c*, the valves *d d′* are opened, and salted water from the reservoir *e* descends through the pipes *i i* into the tanks, playing in jets against both sides of the plate; a pump *f* returns the water from the lower reservoir to the upper one, in order that it may be used again.

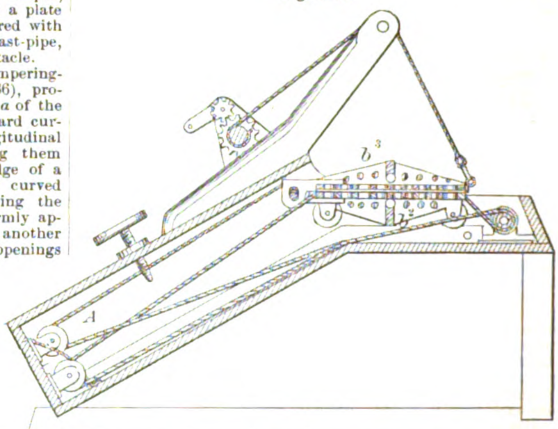
Fig. 6287.

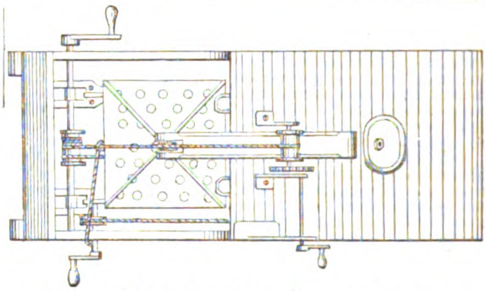




Urban's Tempering-Machine.

Fig. 6288.



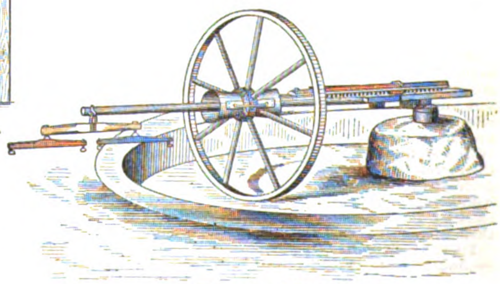


Mercer and Hinton's Machine for Tempering Saw-Plates.

In Mercer and Hinton's machine (Fig. 6288) for tempering saw-plates, the plate is clamped between two perforated plates, strengthened by ribs b^2 b^3, forming a carriage which runs on rails down into the bath *A*. The carriage is raised or lowered by means of a rope or chain passing around pulleys and operated by a winch.

In Crossman's machine for tempering scythe-blades, the blade, after being properly heated, is placed between two jaws, which are forced together by depressing a treadle, clamping the blade, and at the same time immersing it in a tank beneath.

Fig. 6289.



Tempering-Wheel.

Tem′per-ing-wheel. A device for inking and tempering clay for making brick, etc. The wheel is of cast-iron, and revolves on an axis, one end of which is pivoted to an upright in the center of a circular pit, and the other has means of attachment for a horse or horses. A rack and gear-wheels connected with the axle cause the wheel to alternately approach and recede from the center of the pit dur-

ing its onward movement, exposing every part of the clay to its action.

Tem'per-screw. 1. (*Well-boring.*) A piece by which the tools are suspended from the walking-beam, and are lowered as the drilling progresses.

2. A *set*-screw for adjustment. One which brings its point against a bearing or an object.

Tem'plate. See TEMPLET.

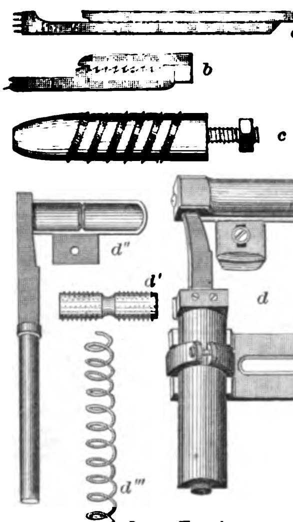
Tem'ple. 1. (*Weaving.*) An instrument for keeping cloth its proper breadth while the reed beats up against it in the process of weaving. In a loom weaving 100 picks per inch, the vibration of the reed being 4 inches, the reed passes over each portion of the warp-threads 800 times. If, therefore, the cloth be not extended so as to bring the warps nearly parallel to the motion of the reed, the selvedge-threads become chafed.

To obviate this difficulty the temple is designed.

The old form is shown at *a*. It consists of two pieces of hard wood with points at the ends to catch the selvedge at either side. They are adjusted as to length for the width of the goods.

b shows Stillman's jaw temple, patented in 1826. The cloth was released and allowed to slide forward when the lay was full up against it, and shut together, holding it out to a proper width when the lay retired. *b* shows the part which held the cloth

Fig. 6290.



Loom-Temples.

The first rotary temple was patented by Ira Draper in 1816. In this, the cloth was held by a horizontal wheel having a row of teeth set obliquely to its axis. It was improved in 1829 in fastening it to the breast-beam by a spring to give it elasticity. George Draper's patent of 1840 added another row of teeth to prevent its leaving a track in the cloth.

c is the Kayser temple which holds the cloth extended by needle-pointed rings turning at an oblique angle to the plane of the breast-beam, thereby automatically stretching the cloth as it passes through

d is the "Dutcher" temple, now in general use. It has small cylindrical toothed rolls holding the cloth by two or more inches of its breadth. It works nearer to the reed than the others, and has a reciprocating action whereby the lay beating against it produces a motion corresponding with and equal to the motion of the cloth. The lower figure shows several parts, — the spiked roller *d'*, its case and bar *d''*, and the spring d''' detached; also the device *d* complete.

2. One of the bars on the outer ends of the spectacle bows by which the spectacles are made to clasp the head of the wearer.

Tem'plet. 1. A mold or pattern used by molders, bricklayers, machinists, etc., in laying off their work. It frequently consists of a flat, thin board, whose edge is dressed and shaped to the required conformation, and is laid against the object being molded, built, or turned, so as to test the conformity of the object thereto.

In the examples, *a* is a *templet* for a *baluster*, which is turned in a lathe.

b is a templet for a steam-engine cylinder, the mold of which is made of *loam work.* See CASTING.

Fig. 6291.

Templets.

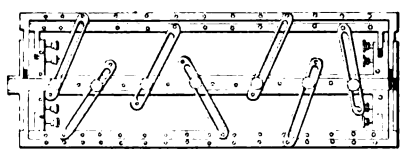
Templets or pattern plates of hardened steel are used for testing the progress and perfection of curved works that are shaped by the file. Sheet-metal works, not required in sufficient quantity to make punches and dies for their production, are fashioned between *templets* in a vice.

The templet for forming the striking wheel of a clock has 12 steps arranged spirally on its edge. A number of brass disks are clamped between two of such templets, and then dressed by a file in correspondence with the pattern at each end of the pack

In making lenses, *templets* of sheet-brass are first made corresponding to the curves of the lenses. These templets are used in making the *shells* and *runners*, between which the lenses are ground to shape.

Perforated templets are used by boiler-makers and others to lay out the holes for punching In order to allow one section

Fig. 6292.



Adjustable Templet.

of pipe to slip into another, the holes around the plate are not punched in rectangular patterns.

Williams's adjustable templet has movable perforated side bars, combined with T-shaped heads upon the central bar; also adjustable and perforated slides combined with each other and with the central bar.

2. (*Shipbuilding.*) *a.* A mold of a certain figure to test or direct the conformation of a timber or other object.

b. A perforated piece or strip by which a line of rivet-holes is marked on a plate to be punched.

c. One of the wedges in a building-block.

3. (*Building.*) *a.* A short piece of timber or large stone placed in a wall to receive the impost of a girder, brestsummer, or beam, and distribute its weight; a wall-plate; a *torsal.*

b. A plate spanning a window or door space to sustain joists and throw their weight on the piers.

4. (*Weaving.*) The templet of the horsehair-loom is a pair of jaws for each selvedge. See TEMPLE.

Temse. (*Milling.*) A bolting cloth or sieve. *Tamise.*

Ten. (*Mining.*) A measure (local) containing 420, and in other cases 440 bolls, Winchester measure.

Te-nac'u-lum. (*Surgical.*) *a.* A fine hook, attached to a handle, which is thrust through the parietes of a blood-vessel to draw it out and enable it to be tied.

a, pocket-tenaculum.

b, aneurism-tenaculum

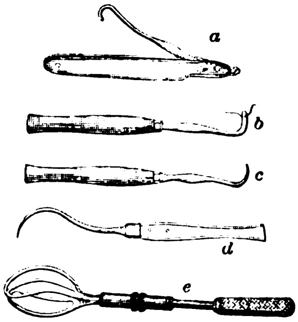
c, aneurism-needle

d, ordinary tenaculum.

e, tenaculum-forceps.

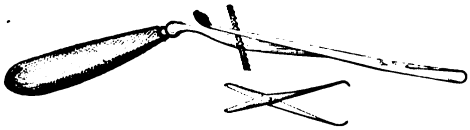
The double tenacula (Fig 6294) consist of two hooks, pivoted after the

Fig. 6293.



Tenacula.

Fig. 6294.



Double Tenacula.

manner of scissors, for more effectually holding the ends of a severed artery.

b. Bone-nippers.

Te-nac'u-lum-for'ceps. (*Surgical.*) An instrument, known as Assalini's tenaculum, for grasping the parietes of an artery, to facilitate tying. The instrument has a pair of bifurcated claws which close into each other upon the artery by the force of a spring.

The tenaculum-forceps with a sliding ring was used in old Rome. One was disinterred at Pompeii in 1819 by Dr Cavenko of St. Petersburg, in the Via Consularis. It is pictured in Smith's "Dictionary of Antiquities," page 274, and is in the Museum of Portici.

e (Fig. 6293) is an instrument invented by Prince, which acts the part of a tenaculum and forceps combined. The upper bow is that of the tenaculum, and beneath it are the bow jaws of the forceps. The blades of the jaws are made wide enough to stop the bleeding, and when the noose of the ligature is over the largest swell of the blades, it slides into its position without catching upon the point of the tenaculum.

Te-naille'. 1. (*Fortification.*) A low work located in the ditch and in front of a curtain to protect the curtain and flanks of the bastions. A passage is left between each end and the adjacent flank. See BASTION.

2. (*Surgical.*) Nippers: *tenaille incisive*, cutting nippers; bone nippers.

Tenettes. Craniotomy forceps.

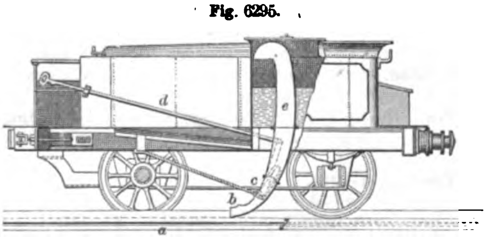
Te-nail'lon. (*Fortification.*) A low outwork having a salient angle; it was formerly usual to place one on each side of a ravelin to increase its strength and cover the shoulders of the bastion.

Ten'ant-saw. See TENON-SAW.

Tend'er. 1. (*Railroading.*) The carriage which is attached to a locomotive and contains a supply of fuel and water. See LOCOMOTIVE.

In 1854, Angus W. McDonald, of New Creek Depot, Va., patented a plan for filling the tanks of locomotive tenders with water without stopping the train, by using an inclined scoop, which was caused to dip into reservoirs placed at suitable intervals alongside of or beneath the track. This method, which met with little favor in this country, has been adopted on several English railways. As there practiced, a long water-trough *a*, made up of cast-iron sections, is laid upon the sleepers between the rails, and at such an elevation that the scoop *b* may be immersed into the water a depth of two inches, just equal to the depth of its mouth, which has a width of 10 inches. The scoop is hinged at *c*, and, when not in use, is tilted upward by a counterbalance weight. When one of the supply-troughs is approached, the scoop is depressed by means of the rod *d*, and the onward movement of the train causes the water to rush into the mouth and be forced up the delivery-pipe *e*, having a downwardly opening mouth through which it is discharged into the tank. On releasing the handle of the rod *d*, the scoop ceases to operate.

Fig. 6295.

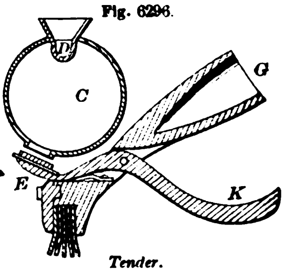


Self-Supplying Tender.

2. (*Nautical.*) A small vessel employed to tend upon a larger one, with supplies of provisions, to carry dispatches, to assist in the performance of shore duty, in reconnoitering, etc.

3. (*Household.*) A small reservoir attached to a mop, scrubber, or similar utensil.

Fig. 6296.



Tender.

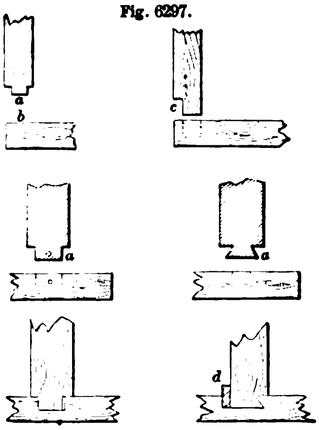
In the example, the socket *G* receives the mop-handle, the tender *C* is supplied through the trough *D*, and the water is caused to flow by compressing the arm *K*, opening the valve *E*, which is afterward closed by a spring.

Ten'der Por'ce-lain. A ware composed of a vitreous frit rendered opaque and less fusible by addition of calcareous clay. Its glaze is a glass of silica, alkali, and lead.

Ten'do-tome. (*Surgical.*) A subcutaneous knife, having a small oblanceolate blade on the end of a long stem, and used for severing deep-seated tendons without making a large incision or dissecting down to the spot. See TENOTOME.

Ten'on. (*Carpentry.*) The projecting end of a piece of timber fitted for insertion into a mortise, formed by cutting away a portion on one or more sides; sometimes made cylindrical. The usual joint in putting up wooden frames, whether of buildings or machines.

Fig. 6297.



Tenons.

a, tenon.
b, mortise.
c, relish.
d, dovetail tenon and key.

Tenons are secured in their mortises by pins, or by giving them a dovetail, which is driven into the undercut mortise by means of a wedge or backing-block *d*.

Fig. 6298 shows tenons of various forms.

A tenon on the top of a post to receive two beams meeting each other at right angles is a *tease*-tenon.

Ten'on-au'ger. The ends of movable blind-slats are usually turned down to a round tenon by a hollow auger *a* (Fig. 6299). The end of the tenon is afterward dressed by a *bur b*; *c* is a shoulder-bur.

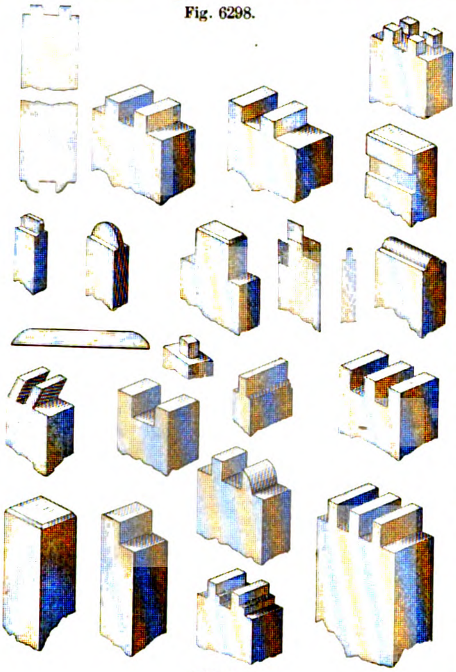
Ellis's blind-slat tenoning-machine operates by a pair of equalizing saws upon each end of the tenon, cutting the shoulders, rounding the tenon, and cutting the slab to a length at one operation.

In Fig. 6300, the cutter is obliquely placed in the snail-shaped holder, so as to make a draw-cut on the stuff. It embraces the hollow mandrel, which in turn incloses the graduated shank. The tube is adjusted on the shank so as to determine the length of the spoke-tenon, and is secured by a temper-screw.

Ten'on-ing-chis'el. A double-blade chisel which makes two cuts, leaving a middle piece which forms a tenon. The two chisels are connected by steady pins and a key to the stock, and are adjusted into exact parallelism by two right and left handed set-screws.

Ten'on-ing-ma-chine'. (*Wood-working.*) A machine for cutting timber to leave a tenon. It may

Fig. 6298.



Tenons.

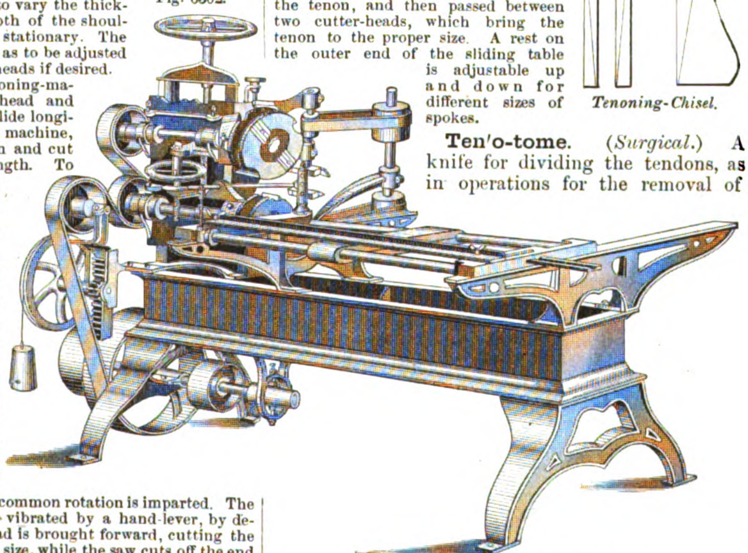
have either a hollow auger, which cuts the stuff away down to the shoulder (see TENON-AUGER); or it may be of the nature of a planing-machine, which, by revolving cutters, removes the stuff from the side, giving the *shoulders* at the sides, and the *relish*, if any (see TENON); or it may be of the nature of a mortising-machine, where chisels cut away the stuff and leave a projecting piece, which constitutes the tenon (see MORTISING-MACHINE).

Fig. 6302 is a machine particularly designed for sash and door work. It is provided with single cutter-heads and double copes. Both cutter-heads are raised and lowered by a screw and band wheel to each, and are readily adjustable, to vary the thickness of the tenon or the depth of the shoulder, the carriage remaining stationary. The coping heads are so arranged as to be adjusted independently of the cutter-heads if desired.

Fig. 6303 is a blind-slat tenoning-machine. The rotary cutter-head and saw-carriers are arranged to slide longitudinally on the bed of the machine, so as to simultaneously tenon and cut off slats of any required length. To provide for this, the main driving-pulleys are made of an elongated form, permitting a considerable range to the belts.

The machine, Fig. 6304, is designed for forming oval tenons on the ends of spokes, obviating the necessity of wedging when the rim is put on. The wheel is held by two chucks which receive the ends of the hubs, and the spoke being operated on is seized by two geared clamps which open and close simultaneously, presenting its end to the action of the cutters and a saw, which are carried on a spindle placed eccentrically to a gear-wheel, by which their common rotation is imparted. The upper part of the machine is vibrated by a hand-lever, by depressing which the cutter-head is brought forward, cutting the oval, which may be varied in size, while the saw cuts off the end of the spoke.

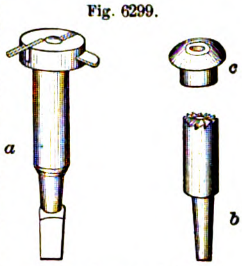
Fig. 6302.



Sash and Door Tenoning-Machine.

Fig. 6305 is a machine for cutting mortises and tenons on the ends of heavy framing-timbers; especially the sill-pieces of railway-car frames. The cutter-heads are fitted to a horizontal spindle running in self-oiling bearings, fixed to a traveling head, which is moved vertically by means of a rack, pinion, and hand-wheel. Tenons may be worked on each end of timbers without turning them around, by passing them along lengthwise across the gap, previously raising the cutters out of the way by turning the hand-wheel.

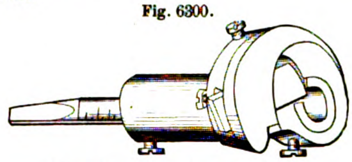
Fig. 6299.



Tenon Auger and Bur.

Ten'on-saw. A thin saw with a thicker metallic backing; used for fine work, such as sawing tenons, dovetails, miters for joints, etc.

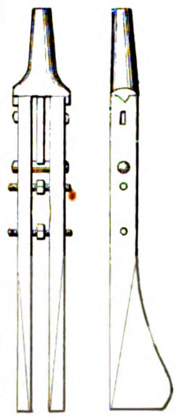
Fig. 6300.



Stearns's Hollow Auger for Spokes.

Some varieties are known as *sash*, *carcase*, and *dovetail* saws. The tenon-saw has 8 teeth to the inch; the carcase-saw, 11 teeth to the inch; the sash-saw, 13 teeth to the inch; the dovetail-saw, 15 teeth to the inch

Fig. 6301.



Tenoning-Chisel.

Ten'on-tru'ing Ma-chine'. (*Wood-working.*) A machine for truing or sizing the tenons of spokes and cutting the tenons to the desired length at the same operation. It has an upright spindle with two cutter-heads, the upper one being adjustable to vary the thickness of the tenons.

The spoke is laid on a small sliding-table, pushed forward to a circular saw, which cuts off the end of the tenon, and then passed between two cutter-heads, which bring the tenon to the proper size. A rest on the outer end of the sliding table is adjustable up and down for different sizes of spokes.

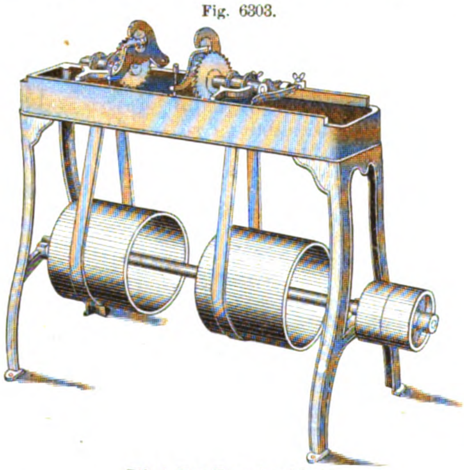
Ten'o-tome. (*Surgical.*) A knife for dividing the tendons, as in operations for the removal of

loxarthrus, or deviation of the joints, as in club-foot.

a, pocket-tenotome.
b c d e, tenotomes of various shapes, to suit special needs.

Ten'sile Strength. The cohesive power by which a material resists an attempt to pull it apart in the direction of its fibers. This bears no relation to its capacity for resisting compression; cast-iron, for

Fig. 6303.



Blind-Slat Tenoning-Machine.

example, which possesses a comparatively low tensile strength, say 30,000 pounds, requires a force of 100,000 pounds or more to the square inch to crush it; while good bar-iron, having nearly double the tensile strength, is crushed by a force of 40,000 pounds to the square inch. The difference is still more marked in the case of stone and similar materials. The table appended gives the usually accepted data. The experiments of General Rodman, Ordnance Manual, 1861, give generally much higher tenacities to the different specimens of wood tested by him. See TESTING-MACHINE.

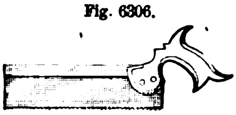
Ten'sion. 1. (*Telegraphy.*) Power of overcoming resistance.

2. (*Mechanics.*) The lengthwise straining force on a member of a truss or frame.

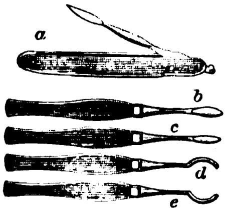
3. (*Sewing-machine.*) A pressure upon the thread to prevent its running too easily from the spool. By adjustment of the pressure at the tension device, the required tightness of stitch is obtained.

Fig. 6306.



Tenon-Saw.

Fig. 6307.



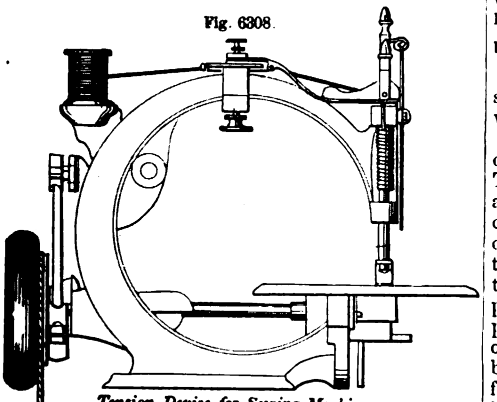
Tenotomes.

In Fig. 6308, the thread passes between two plates secured to the pressure-foot arm, one of which plates is operated by means of a spring acting as a lever, by which the tension is rendered self-adjusting, according to the thickness of the cloth.

There are many other kinds of *tensions*, in different machines. See list, Division F, section 25, page 2112.

Fig. 6309 shows the Willcox and Gibbs automatic tension, a mechanism to hold the thread firmly, so that none can be drawn through until at a fixed point, and then suddenly release it, allowing whatever is required to be freely drawn through. The amount of thread taken at each stitch being of course just what is required to inclose the goods being taken out of the slack

Fig. 6308.



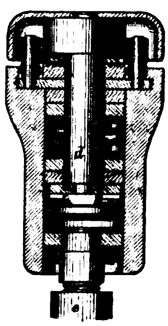
Tension-Device for Sewing-Machines.

thread formed by the descent of the needle-bar take-up, it follows that when the take-up rises and the looper continues to revolve, a point is reached when some more thread must be allowed to escape through the tension, or the thread will be broken. At this time the loop cast off from the looper being drawn up to the under side of the material, the tension opens, and just enough thread is taken to make good the loss.

The automatic tension-device, shown above the actual size in Fig. 6309, and in situ in Fig. 4865, is placed in the standard of the machine, and the thread passing from the spool to the *pull-off* is then led past two pins and between two disk surfaces, one of which is ridged to make the bite upon the thread more effective. The spiral spring shown around the stem *d* is the agent in this grasp of the thread, but at a certain part of the stroke, as above explained, the rod *e* is lifted by an eccentric, and by this positive motion the stem *d* and upper disk are lifted, allowing the thread to be pulled through by the motion of the needle-arm. This elegant device is worthy of a more detailed description.

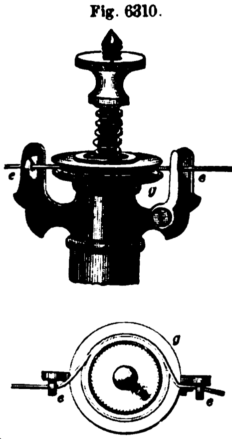
Fig. 6310 shows the W. G. Wilson device for controlling the degree of tightness of the thread of a sewing-machine. The upper thread and the shuttle-thread should have the same tension in a lock-stitch machine, so as to pull the bights of the threads into the middle of the fabric. The under-thread tension is regulated by springs or pins on the shuttle, or by holes in it,

Fig. 6309.



Willcox and Gibbs Automatic Tension

Fig. 6310.



Wilson Tension.

and, in revolving-hook machines, by other means. The upper thread is usually passed against two standards *e e*, between which it is wrapped around a grooved sheave *g*, and its tightness is controlled by the pad, spring, and tension nut, which offers more or less impediment to the rotation of the sheave.

Ten'sion-bridge. A bridge constructed on the principle of the bow, the arch supporting the track by means of tension-rods, and the string acting as a tie. See BOWSTRING-BRIDGE.

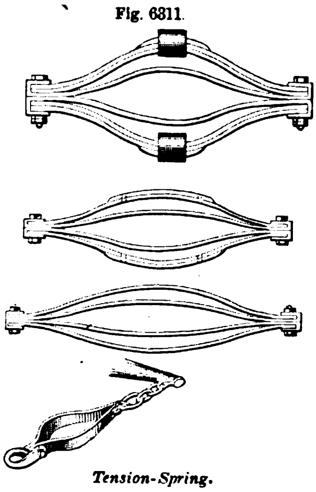
The name may also be applied to a bridge much advocated some years back, for short spans, in which long wooden strips were anchored at each end, and strained as nearly level as possible.

The tension principle abounds in the lower longitudinal members of all truss-girders.

Ten'sion-rod. A *stay* or *tie-rod* in a truss or structure, which connects opposite parts and prevents their spreading asunder.

Tension-spring. A spring for wagons, railway-carriages, etc. The inner leaves, and, in some cases, the outer ones, are free in the center, so as to elongate independently under pressure. The outer leaves may be of any suitable form, so that they impart a tensile strain to the inner ones, which are preferably of *cyma reversa* curvature. Under heavy strains the inner leaves elongate, so as to nearly form cords to the arc of the outer leaves; this limits the inward flexibility of the spring.

Fig. 6311.



Tension-Spring.

Tent. 1. A portable shelter of fabric or other flexible material. Skins have been used for the purpose among barbarous tribes from time immemorial.

The tent is the original of the most graceful of all styles of

architecture, — the Chinese. No plane-surfaced roof, whatever its pitch, can vie in beauty with that which simulates the covering of a tent or pavilion.

Its form permits an amount and kind of graceful ornamentation, checker-work, stripes, barge-boards, and scalloped bordering, which become *it*, and are mere arbitrary and extraneous ornaments to the more formal styles.

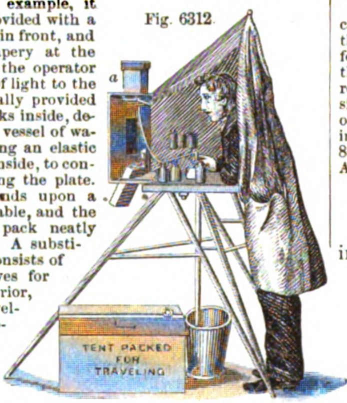
Tents form an important part of the equipment of an army in the field, and much ingenuity has been exerted in endeavoring to secure the maximum of accommodation and comfort with a minimum of weight and space. See ACCOUTERMENTS, Fig. 19. They are known as

Bell-tent,	Marquee,	Sibley-tent,
Hospital-tent,	Shelter-tent,	Wall-tent, etc.

The tent of Achilles was a wooden hut covered with reeds. Such were sometimes used by the Romans in winter. On the Trajan and Antonine columns are four-square tents with slanting roofs, and also conical tents. They were sometimes of leather, usually of cloth. Nero had an octagon tent of great beauty. The Oriental tents were of silk, and gorgeously furnished. That of Attila was very spacious and magnificent. Alexander placed 200 persons in one pavilion.

2. (*Photography.*) An instrument for field-photography; a substitute for the usual dark room.

Fig. 6312.



Photographer's Tent.

As shown in the example, it consists of a box provided with a yellow glass window in front, and furnished with drapery at the back, so as to cover the operator and prevent access of light to the interior. It is usually provided with shelves and racks inside, developing-tray, and a vessel of water *a* overhead, having an elastic tube passing to the inside, to convey water for washing the plate. The instrument stands upon a tripod or skeleton-table, and the whole is made to pack neatly for transportation. A substitute for the tent consists of arm-holes and sleeves for reaching the interior, the progress of development being observed through a yellow window.

3. (*Surgical.*) A roll of lint, sponge, etc., of cylindrical or conical shape, introduced into an ulcer or wound to keep the external portion open and induce it to heal from the bottom.

Sponge-tent is made by dipping the sponge into melted wax plaster and pressing it till cold between two iron plates. It is then cut into pieces.

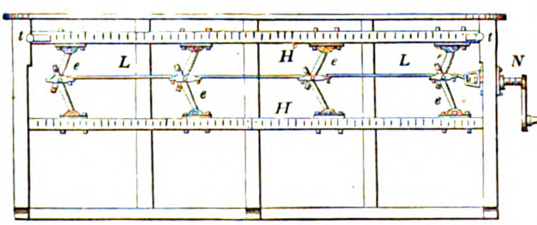
Paper pulp, to which grated sponge has been added, is used for making a paper which may be rolled up to form a tent.

Ten-ta′tion. A mode of operating or adjusting by essay, trial, or experiment, as in

1. (*Locksmithing.*) A mode of picking locks in which the bolt is pressed backward constantly, and the tumblers released one by one from the stud.

2. (*Compass-adjusting.*) Professor Airy's mode of adjusting compasses in iron ships, in which boxes of iron chain and magnets are experimentally placed and shifted in position until the disturbing influence of the iron hull is neutralized. See page 1398.

Fig. 6313.



Tenter-Bar.

Ten′ter. 1. A frame used to stretch pieces of cloth, to make them set even and square. The selvedges of the cloth are attached to the frame by sharp hooked nails, called *tenter-hooks.*

2. A drying-room.

Ten′ter-bar. A device for stretching cloth.

In the apparatus, Fig. 6313, the cloth is attached by hooks to bars *H H′*, which are then drawn apart equally throughout their length by a succession of toggle-levers *e e* actuated by a crank-screw *N* and rods *L L*, which connect the hinging-joints of the toggles.

Ten′ter-hook. One of a set of hooks arranged on the inside margin of a frame and used in stretching cloth, the margin of which is held fast by the hooks.

Ten′ter-ing-ma-chine′. A machine for stretching fabrics.

In one form of the machine, combinations of adjustable oblique traveling selvedge-feeding and carrying devices are used, which, in some cases, operate in connection with endless belts, bands, or cords arranged to hold the selvedges of the fabric in between them and the carrying-devices; the intermediate portion or body of the fabric is run over a divided longitudinally expanding and contracting friction-frame or drag arranged between the selvedge carrying and stretching devices.

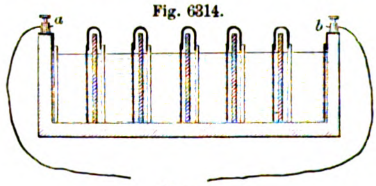
Another machine has an arrangement of separate selvedge carrying, stretching, and feeding devices on opposite sides of the machine, driven in a positive manner, with facility not only for driving said devices on one side of the machine and not on the other, but of positively driving them at different velocities relatively with each other, to adjust the stretch or feed on opposite sides, as required. A roller on the delivery side at the foot of the chains stretches the fabric in its passage from the stretching-devices to the first drying-cylinder. See Palmer's patents, 88,504, March 30, 1860; 148,082, March 3, 1874; and 161,896, April 13, 1875.

Tent′ure. Paper-hangings; wall-paper.

Term. (*Shipwrighting.*) See TERM-PIECE.

Ter′mi-nal. (*Electro-magnetism.*) The clamping-screw at each end of a voltaic battery, used for

Fig. 6314.



Battery.

connecting it with the wires which complete the circuit. One terminal *b* is at the copper or *negative pole*, and the other *a* at the zinc or *positive pole*. Their connection by wire starts the battery into action.

Ter′mi-ni. (*Architecture.*) Busts or figures of the upper portion of the human body, terminating in a downwardly tapering block; employed as pillars, balusters, or detached ornaments for niches. Non-detached ornaments for support may be found under ATLANTES; CARYATIDES; PERSIANS; TELAMONES; etc.

Term-piece. (*Shipbuilding.*) One of the pieces of carved work extending from the end of the taffrail to the foot-rail of the balcony.

Terne-plate. Thin iron plate coated with an alloy of tin and lead.

Ter′ra-al′ba. Literally, *white earth.* Armenian bole; pipe-clay. Used as an adulteration of confectionery, for adding to paper to increase its weight, and for other purposes. The name is also applied to other materials similarly used: as, for instance, calcined or powdered gypsum; calcined, powdered, and floated sulphate of barytes.

Ter′ra-cot′ta. (Fr. *terre cuite*, baked clay.) A compound of pure clay, fine-grained, colorless sand or calcined flints, and pulverized potsherds, is molded, dried in the air, and baked in a kiln. It is especially used for architectural decorations, figures, vases, etc.

Blanchard's terra-cotta (Exposition, London, 1851) was a composition of white pipe-clay, crushed potsherds, calcined flint, flour glass, and white sand, well compounded. The molded articles were burned at a high temperature.

A good article of terra-cotta is more durable when weather-exposed than most stone.

Ter'ras-es. (*Masonry.*) Hollow defects in marble or fissures filled with nodules of other substances. The hole, being cleaned out, is filled with marble dust and mastic of the same color. See BADIGEON, page 207.

Ter'ra-sphere. A term for the TELLURIUM (which see).

Terre'-plein. (*Fortification.*) The upper part of the rampart which remains after constructing the parapet. See BASTION.

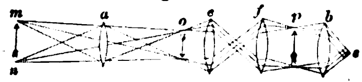
Ter-res'tri-al Eye-piece. (*Optics.*) An eye-piece with three or four lenses, so arranged as to present the image viewed in an erect position. An *erecting eye-piece.* See TERRESTRIAL TELESCOPE.

Ter-res'tri-al Globe. A spherical map representing the land, seas, etc., of the world. In contradistinction to the *celestial* globe, on which are depicted the constellations.

Ter-res'tri-al Tel'e-scope. A telescope differing from the *astronomical refracting* in having two additional lenses, so as to restore the inverted image to an erect position.

The focal lengths of the additional lenses *f b* are usually the same as that of the eye-glass. The two pencils of rays proceeding from the points *m* and *n* cross each other in the anterior

Fig. 6315.



Terrestrial Telescope.

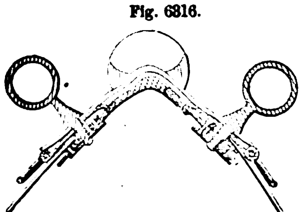
focus of the second lens *f*, and, falling parallel on that lens, form in its principal focus an inverted image of *o*, and consequently an erect image of the object *m n*.

This image *p* is seen by the eye at *s* through the lens *b*, as the rays diverging from *p* in the focus of *b* enter the eye in parallel pencils.

When the first three lenses are equal, the magnifying-power is the same as that of the astronomical telescope, whose object and eye glasses are the same as *a e*. See TELESCOPE.

Rheita was the first to employ the combination of three lenses, known as the *terrestrial* telescope. Scheiner, in 1630, had used a combination of two convex lenses, the image being inverted; to this he afterward added two other glasses, which again reversed the images, making them appear in their natural position.

Fig. 6316.



Gig-Saddle, with Terrets.

Ter'ret. (*Saddlery.*) A ring attached to the pad or saddle and hames of harness, through which the driving-reins pass.

Ter'ri-er. An *auger.* A *wimble.*

Ter'ro-met'al. A composition of several clays, possessing, when baked, peculiar hardness, introduced by Mr. Peake, a potter, of Burslem, England.

It is principally employed for making tiles of various kinds.

Ter'ry. (*Rope-making.*) An open reel.

Ter'ry-fab'ric. (*Weaving.*) (Fr. *tirer*, to draw, to draw out.) A pile fabric, such as plush or velvet; probably from the *drawing out* of the wires over which the warp is laid to make the series of loops seen in Brussels carpet or uncut velvet.

In some looms for weaving pile fabrics, mechanism is employed for actuating the wires, the *terry* loop forming the pile being obtained by inserting wires in a shed formed between the body warp and pile warp, which wires are woven in the fabric, to be again withdrawn in succession when a sufficient number of wires have been woven in the fabric to secure the loops or woven pile against the strain produced in the process of weaving.

Ter'ry-vel'vet. A silk plush, or ribbed velvet.

Tes'sel-at-ed Pave'ment. A pavement composed of square dies or tesseræ made of baked clay or stone, generally of various colors, and forming regular figures. It was employed by the ancients, particularly by the Romans, whose remains furnish the greatest number of existing specimens of ancient art in this line, and is much in vogue in the East, particularly at Damascus.

A pavement of this character, made of cubes of red, blue, black, and white marble, is mentioned in Esther i. 6.

Colored glass cubes were substituted for marble, and were common in the time of Augustus.

Tes'sel-at-ed Tile. Tile made of clay of a particular color, or mixed with coloring matters and formed into flat cakes by cutting or pressing, and used for making a tesselated pavement.

Tes'se-ræ. Colored tiles or bricks, usually cubical, laid in patterns, as a mosaic pavement. See Adam Clark on Revelation ii. 17. See also ABACUS.

Test. 1. (*Metallurgy.*) *a.* A *cupel.*

b. A cupeling-hearth used in a refining-furnace where lead is separated from silver on a large scale. The *test* is an oval iron frame containing a basin-shaped mass of powdered bone-ash, which is brought to a consistence by a solution of pearlash. The *test* is fixed as a cupeling-hearth in the reverberatory furnace, and is subjected to a blast from a tuyere, which removes the floating oxide of silver and furnishes oxygen for its elimination from the alloy under treatment.

Pattinson's process has nearly superseded the plan just described. See SILVER FROM LEAD, EXTRACTING.

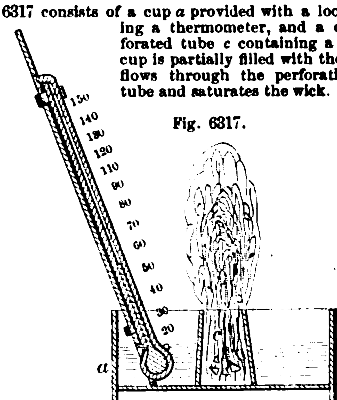
2. The proof of condition of a sirup, which is generally a matter of practice with the sugar-boiler, but has been reduced to a system by Payen. See PROOF.

3. In chemistry, a body which is used to detect the presence of another body in solution, indicating the said presence by a peculiar behavior, or by producing a specific effect. The behavior may be a change of color, as with litmus or turmeric paper. The effect may be a change in the solution as to color, limpidity, evolution of gas, precipitation, heat, congelation, etc.

4. An apparatus for proving petroleum and similar hydrocarbon oils by ascertaining the temperature at which they evolve explosive vapors.

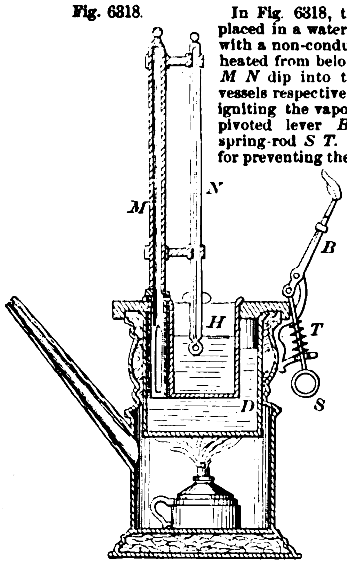
Fig. 6317 consists of a cup *a* provided with a loop for holding a thermometer, and a central perforated tube *c* containing a wick. The cup is partially filled with the oil, which flows through the perforations in the tube and saturates the wick. The latter, being ignited, heats the oil to the vaporizing point and sets fire to the vapor.

Fig. 6317.



Petroleum-Test.

Fig. 6318.



Carbon-Oil Fire-Tester.

In Fig. 6318, the oil-vessel H is placed in a water-bath D provided with a non-conducting jacket, and heated from below. Thermometers M N dip into the water and oil vessels respectively. The brand for igniting the vapor is carried by a pivoted lever B operated by a spring-rod S T. A cap is provided for preventing the vapor from being disturbed by currents of air, and a spigot for ensuring a uniformity in the level of the water and oil.

Test-cock. (*Steam-engine.*) A small cock fitted to the top or bottom of a cylinder for clearing it of water. It is generally constructed with a ball or reverse valve at its mouth, so as to allow of being kept open without the entrance of air, when there is a vacuum on the side of the piston with which it communicates. A *cylinder cock*.

Tes'ter. 1. The square canopy of a four-post bedstead.

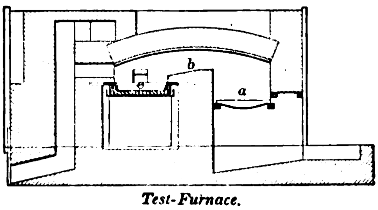
2. The canopy over a pulpit or tomb.

Tes'tes-sup-port'er. A suspensory bandage for the scrotum.

Test-fur'nace. (*Metallurgy.*) One form of refining furnace for treating argentiferous alloy, such as that of lead rich in silver.

It is of the reverberatory kind, a being the fire-grate, b the fire-bridge; c is the cupel or test, consisting of an oval ring of iron provided with cross-bars, into which a bone-ash mixed with water containing a small proportion of pearlash is packed, so as to form a reservoir for the molten metal. The test, when packed, is secured to an iron ring built into the masonry, and a low heat is applied to expel the moisture; this is afterward in-

Fig. 6319.

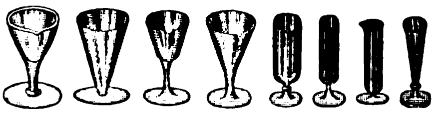


Test-Furnace.

creased until the test becomes heated to a cherry red, when the argentiferous lead previously melted in another furnace is poured in. This soon becomes covered with a grayish dross, and on increasing the heat litharge begins to form. The blast is now turned on, sweeping the litharge from the surface of the alloy and over the breast, where it is received in a proper vessel. As the metal decreases in volume, more is added, and the operation continued until that remaining at the bottom of the test is sufficiently rich to be drawn off; unless this be done at the proper point, a proportion of the silver is carried off with the litharge. When all the argentiferous alloy has been thus treated, it is again subjected to cupellation in the same or a similar furnace, by which the lead is converted into litharge, the silver remaining at the bottom of the cupel, which is then allowed to partially cool, is removed from the furnace, and the plate of silver detached. See ALLOY; AMALGAMATION; ASSAY; PARTING; CUPEL.

Test-glass. A glass vessel of conical or cylindrical form, having a foot and sometimes a beak; used for holding chemical solutions.

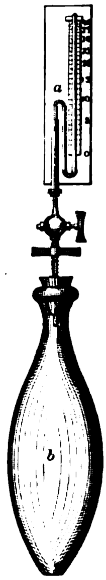
Fig. 6320.



Test-Glasses.

Test'ing-gage. In Fig. 6321, a is an instrument for ascertaining the pressure of gas in soda-water bottles, in order to check the work of the bottlers or test the soda-water of different makers.

Fig. 6321.



Testing-Gage.

It consists of a bent mercurial gage with graduated scale, having a tube with cock and screw-point at its lower end, which is inserted through the cork; on the cock being turned, the gas in the bottle b operates on the mercurial column in the bent tube. The ordinary pressure in bottles of soda-water is found to be from 40 to 60 lbs. per square inch, seldom rising to 70 lbs. See also TEST-PUMP.

Test'ing-ma-chine'. *a.* One for determining the strength of materials with strains of different kinds, tensile, transverse, and what not.

b. A machine for determining the lubricity of oils and other materials used to avoid friction between moving parts.

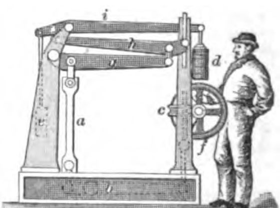
c. A machine for testing the power of motors. See DYNAMOMETER; also *infra*.

The machine, Fig. 6322, is designed for testing the tensile strength of metals. The rod a to be tested is cut to one square inch in section, and is held between clamps attached respectively to the levers b g. The lever b is acted on by a worm-wheel c and worm operated by a hand-wheel f, bringing the tensile strain upon the scale-beam levers g h i; to the long arm of the latter weights d are applied until the bar a is ruptured or the required testing-strain is reached. e is a counterbalance-weight for the levers g h i.

In Fig. 6323, A is an end and B a side elevation of a testing-machine designed by Major Wade for the United States Ordnance Department.

The lever a to which the power is applied has its fulcrum at a', supported by an interior frame b attached to the screw c, which passes through the axis of the bevel-wheel d above. The knife-edge e, from which the weights are suspended, is 72 inches, and the knife-edge f is 3.6 inches, from the fulcrum, or in the proportion of 20 to 1. From the latter is suspended the stirrup g, which receives the knife-edge of the long arm of the lever h, fulcrumed at h', 60 inches distant, and supporting the knife-edge of the stirrup i at a point 6 inches distant from the fulcrum. A force applied at e is thus multiplied 200 times at the latter point. By means of a crank j having a pinion gearing with the wheel k, the axis of which carries a bevel-pinion mashing with the wheel d, the screw c is raised, lifting the frame b, and with it the lever a. The long arm of this lever passes through a slotted guide l, which is simultaneously lifted by the turning of the rod m, which has a pinion at each end mashing with racks on the frame b and guide l respectively. The object of these arrangements is to keep the lever always in a very nearly horizontal position.

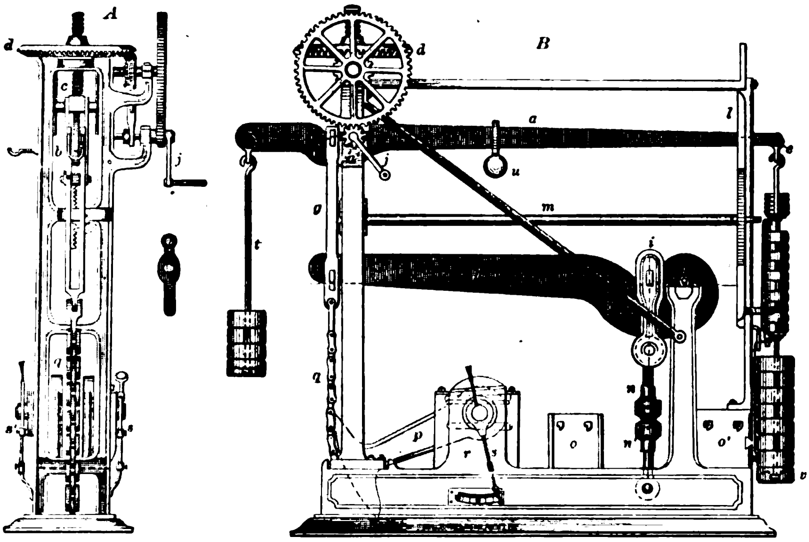
Fig. 6322.



Testing-Machine.

n n' are the devices for holding a bar which is to be tested by extension; these may be replaced by suitable devices for exerting a crushing force, and others for exerting a transverse upward pressure on a bar when drawn up against steel cross-bars placed transversely in the hollow blocks o o', cast with the bed-plate of the machine. p is the torsion-lever connected by a chain q with the stirrup g. In experiments in torsion the lever a is elevated bodily by the screw c through the medium of the crank j and its gearing, the bar to be tested being firmly held by the pedestal r at one end, and keyed to the journal of the torsion-lever at the other. The lever h is not in this case

Fig 6323.



Ordnance Department Testing-Machine.

brought into action. There is an index s s' on each side for indicating the degree of torsion, which, as the bar has a limited amount of play in its fastenings, is determined by the difference of the indexes.

The weights usually employed are of ½ pound, 5 pounds, and 25 pounds, representing strains of 100, 1,000, and 5,000 pounds.

The rod t with its platform and weights is used for adjusting the equilibrium of the machine, and also for counterbalancing the platform v suspended from the long arm of the lever when tensions of less than 5,000 pounds are being investigated. u is a movable weight for equilibriating the holding devices suspended from the stirrup i.

The apparatus (Fig. 6324) invented by Professor R. H. Thurston, of the Stevens Institute of Technology, Hoboken, N. J., is designed for testing and automatically registering variations in strength, elasticity, and ductility of materials; also showing the absolute tensional or torsional strength.

The framework a a' supports two arms b c turning upon independent axes in the same line. The arm b carries a weight d, and the arm c a handle e by which it is moved. To the frame is attached a guide-curve f, so formed that its ordinates are precisely proportional to the strain exerted by the arm b on the material to be tested. This arm also carries a pencil-holder containing a pencil which is pushed outward by the curve f as the arm is deflected from the perpendicular. A table g, to which the record paper is fastened, is attached to the arm c. A pointer j traversing the arc k serves as a check upon the record of maximum strength made by the pencil on the paper.

The axes of the arms b c are alike (B), and have rectangular recesses l designed to receive the ends of the pieces of material when experimenting with torsional strains; the ends of the pieces are made square, and are turned circular at the center, as shown at C D; one end is accurately fitted into the recess on the axis b', and the other into the corresponding recess in c', and force is applied to the arm c, which is transmitted through the piece being tested to the weighted arm b. The normal position of this arm is vertical, but under the influence of the applied pressure it rises, the weight d exerting a greater leverage as it rises; the guide-curve f is therefore so shaped as to cause the pencil to move equal distances with equal increments of force.

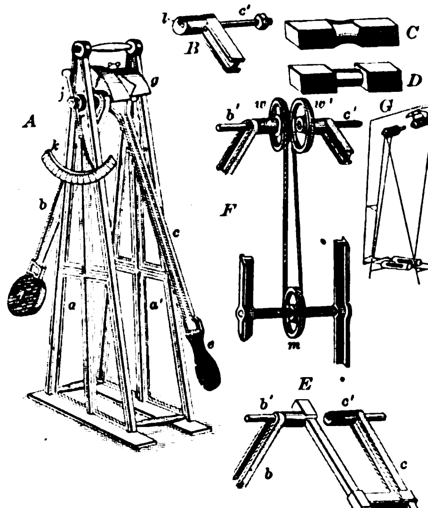
If the material to be tested were devoid of elasticity, the amount of movement of the arms b c would be exactly equal, and the pencil would describe a straight line; but as all materials yield more or less, the arm b will have less angular movement than c after the point is reached at which the fibers of the test-piece begin to change their relative positions, and the difference of their angular movements affords a measure of the distortion produced in the specimen, which is recorded by the curve traced by the pencil.

The paper may be ruled previous to being placed on the table g, according to a scale previously determined from the total movement of which the pencil is capable and the known powers required to lift the weight d to any angle between the vertical and horizontal; in this case the base line of the diagram is placed parallel to the planes in which the two arms move; the pencil is placed at the intersection of one of the lines parallel thereto with one of the other series, which are vertical to it; these serve respectively as the ordinates and abscisses by which the curve showing the behavior of the material being tested is measured. If the paper be not previously ruled, a line drawn between the points at which the pencil was first applied, and at which it rested when the separation of the piece was effected, serves as a basis for constructing the co-ordinates, their origin being reckoned from the first point.

The record thus made is a curve, whose length depends on the amount to which the specimen was twisted before giving way entirely, and its depth shows the maximum force exerted to produce this result. The position of the pencil momentarily changes with each variation in the resistance of the material, and it is at the same time carried along on the periphery of the recording cylinder to a distance proportional to the amount of distortion or the total angle of torsion. As the applied force increases, the specimen yields, and finally, rupture occurring, the pencil returns to the base line at a distance from the starting-point which measures the angle through which the test-piece yielded before its fracture became complete.

The curves described vary greatly according to the character of the material. Considerable irregularities in their outline denote a want of homogeneity. They afford means of determining the elastic resistance, the resistance producing a given set, the ultimate resistance, the resiliency, the effect produced by a given weight on a given cross-section, the effect of blows or shocks either originally or when the material has been already subjected to a given tension, and the effect of a series of stresses.

Fig. 6324.



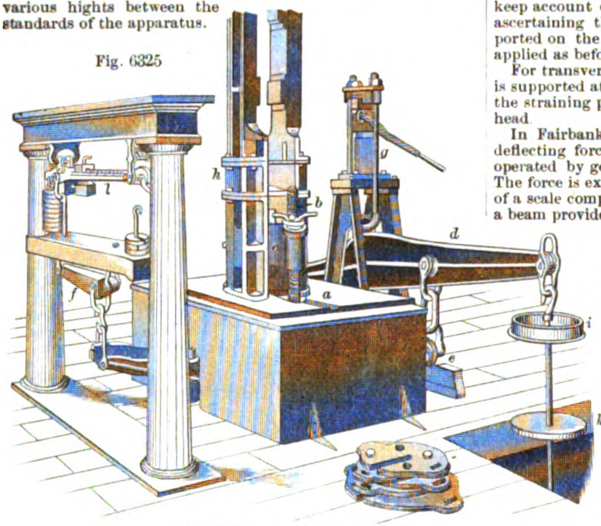
Thurston's Testing-Machine.

E shows the arrangement for investigating transverse strains; the bar to be tested is held in sockets n n, one of which is fitted to the recess l in one of the axes, and the other in a socket adjustable on the arm c.

F is employed for directly testing tensile strengths; the wire or rod is fastened at its extremities to the two wheels w' w' at-

tached to the ends of the axes $b' \ c'$ and passes around a wheel m, which may be adjusted at various hights between the standards of the apparatus.

Fig. 6325

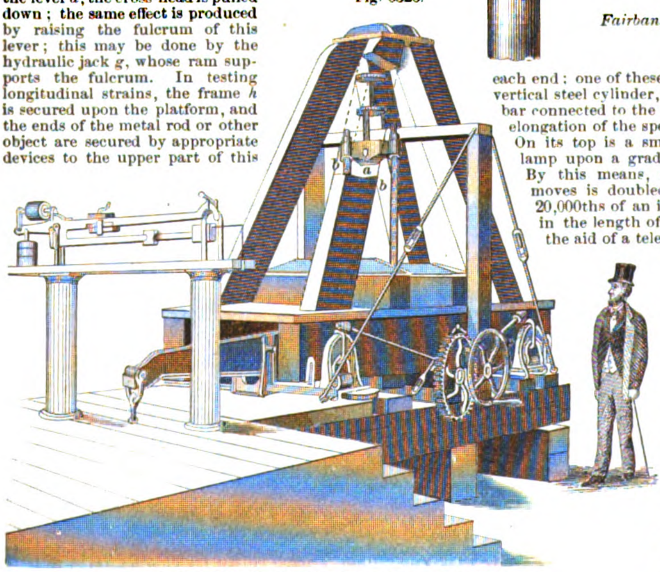


Colt's Armory Testing-Machine.

For heavy work a modification G of the machine is employed in which a spring balance or balances, instead of the weight, and a worm-wheel and worm in place of the simple lever c, are used; the recording apparatus is somewhat differently arranged, the pencil guide-plate being replaced by a spring, cords, and guide-pulleys.

Fig. 6325 is Richards's machine, used at Colt's Armory, Hartford, Conn. It has a platform a with a central opening, through which pass two screws (one shown at b) entering the cross-head c, and connected at their lower ends to the two arms of a forked lever below the floor; the long arm of this lever is coupled with the differential levers $d \ e \ f$, which act upon the scale-beam in such a manner that by depressing the free end of the lever d, the cross-head is pulled down; the same effect is produced by raising the fulcrum of this lever; this may be done by the hydraulic jack g, whose ram supports the fulcrum. In testing longitudinal strains, the frame h is secured upon the platform, and the ends of the metal rod or other object are secured by appropriate devices to the upper part of this

Fig. 6326.



Fairbanks's Testing-Machine (Perspective View).

frame and to the cross-head; weights are then applied upon the scale-pans $i \ k$ until the desired stress is applied, or the tensile limit of the specimen reached. The arms of the levers are so proportioned that one pound in either of the pans exerts a force of 120 pounds upon the specimen, and the strain thus applied is measured upon the scale-beam l, so that it is not necessary to keep account of the weight actually placed in the pans. For ascertaining the resistance to crushing, the specimen is supported on the platform beneath the cross-head, and pressure applied as before.

For transverse strains, the frame h is removed, the specimen is supported at each end over the opening in the platform, and the straining pressure exerted by a knife attached to the cross-head.

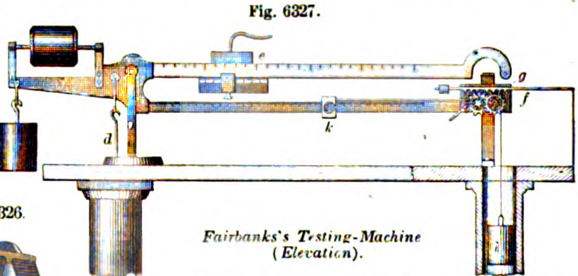
In Fairbanks's testing-machine, the crushing, breaking, or deflecting force is applied to the specimen by a cross-head a operated by gearing and screws $b \ b$ moved by a hand-wheel c. The force is exerted through the specimen upon the platform of a scale composed of a series of multiplying levers and having a beam provided with peculiar arrangements for automatically indicating the equivalent weight of the force.

In the illustration, d is the rod connecting the beam with the multiplying levers, e a sliding poise which is set at a point rather below the stress which it is intended to apply. When the force is applied, the beam rises, causing the small lever f pivoted at g to engage a stop h; this lifts the teeth of a rack on its under side out of engagement with one of the wheels of a clock-work train, and permits the weight i connected to the poise k on the lower beam to act, drawing out the poise until the equilibrium is restored, when the weighted end of the lever falls, re-engaging the wheel; the poise indicating the exact weight equivalent to the force applied. A fly l retards and equalizes the motion of the clock-work.

If greater force be then applied, the beam again rises, and the mechanism operates as before, until the crushing or breaking strain is reached.

In the machine designed by Colonel Flad, used for testing the stone employed in constructing the St. Louis bridge, the specimen is inserted into two collars, one at

Fig. 6327.

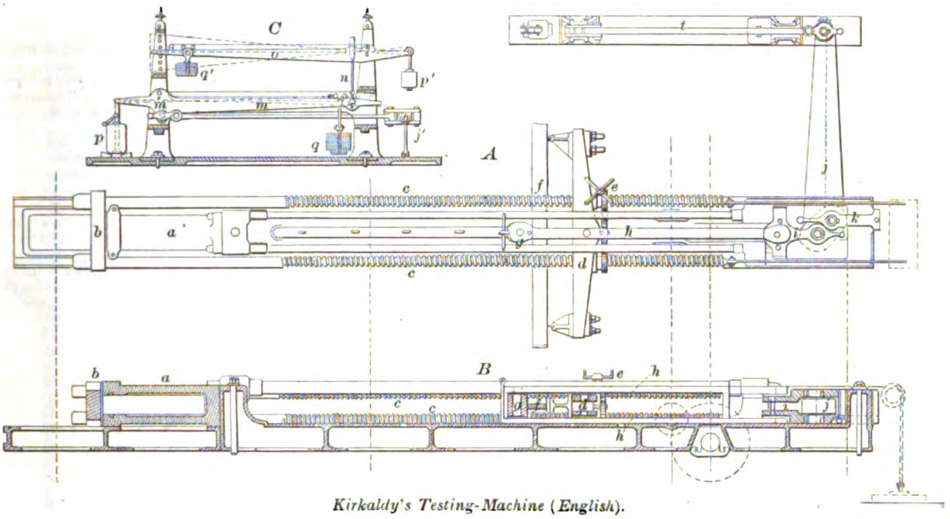


Fairbanks's Testing-Machine (Elevation).

each end; one of these has a flat projection supporting a small vertical steel cylinder, which is pressed by a spring against a bar connected to the other collar, so that any compression or elongation of the specimen tends to turn the cylinder around. On its top is a small mirror, which reflects the light of a lamp upon a graduated arc concentric with the cylinder. By this means, the angle through which the cylinder moves is doubled upon the arc, which is graduated to 20,000ths of an inch, so that alterations of that amount in the length of the specimen become visible, and, with the aid of a telescope, 200,000ths of an inch may be estimated.

Fig. 6328 illustrates Kirkaldy's testing-machine (English patent, No 2970 of 1863). A is a plan, B an elevation of the main frame, and C an elevation of the strain-indicating apparatus. The ram of a hydraulic cylinder a is connected to a cross-head b, which slides upon guides on the frame of the machine, and to this cross-head are attached four screw-threaded rods $c \ c$, passing through a second cross-head d, which by means of nuts simultaneously turned by connected bevel-gears operated by the handle e is caused to have a longitudinal movement along the rods $c \ c$, for the purpose of adjusting it at the proper position on the frame, according as a bending, crushing, or tearing effect is to be produced. At A the machine is represented in the act of bending a bar of metal f, the center of which bears against a knife-edged projection on the hollow block g, secured in the frame by a strong pintle, and connected by rods h to a T-piece i, having a central opening to receive the end of the lever j. A pin passes through i and j, having a knife-edge rest-

Fig. 6328.



Kirkaldy's Testing-Machine (English).

ing against a suitable bearing in the former. A forked piece k receives a similar pin passing through it and the lever j, and serving as a fulcrum when a strain is brought on the lever through the medium of the rods h. The lever is supported at each end upon struts (one seen at j'), and its longer end acts upon a link l connected with the downwardly projecting branch m' of a steel-yard-beam m, so as to convert the horizontal movement of the lever into a vertical movement of the beam m. This beam is used in testing strains of moderate amount. When powerful strains are to be tested, the pressure is transferred by means of an extensible strut n to an upper beam o. In each case, as throughout the machine, the levers turn on knife-edge bearings.

The longer arms of each beam are counterpoised by weights $p\ p'$. The weights $q\ q'$ by which the strain is measured are suspended from carriages running on the upper edges of the beams, and traversed by cords passing over pulleys.

The arrangements for testing, crushing, bending, transverse, compressing, punching, or indenting strains are in general similar; the specimen being placed in the space between the cross-head and cylinder, so as to be subject to a compressive force, while for applying tensile or drawing and similar strains it is placed on the other side of the cross-head, so as to be drawn toward the cylinder a. Special appliances for each of these requirements are provided.

See also Greenwood's testing-machine, page 58*, Class VII. Vol. I., "Official Catalogue of English Exhibition of 1862." See also WEIGHING-SCALE.

In the hydraulic tensile testing-machine (Fig. 6329), the ram of the cylinder being pushed back, the specimen is held by the two clips $a\ b$, and the pump, operated by the lever c, causes the ram to exert a pulling strain upon it, which is communicated to a rod connected with the scale-beam, which has a sliding weight and removable weights, indicating the force applied in tons and hundredweights (112 pounds). To remove the iron under test, release the top valve and push back the ram for another test. It is used in testing rods for various purposes, and also for testing links of chain-cables.

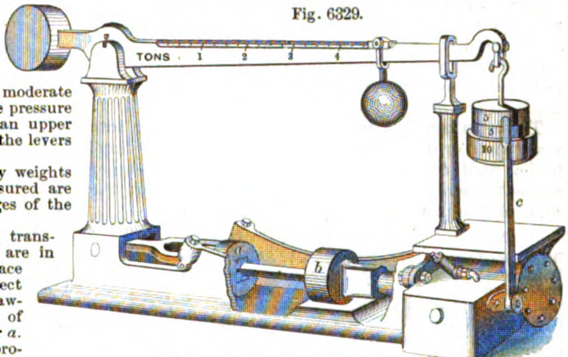
Fig. 6330 is Professor R. H. Thurston's machine for testing the value of lubricants, simultaneous dynamometrical and thermometrical readings being obtained.

In using the machine, a small and determinate quantity of the oil to be tested is placed on the journal F, and the pressure being adjusted by the screw K to that at which the oil is desired to run under test, the machine is started at a speed which will give the desired relative velocity of rubbing surfaces. Observations are made at short intervals, and recorded, until the test is closed by rapid heating, as shown by the thermometer, and excessive increase of friction, as indicated by the arm $H\ H$ swinging up against its chocks. Competing oils are similarly tried, and the records afford a perfect means of comparison.

Thus sewing-machine builders desire oil of long endurance, and small frictional resistance and viscosity; on locomotives, an oil that will bear high pressure for the greatest length of time without heating is the most desirable, even although not as limpid and of as slight frictional resistance. The relative power of resisting high temperatures without decomposition is another important point which may be tested. See THERMO-ELECTRIC ALARM; TEMPERATURE-ALARM; THERMOSCOPE; etc.

Fig. 6331 is Emerson's apparatus for testing water-wheels. The wheel b is secured to the shaft of the water-wheel, and its speed is regulated by the friction-band a, which is connected

Fig. 6329.



Hydraulic Tensile Testing-Machine.

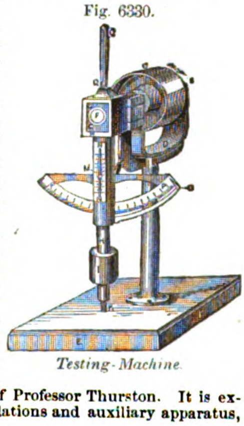
with the scale-beam as shown, the point of connection describing a circumference of 15 feet. The rim of the wheel and the friction-band are hollow, and are kept cool by streams of cold water passing through them. The wheel b is made of cast-iron, and the friction-band of gun-metal. The hands of the counter are operated by worm gear, and move like the hands of a clock.

The hand-wheel m has a universal joint, to prevent fraud. The pivot of the scale-beam and its connections with the friction-band are knife-edged.

The weights are suspended at one end of the beam, as shown at c: the other end has attached a plunger working loosely in the cylinder d, which is filled with water; this forms the hydraulic regulator for steadying the scale-beam.

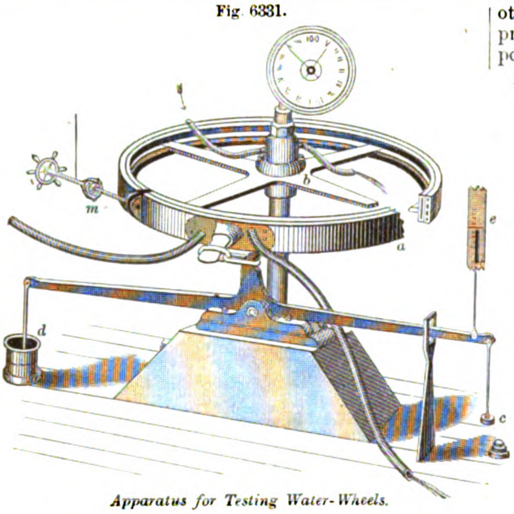
The A. H. Emery testing-machine of 400 tons capacity is expected to be completed and at work at the Watertown Arsenal this year. It has an independent straining mechanism, fitted with a strain diagram apparatus, designed by C. E. Emery to produce diagrams somewhat like those of the autographic testing-machine of Professor Thurston. It is expected to cost, including foundations and auxiliary apparatus, about $ 50,000.

Fig. 6330.



Testing-Machine.

Fig. 6331.



Apparatus for Testing Water-Wheels.

Test′ing-slab. A square plate of white glazed porcelain, having cup-shaped depressions for containing liquids to be examined which give colored precipitates.

Test-mix′er. A tall cylindrical bottle having a wide foot and provided with a stopper. It is graduated into 100 or more equal parts, commencing at the bottom, and is used in preparing test-alkalies, test-acids, and similar solutions, by diluting them down to the required strength.

Test-pa′per. A paper prepared by dipping into a solution or decoction of a substance and drying; to be used to detect the presence of a substance whose presence causes a reaction and a change in the color of the paper.

Paper.	*Changes to*	*By presence of*
Brazil-wood paper	Purple	Alkali.
Brazil-wood paper	Red	Strong acid.
Buckthorn-paper	Red	Acid.
Cherry-juice paper	Red	Acid.
Dahlia-paper	Green	Alkali.
Dahlia-paper	Red	Acid.
Dahlia-paper	Yellow	Caustic alkali.
Indigo-paper	Decolored	Chlorine.
Iodine-paper	Blue	Acid solution of starch.
Lead-paper	Black	Sulphuric hydrogen.
Litmus-paper (blue)	Red	Acid.
Litmus-paper (blue)	Green	Alkali.
Rose-paper	Green	Alkali.
Starch-paper	Blue	Iodine.
Turmeric-paper	Brown	Alkali.

Fig. 6332.

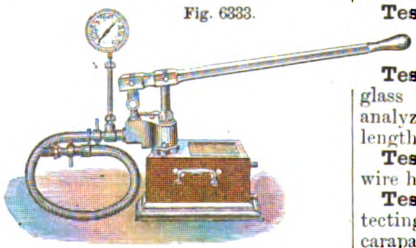
Test-Mixer.

Test-plate. 1. A finely ruled glass plate used in testing power and defining quality of microscopes. See NOBERT'S TEST-PLATE, pages 1531, 1532.

2. A glass slip used in stirring tests.

Test-pump. A force-pump for testing the strength of boilers, tubes, and other hollow articles by hydraulic pressure. It is provided with a gage for showing the pressure in pounds applied to the square inch.

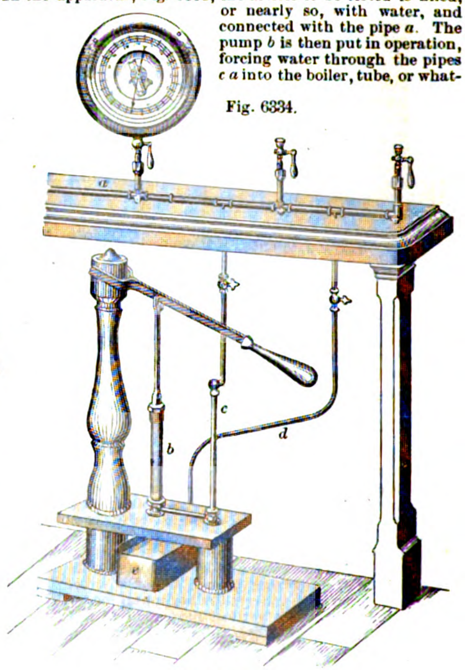
Fig. 6333.



Test-Pump.

In the apparatus, Fig. 6334, the article to be tested is filled, or nearly so, with water, and connected with the pipe *a*. The pump *b* is then put in operation, forcing water through the pipes *c a* into the boiler, tube, or whatever the object may be, until it bursts or the maximum proof-pressure is reached; its amount is shown by an index upon a dial. The water in the pipes is, after use, returned to the cistern through the pipe *d*.

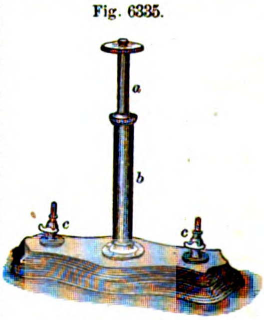
Fig. 6334.



Test-Pump.

Shaw's (Fig. 6335) is particularly designed for testing steam and hydraulic gages. The plunger *a* has an interior screw-thread fitting over a screw running the whole length of the cylinder *b*, and is turned by means of a hand-wheel, testing pressures up to 800 lbs. to the square inch; water is introduced into the cylinder through an opening at the top of the plunger, which is closed by a thumb-screw. *c c* are the valves, having screw-threaded nipples, to which gages to be tested are attached.

Fig. 6335.



Shaw's Test-Pump.

Test-spoon. A small spoon used for taking up small quantities of powders, fluxes, etc.; used in blow-pipe or chemical experiments. The handle may be used as a spatula.

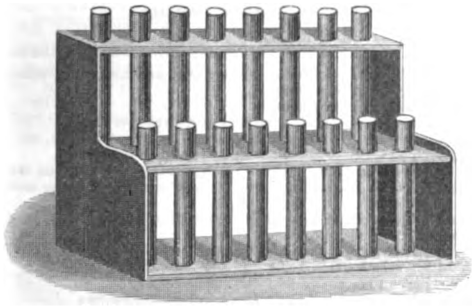
Test-stir′rer. A round glass rod, having one end pointed for dropping tests, and the other end rounded.

Test-tube. (*Chemical.*) A thin cylinder of glass with a rounded bottom, used in testing and analyzing liquids. They are made of various sizes and lengths. Fig. 6336 shows a stand with test-tubes.

Test-tube Brush. A small spiral brush with a wire handle for cleansing test-tubes.

Tes′tu-do. 1. (*Military Engineering.*) A protecting device; so called from its resemblance to the carapace of a tortoise. The term was applied by the ancient Romans to a covering formed by joining the

Fig. 6336.



Test-Tubes and Rack.

shields of the soldiers over their heads, so as to constitute a species of roof, affording protection from missiles thrown from above; also to a structure movable on rollers or otherwise, for protecting sappers in an attack; and is now applied to objects similar in shape and design employed as defenses for miners, etc., when working in ground or rock which is liable to cave in.

Fig. 6337.

Test-Tube Brush.

2. (*Music.*) A species of ancient lyre, the idea of which is said to have been derived from the carapace of a tortoise. See LYRE.

Tete-a-tete. Two chairs with seats attached and facing in opposite directions, the arms and backs forming an S-shape.

Tete-de-pont. (*Fortification.*) A *redan* or *lunette* resting its flanks on the bank of a river and inclosing the end of a bridge for the purpose of protecting it from an assault.

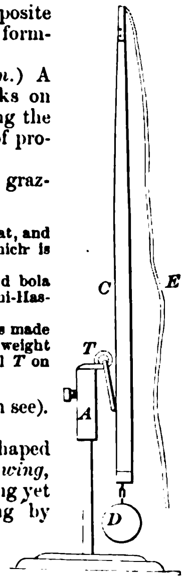
Teth'er. A rope by which a grazing animal is tied to a stake.

The rope is frequently termed a lariat, and is secured to an iron picket-pin, which is driven into the ground.

Catching animals with the lasso and bola are both shown on the paintings of Beni-Hassan in Egypt.

In Fig 6338, the tethering-rope *E* is made fast to a swinging upright *C*, having a weight *D* at bottom and connected to a swivel *T* on the post *A*.

Fig. 6338.



Tether.

Tew'el. 1. A TUYERE (which see).

2. A pipe or chimney.

Tew'ing-bee'tle. A spade-shaped instrument for beating hemp; *tewing*, *touseling*, *tawing*, or *teasing* being yet existing terms for the working by pulling and beating.

Tex'as. (*Nautical.*) A structure on the hurricane-deck of a Western steamboat, containing the pilot-house, officers' cabins, etc.

Tex'tile Fab'ric.

RAW PRODUCTS USED IN TEXTILE MANUFACTURES.

Common Name.	Botanical Name of the Genus and Species of the Plant by which the Fiber is produced.	Native Place, or where chiefly grown.	Qualities, Uses, etc.
Agave, or American aloe	Agave americana	Mexico, etc.	Various fabrics and paper are made from this and other species of agave.
Amadon	Polyporus formentarius.	Europe	The source of "German tinder."
Bamboo	Bambusa arundinaceæ.	Tropics	Paper, cloth, etc., of coarse kinds.
Banana	Musa sapientum	Tropics	Various fabrics; the fiber resembles flax.
Bast	(See Cuba and Lime)		Twine. Tying up cigar-bundles, etc.
Bowstring-hemp	Sanseviera zeylanica	India	Strong. Used for cordage, etc.
Cactus fiber	Opuntia tuna, etc	Tropics	From layers of the stem. Baskets, ornamental work, etc.
China grass, or Rhea	Bœhmeria nivea	China, India, etc.	Fine. Linen, cambrics, nets, etc.
Cocoa-nut, or Coir	Cocos nucifera	Tropics	Strong and coarse. Cordage, mats, brushes, bags, ropes, etc.
Cotton	Gossypium herbaceum, etc.	Warm countries	Length, strength, etc., of fiber, various. East Indian generally coarse and short: American finer and longer. Sea Island and Egyptian have the longest fibers.
Cotton (silk)	Bombax ceiba	S. America	A silky substance unfit for spinning. Used for stuffing cushions, etc.
Cuba bast	Paritium elatum	Cuba, etc.	A bark. Used to tie up cigars.
Daphne	Daphne papyracea; Edgeworthia gardneri.	India	Fibrous bark. Used for making paper, etc.
Date-palm	Phœnix dactylifera	N. Africa and interior deserts	Plaited work, baskets, from the leaves.
Esparto-grass	Lygæum spartum	S Europe, etc	Coarse. Matting, cordage, baskets, paper, etc.
Fan-palm (dwarf)	Chamærops humilis	Spain, Italy, Tropics	Mats, baskets, caps, etc., from the leaves.
Flax	Linum usitatissimum	Temperate climes	Varieties numerous. Yarn, linens, cambrics, etc.
Flax (New Zealand)	Phormium tenax	New Zealand, etc.	Strong. Cloth, baskets, cordage, etc.
Grasses	Very numerous	Generally	Some species, as wheat-straw, used for making paper. All afford fiber variously used; plait for bonnets, brushes, etc.
Grass-wrack	Zostera marina	Europ'n sea-coasts	A sea-weed. Used for making mattresses, packing, etc.
Gunny, or jute	Corchorus capsularis	India	A coarse kind of jute. Used for making bags, matting, etc.
Hair-moss	Polytrichum	England	A moss. Used for stuffing cushions, etc.
Hemp	Cannabis sativa	Cool climates and India	In Europe used for cordage, coarse cloth, etc. In India grown for its intoxicating qualities.
Ita-palm	Mauritia flexuosa	British Guiana	Affords thread from leaves; of which baskets, fans, mats, etc., are made.
Ivy	Hedera helix	Temperate climes	Coarse. Rope, etc.
Jute	Corchorus capsularis	India	In India for "gunny-bags." In England used as an addition or substitute for hemp, flax, and silk.
Lace bark	Lagetta lintearia	Jamaica	A bark resembling fine lace; made into collars, sleeves, purses, etc.
Lime bast	Tilia europæa	Europe	Affords the material of "Russia matting," etc.

Common Name.	Botanical Name of the Genus and Species of the Plant by which the Fiber is produced.	Native Place, or where chiefly grown.	Qualities, Uses, etc.
Mallow	Malva (numerous)	Generally	The tribe comprises cotton, etc., and numerous other fiber-giving species.
Manila-hemp	Musa textilis	Philippine Islands.	Various textile fabrics.
Maroot-fiber	Sanseviera zeylanica	Madras, etc.	Resembles and is used as a substitute for flax.
Marsh-gladden	Scirpus lacustris	British marshes etc.	A sedge. Made into baskets, bee-hives, hassocks, etc.
Mulberry	Morus nigra, etc.	China, etc.	The Chinese make coarse cloth out of the bark.
Mulberry (paper)	Broussonetia papyrifera.	Polynesia, etc.	The source of "Tapa" cloth, made by beating out the bark by mallets, etc.; resembles both hemp and paper.
Namaqua bark	Brosimum namaqua	Grenada, North of S. America, etc.	Resembles hemp. Bark made into sacking, and used for beds, etc.
Nettle-fiber	Urtica dioica, etc.	Generally	Irish variety, worked up into collars and other fancy articles.
New Zealand flax	Phormium tenax	New Zealand, etc.	(See Flax.)
Neyanda-fiber	Sanseviera zeylanica	Ceylon	Resembles and is used as a substitute for flax
Palm	Very numerous	Tropics	Species very numerous; all afford fiber of some kind.
Palmite	Juncus serratus	S. Africa	A rush. Used for plaiting, thatching, baskets, etc.
Palmyra-palm	Borassus flabelliformus.	Tropical Asia	Leaves made into mats, baskets, carpets, hats, umbrellas, etc.
Paper mulberry	Broussonetia papyrifera.	Fiji, etc.	(See Mulberry.)
Papyrus (paper)	Cyperus	Egypt, etc.	A kind of sedge from which ancient Egyptian paper was made.
Piassaba	Attalea funifera	Brazil, etc.	Coarse fiber. Made into brooms, ropes, etc.
Pine	Pinus (various)	Europe, etc.	Coarse fiber. Fit for ropes, etc.
Pine	Thuja gigantea	N. W. America	Bark affords a fiber resembling hemp. Baskets, hats, mats, etc.
Pineapple	Bromelia ananas	Tropics	Fiber suitable for fine articles; as muslin, cambrics, etc.
Pita-fiber	Bromelia pita, etc.	Tropics	Resembles flax, for which it is an excellent substitute.
Plantain	Musa paradisiaca, etc.	Tropics	Various fibers for cordage, etc.
Rattan-cane	Calamus rotang	Tropics	When split, used for caning chairs, brooms, etc.
Rhea-fiber	Bœhmeria nivea	China, India, etc.	Various textile fabrics; the coarse kinds afford cordage, sails, fishing-nets, etc.
Rice	Oryza sativa	Europe, India, etc.	Fiber affords a soft porous paper.
Rice-paper	Aralia papyrifera	Formosa, China.	The pith of the tree is cut cylindrically, by sharp knives, into thin sheets, affording "Rice paper," used for artificial flowers, painting, etc.
Ruffia	Raphia ruffia	Madagascar	Thread is made from the leaves of the palm, and woven into Malagasy cloth, used as garments by the natives.
Rushes	Juncus (various)	Generally	Brooms, mats, brushes, baskets, hassocks, etc.
Screw-pine palm	Pandanus spiralis	Tropics	The fiber resembles hemp, and may be similarly used.
Sedges	Cyperus (various)	Generally	Brooms, mats, brushes, baskets, etc.
Silk-cotton	Bombax ceiba	S. America	(See Cotton.)
Straw	Various, as from wheat, rye, barley, rice, etc.	Generally	Largely used for making paper, bonnet plait, etc.
Sugar-cane	Saccharum officinarum, etc.	India, W. Indies, America, etc.	Fiber may be used for making paper, etc.
Sunn-hemp	Crotalaria juncea	India	Fiber; an excellent substitute for flax.
Talipot-palm	Corypha umbraculifera.	Ceylon	Leaves used as umbrellas, tent-covers, etc.
Teazle	Dipsacus fullonum	England, etc.	The flower of the plant used to raise the nap of woolen cloth.
Tucum-palm	Astrocaryum vulgare	Brazil, etc.	Leaves woven to make hammocks, etc. They also afford thread.
Willow	Salix (various)	Temperate climes.	Baskets, bonnets, plait, etc.
Yercum-fiber	Calotropis gigantea	India	Resembles flax; the seeds are inclosed in a silky fiber, like thistle-down.

Text-pen. An engrossing pen.

Thal-las-som'e-ter. A TIDE-GAGE (which see).

Thal'li-um. A metal discovered by means of the spectroscope by W. Crookes, in 1861. A rare metal resembling lead in appearance, allied by action with the alkaline metals.

Tharm. Twisted gut.

Thatch. Roof covering of straw, reeds, or rushes; of dried grass or palm-leaves in the tropics.

Thatching is performed with reeds, straw, or fern. It is very unusual in the United States, but is a common and excellent roof in many countries of Europe. The best material is the marsh reeds of Eastern England and of Holland. The reeds are cut in the winter, made into sheaves, dried and stacked With care, a roof of thatch will last over 100 years. Reed-thatched roofs in Holland are shown which are 200 years old, and in good preservation.

The reeds are laid in successive courses 8 or 9 inches in thickness, the buts toward the eaves, and are held down to the roof spars by *sways* or rods, which are tied to the roof-spars by rope-yarns passed through the reeds by a needle. The total thickness given at the eaves is 18 or 20 inches, and the buts of each succeeding course overlap on the course below. The *legget*, a square piece of board with an oblique handle, is used for driving up the buts of the reeds and making them lie compactly. The ridge of the roof, where the small ends of the reeds meet, is capped with straw.

The most ancient mode of roofing was of boughs, or, in Oriental countries, of leaves. Thatch of reeds or straw is also very ancient. Servius and Plautus mention thatch, and Herodotus mentions a thatch of reeds as the usual covering of the houses in Sardis. The northern nations of Europe are noticed as using thatch, as did also the Helvetii and Anglo-Saxons.

Shingles were used in Rome till A. U. C. 470. Slates, with iron pins, have been found in Roman remains, and in England of the date 1322.

Tiles of clay are declared by Pliny to have been invented by Cinyra, son of Agriopé. Byzes used stone slabs; others marble, even gold, but more usually bronze gilt. Hollow tiles were used in the construction of tombs. Anglo-Saxon and Norman tiles were taken from the Roman. Pantiles were used in the Middle Ages, and very generally in the fifteenth century.

The most ancient existing roofs in England are of wooden boards covered with lead.

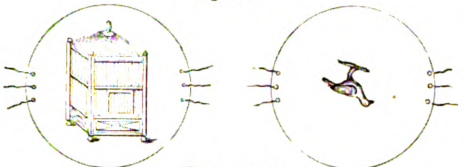
Thatch-wood Work. (*Hydraulic Engineering.*) A mode of facing sea-walls with brushwood. Underbrush of say twelve or fourteen years' growth is cut down, fagoted at its full length, and spread over the face of the banks. It is kept down by strong stakes, which have cross pins at their upper ends to rest upon the brush, which breaks and disperses the waves and protects the earth beneath.

Thau'ma-trope. The theory of the duration of visible impressions was taught by Leonardo da Vinci, who was born in 1452. Many curious toys and scientific devices have been made, founded upon this

principle. The THAUMATROPE, and, more lately, the PHENAKISTOSCOPE, ZEOTROPE, STROBOSCOPE, and ANORTHOSCOPE, are examples. See under these heads.

The idea of this contrivance originated with Sir John Herschel, and depends upon the limit to the rapidity with which visual images may be substituted and separately distinguished Mr. Babbage mentions the circumstances under which the idea was

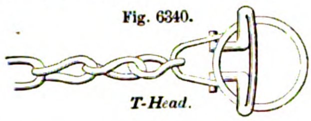
Fig. 6339.



Thaumatrope.

brought into practice, which was effected by spinning a shilling with such rapidity that the visual image combined the figures on each side of the coin. It was subsequently made in the form of a toy, in which the respective sides showed a horse and his rider, a bird and his cage, a rat and a trap, etc., according to the taste or ingenuity of the contriver.

Fig. 6340.



T-Head.

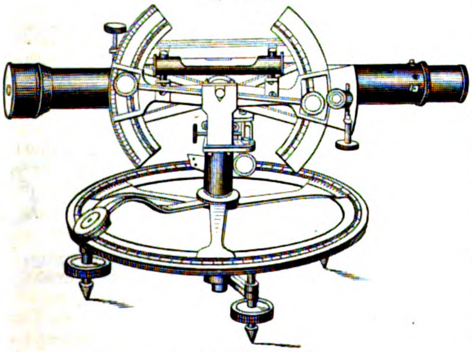
T-head. A cross-bar with two prongs on the end of a dog-chain, watch-chain, or elsewhere, to engage in a ring.

The-at′ri-cal Ma-chine′. Made of wire cloth running on rollers, and wound up and unwound by power. Parsons' patent, June 2, 1874.

The-od′o-lite. An instrument for measuring horizontal and vertical angles, but particularly adapted for accurately measuring the former. Its principle is identical with that of the altitude and azimuth instrument; the construction and purpose of the two, however, differ, the latter being employed for astronomical purposes, while the theodolite is used for land surveying; but the better instruments of this class may be employed for observing the altitudes of celestial bodies. The vertical circle is not generally, however, of sufficient size, nor so graduated as to be available for very accurate astronomical observations.

This instrument has been used in extensive geodetical operations in England and in this country, such as the British Ordnance Survey and the United States Coast Survey, while in France the repeating circle of Borda has been preferred The telescope has a motion on a horizontal axis, and has a vertical graduated circle, which has also a horizontal.

Fig. 6341.



Everest's Theodolite.

See under TELESCOPE for notice of the first use of telescopes in triangulation or measuring angles.

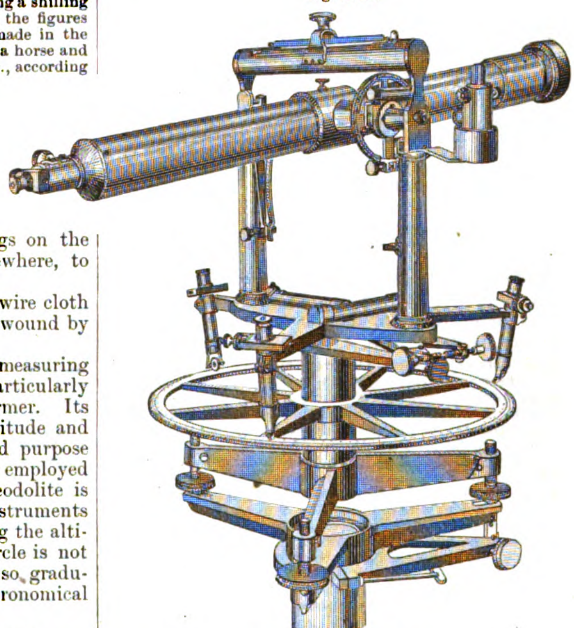
The first survey made by an instrument with a perfect circle is said to be that of Zealand, by Bugge, in 1762 - 68.

Ramsden's theodolite had a circle 3 feet in diameter, and was completed in 1787. It had two telescopes of 36 inches focal length. It was used for a triangulation to connect the observatories of Greenwich and Paris, and also in the English, Irish, and Indian trigonometric surveys.

The telescope circle and stand are capable of motion round a vertical axis. The altazimuth may be considered a modification of the transit instrument, and has been called a transit theodolite, being adapted for meridional or extra-meridional observations indifferently. Everest's theodolite is so called from its designer, Sir G. Everest, late of the East Indian Survey, and is among the best of its class.

The Wurdemann's theodolite, used by the Coast Survey, is mounted upon a repeating stand, that is, one which has an axis of its own, having a clamp and tangent so as to read any angle on any part of the limb. This stand has adjusting feet for leveling, so as to bring the axis vertical on uneven ground. The base of the instrument proper consists of a leveling tripod, from which rises a central column forming the barrel of the

Fig. 6342.



Würdemann's Theodolite.

axis; on the outside of the column the main *limb* of the instrument is fastened. The central column is of cast-iron, and the principal vertical axis of steel plays within the column. The upper or large end of the axis has attached to it a plate carrying, firstly, three reading micrometer microscopes, 120° apart; secondly, two columns with Y's for receiving the pivots of the telescope axis. The pivots rest with one half of the diameter in the Y's, the other half projecting for the legs of the striding level to rest upon.

The telescope is 38 inches focal length, the object-glass $2\frac{9}{10}$ inches aperture, provided with a 4-inch vertical finder-circle for use in taking solar or star azimuths, and on the right-hand side of the telescope is the usual clamp and tangent for vertical fixture and movement. A small central reflector of $\frac{1}{10}$ inch diameter throws the light from a lamp attached outside to the cross lines of the eye-piece. The light from the lamp, passing through the telescope axis to the center of the tube, is reflected upon the wires by the reflector. The wires are contained in a micrometer eye-piece.

The clamp and tangent for the horizontal movement of the alidade is not, as usual, attached to the horizontal circle, but on a collar immediately underneath the alidade on a separate disk. The clamp arm fitting on this disk contains a piece of steel which is pressed against the disk by means of the clamp-screw, which fixes the arm, a small portion of the clamp-ring being cut out opposite to the screw, so that there are but three points of contact in clamping. To the outer end of this clamp-arm is attached one portion of the tangent screw, whilst the other holds to a projecting part of the alidade plate.

Two cross levels on the alidade plate afford means for perfectly leveling the instrument. The micrometer microscopes read to one minute of arc to one revolution of the screw. The drum of the screw is divided into 60 divisions, each having the value of 1″, of which tenths are generally estimated, and are quite perceptible.

The peculiar features of the instrument are, —

1. The circle is freed from the clamp and tangent, being independent.

2. The optical power is high. Without this, mere size of the instrument is of little advantage. For instance, the microscopic readings on the limits may be read to as great accuracy, 10‴, as the five-foot mural circle of the Naval Observatory, Washington.

Lengths of a Degree of Longitude on the Parallels of Latitude, for each Degree of Latitude from the Equator to the Pole.

NOTE. — Degrees of longitude are to each other in length as the cosines of their latitudes.

The-od′o-lite–mag′net-om′e-ter. An instrument employed as a declinometer to measure variations in declination, and as a magnetometer in determinations of force.

It consists of a graduated horizontal circle, mounted as in the ordinary surveyor's theodolite, upon which is fixed a small wooden box. In the top of this box a vertical glass tube is fastened. The magnet is suspended in the box by means of one or two filaments of unspun silk, which pass up through the tube and are fastened at its top. The magnet consists of a perfectly turned steel tube, in one end of which there is a glass head. On this head a scale is engraved, which is so delicate that it is scarcely visible to the naked eye. The other end is closed with a lens which brings the rays of light in parallel directions to the scale. Connected with the horizontal circle of the instrument is a small telescope, mounted so that its axis shall lie in the produced axis of the box. In each end of the box is a small glass window, so that when the apparatus is properly adjusted, the light will come through the magnet to the eye of an observer, and the scale on the magnet-head will be visible.

To determine the magnet declination we have only to make the vertical wire of the telescope coincide with the axis of the magnet, and note on the horizontal circle the angle which this line makes with the direction of the true meridian, which is before determined. The variations in declination may then be determined from time to time by noting the reading of the magnet-scale.

In observations for magnetic force, Gauss's method is generally employed. The suspended magnet is made to swing horizontally in the box through a very small arc, and the time of a single oscillation is noted. The same magnet is then made to deflect another suspended magnet, from a certain fixed position and at a known distance, and the angle through which the second magnet is deflected is observed. Each of these experiments determines a value which is due to the combined effects of the magnetism of the earth and of the magnet. But these effects are, in the two cases, combined in different ways, so that, by a proper combination of the two values, we may eliminate the effect due to the magnetism of the magnet, and obtain that due to the horizontal magnetic intensity of the earth alone.

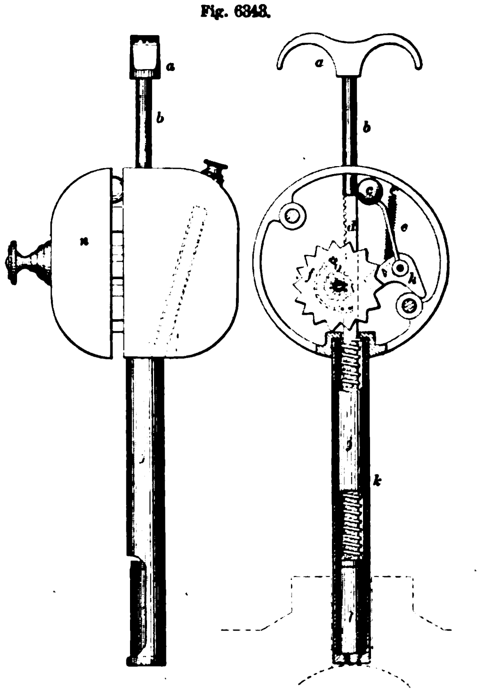
The-or′bo. (*Music.*) A large lute, having two heads, to each of which strings are attached.

"One slovenly and ugly fellow, Signor Pedro, who sings Italian songs to the theorbo most neatly." — PEPYS's *Diary*, 1664.

Ther′mal A-larm′. An attachment for giving indication of a hot-bearing.

A tube *j* has a plug *l* of such material or alloy as will melt at the degree at which it is desired the alarm should be given.

Fig. 6343.



Hot-Bearing Alarm.

See table of fusible alloys, page 62. As the plug melts on the hot-bearing and escapes at the hole beneath, the spring *k* forces down the spindle *b*, giving motion to the rack *d*, pinion *o*, and striking-wheel *f*. The wheel *f* operates the pallet *h* and hammer *c*, causing the latter to strike the gong *n*. *a* is the handle for withdrawing the spring in inserting a plug. See Fig. 6346.

Ther′mal Mo′tor. A machine in which the expansion and contraction of an object or material, by changes in the temperature, is made a means of motion. The term is usually applied to machines operated by natural thermometric changes.

Coxe, 1827, in London exhibited a timepiece which was kept in continual action by the rise and fall of a column of mercury in a barometric tube attached thereto.

The plan has been frequently tried elsewhere.

In Washburn's thermal motor, July 4, 1865, the expansion and contraction of a bar of metal, under the influence of natural heat, are gathered up by means of springs and levers, so that the power can be used for propelling machinery, clock-work, and similar purposes.

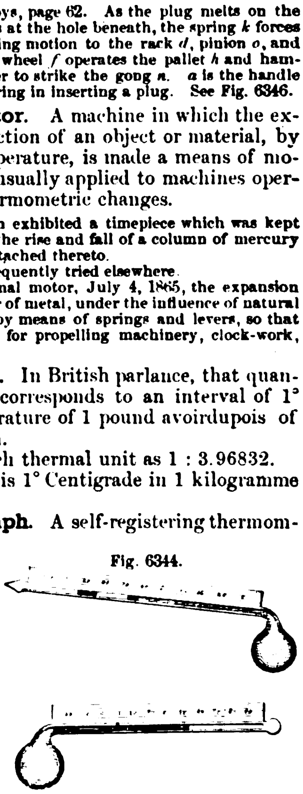
Ther′mal U′nit. In British parlance, that quantity of heat which corresponds to an interval of 1° Fah. in the temperature of 1 pound avoirdupois of water at 39.10° Fah.

It is to the French thermal unit as 1 : 3.96832.

The French unit is 1° Centigrade in 1 kilogramme of water.

Ther-met′o-graph. A self-registering thermometer, recording the maximum and minimum of temperature in a given time.

Fig. 6344.



Rutherford's Thermetograph.

Fig. 6344, Rutherford's thermetograph, consists of two thermometers, one containing mercury and the other alcohol. A steel wire is pushed before the column of mercury and left at the maximum point reached. An enamel slide in the

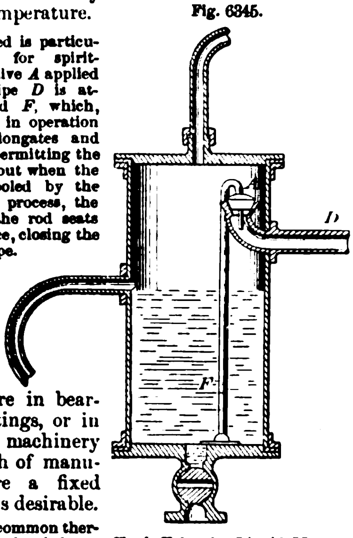
alcohol thermometer is drawn back by the liquid and left at the minimum point.

Ther'mo-ba-rom'e-ter. An instrument for measuring altitudes by means of determining the boiling-point of water. See HYPSOMETER; EBULLIOSCOPE; BAROMETER.

Ther'mo-dy-nam'ic Valve. A valve depending for its operation upon the expansion and contraction occasioned by changes of temperature.

That illustrated is particularly designed for spirit-meters. The valve *A* applied to the pump-pipe *D* is attached to a rod *F*, which, when the still is in operation and heated, elongates and lifts the valve, permitting the liquor to flow; but when the apparatus is cooled by the stoppage of the process, the contraction of the rod seats the valve in place, closing the mouth of the pipe.

Fig. 6345.

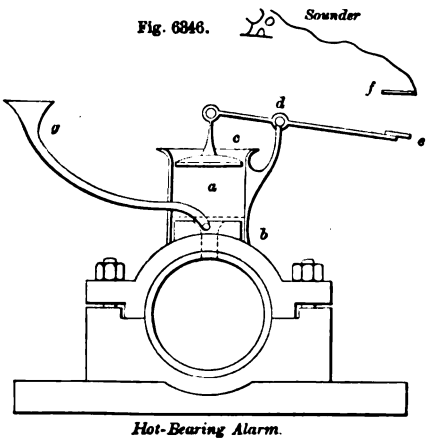


Check-Valve for Liquid-Meters.

Ther'mo-e-lec'tric A-larm'. An apparatus designed to indicate the rise of temperature in bearings for shaftings, or in any kind of machinery or any branch of manufacture where a fixed temperature is desirable.

It resembles a common thermometer, except that it has a wire secured at top and bottom. The wire at the bottom passes through the bulb and touches the mercury. The other wire enters the glass at the top and extends part way down the inside Each of these wires is connected with a small open circuit having a battery and an electric bell. When this connection is made and the battery in order, the glass may register (say) 40°. The upper wire hangs down in the glass (say) to 85°, the circuit being open by the space between the top of the column of mercury and the bottom of the wire. When the mercury rises and touches 85°, the circuit is closed and the bell sounded. When the column of mercury sinks, the circuit is broken and the bell stops. The upper wire may be adjusted to any figure on the scale. For refrigerators, the end of the wire may touch the freezing-point; for chambers or school-rooms, it can be set at 70°; to indicate the presence of fire, it may be set at 100° or upward. In the case of hotels, a glass in every room, each with its wire circuit, may ring an alarm-bell in the office the instant the temperature rises above a fixed hight. To indicate the particular room, a common electric annunciator is attached to the system of circuits, and the clerk or watchman informed of the exact position of the danger. By fixing the glasses at a comparatively low figure (say 90°), they serve a double purpose, — show if the room is too warm from overheating or in danger from fire. When used as an indicator of the want of oil or other lubricant on bearings for car-wheels, shafts, and the like, the hot journal quickly raises the mercury, and, by closing the circuit, starts the alarm-bell, which continues to ring till the shaft is stopped or cooled. For this purpose a hole is drilled in the bearings, and the thermometer sunk in it till the bulb rests on the shaft. This device is also used to indicate any required temperature in boiling drugs, dye-stuffs, or other liquids.

Fig. 6346.

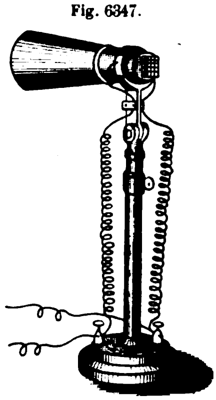


Hot-Bearing Alarm.

Fig. 6346 consists of a cylindrical box *a* provided with a perforated bottom *b*, and placed directly over the journal. The box is filled with a prepared grease which melts at a certain temperature, to which it must be raised by the shaft becoming hot. As the compound liquefies and escapes through the perforations, a disk *c*, which rests thereon, descends, thereby tilting the lever *d*, and so making contact between the plates *e* and *f*. The latter are connected by an electric circuit with a bell which sounds when the current is established. The pipe *g* serves for the ordinary lubrication of the journal.

See also TEMPERATURE-ALARM; THERMOSCOPE; THERMOMETRIC ALARM; etc. See also TESTING-MACHINE, Fig. 6330.

Fig. 6347.



Thermo-Electric Pile.

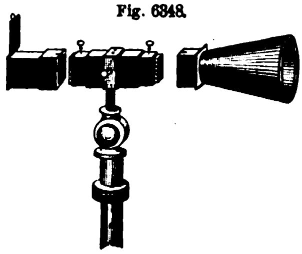
Ther'mo-e-lec'tric Bat'tery. (*Electricity.*) One in which an electric current is established by applying heat or cold to one of the junctions in a circuit composed of two different metals. It was first shown by Seebeck of Berlin in 1821. See Deschanel's "Natural Philosophy," Part III. pages 652, 653.

Figs. 6347, 6348, illustrate ordinary forms of the apparatus.

Fig. 6349 shows the battery or pile of Melloni. *b c* are an enlarged view and a section of the elements.

At the Exposition of 1867 were exhibited three batteries of this class: those of Farmer, American; Marcus, Austrian; and Ruhmkorff, French.

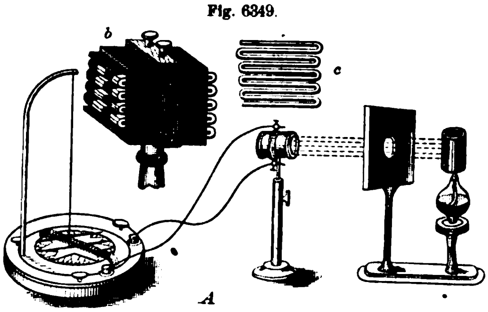
Fig. 6348.



Thermo-Electric Pile.

The former consists of strips of copper and wedge-shaped blocks of an alloy arranged alternately in the form of a ring. The strips of copper are soldered at each end alternately, and insulation between the metals is effected by interposed plates of mica. Heat is applied to the inner edge of the ring by means of a circular gas-burner. It was stated that thirty-six elements of this battery were equal to one of Grove's.

Fig. 6349.



Melloni's Thermo-Electric Battery.

In the battery of Professor Marcus, the positive and negative elements are both alloys: the former consisting of 10 copper, 6 zinc, and 6 nickel; and the latter of 12 antimony, 5 zinc, and 1 bismuth. The bars are arranged after the manner of the rafters of a house, and soldered together at their alternate extremities, separated by a slight interval, no insulating material being

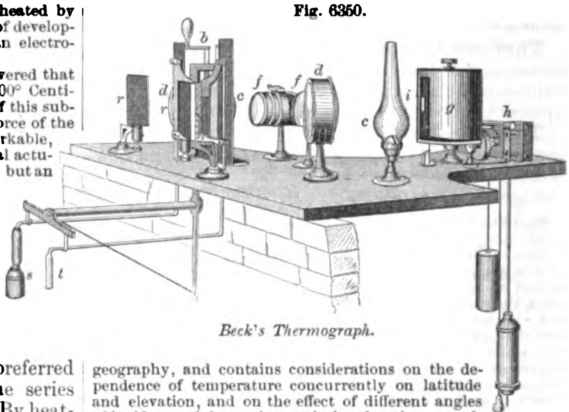
employed. Their lower ends are immersed in water heated by a spirit-lamp. 65 pairs of this battery were capable of developing a lifting force of from 25 to 50 kilogrammes in an electro-magnet.

Becquerel's battery was invented in 1865. He discovered that artificial sulphide of copper when heated to 200° or 300° Centigrade is strongly positive, and that a couple formed of this substance and metallic copper has nearly ten times the force of the ordinary antimony and bismuth couple. This is remarkable, as the native sulphide is strongly negative. The metal actually used for the negative element is not pure copper, but an alloy of 90 copper and 10 nickel (German silver). The elements are arranged in a manner resembling that of Marcus, their ends being immersed in water heated by means of a gas-burner. Eight or nine of these elements are considered by M. Becquerel to be equal to one of Daniell's. With fifty couples an electro-magnet has been made to sustain a weight of 100 kilogrammes (220 lbs.).

Ther'mo-e-lec'tric Pile. A series of metallic plates, or a chain of links of alternate metals, — antimony and bismuth are preferred as being farthest apart of the metals in the series Bi., Pt., Pb., Sn., Cu., Ag., Zn., Fe., Sb. By heating one or more of the junctions, electricity is developed. See THERMO-ELECTRIC BATTERY.

Ther'mo-graph. An instrument for automatically recording variations of temperature.

Fig. 6350.



Beck's Thermograph.

In the apparatus, Fig. 6350, this is effected by means of photography. The instrument when in use is inclosed in a box, and all light is excluded except that which is admitted through an air-speck in each thermometer. *g* is a cylinder on which the photographic paper is wound, and is rotated by clock-work *h* once in forty-eight hours; *i*, shutter cutting off the light for four minutes every two hours, and leaving a white line when the paper is developed; *s*, wet-bulb thermometer; *t*, atmospheric thermometer; *b*, screw for adjusting thermometers to the required hight; *c c*, gas-lights; *d d*, condensers throwing the light on to the mirrors *r r* through air-specks in the thermometers, the light passing through slits *e e*; *f f*, photographic lenses throwing an image of the air-speck in each thermometer upon the paper on the cylinder *g*. and leaving two irregular dark lines corresponding to the varying hights of the wet-bulb and atmospheric thermometers.

Ther-mom'e-ter. A heat-measurer. The term is generally applied to a glass tube, terminating in a bulb, which is charged with a liquid, usually mercury or colored alcohol. The liquid contracts or expands with changes of temperature, falling or rising in the tube against which is placed a graduated scale.

Perhaps the earliest account we have of an instrument for measuring the heat of the atmosphere is that noticed in the "Spiritalia" of Hero of Alexandria, about 150 B. C., which is described as a tube or vessel wherein the water is made to rise or fall by the changes of heat and cold.

The Spanish Saracens had detected the variation in the density of liquids by changes in temperature, but appear not to have noticed the variation in volume. They therefore used a *hydrometer* as a measurer of temperature See AREOMETER.

The air-thermometer of Santorio, of Padua, constructed about the beginning of the seventeenth century, consisted of a glass tube *a* having at one end a glass ball and open at the other; this tube, having been heated to rarefy the internal air, had its open end placed in a cup of colored liquid, which, by the pressure of the atmosphere, was forced up into the tube.

The expansion by heat of the air in the bulb depressed, and its contraction at a lower temperature elevated, the liquid in the tube. This instrument still lives in a modified form in the SYMPIESOMETER (which see), and was in fact a better barometer than thermometer, though in fact all barometric readings need thermometric corrections. See also AIR-THERMOMETER, Fig. 116.

Santorio employed the instrument as a clinical thermometer to measure the heat of the skin in diseases, and at different periods in the same disease. See also SPHYGMOMETER.

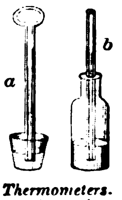
The instrument of Santorio was improved by Boyle, who inserted a tube *b*, open at both ends, through the neck of a bottle containing some colored liquid. A portion of the liquid was then drawn up into the tube The mouth of the bottle being hermetically sealed, the expansion of the contained air caused the column of liquid to rise, and its contraction caused it to fall The bottle could be dipped in hot or cold liquids. The instrument was faulty, as the liquid was subject to contamination and evaporation. This was before the time of mercury as a charging liquid.

The Florentine Academicians introduced the present mode of construction, — a tube with a bulb on its lower end to contain the liquid, and an exhausted stem hermetically sealed.

A work of Albertus Magnus, bearing the title of "Liber Cosmographuris de Natura Locorum," is a species of physical geography, and contains considerations on the dependence of temperature concurrently on latitude and elevation, and on the effect of different angles of incidence of the sun's rays in heating the ground.

"In the department of the distribution of temperature and meteorology, attention was already directed, at the end of the fifteenth and beginning of the sixteenth centuries, to the decrease of temperature with increasing western longitude (the inflection of the isothermal lines); to the law of rotation of the winds, generalized by Francis Bacon; to the diminution of atmospheric moisture and of the quantity of rain, caused by the destruction of forests; and to the decrease of temperature with increasing elevation above the level of the sea and the lower limit of perpetual snow. That this limit is 'a function of the geographical latitude' was first recognized by Petrus Martyr Anghiera in 1510." — HUMBOLDT.

Fig. 6351.



Thermometers. *a. Santorio.* *b. Boyle.*

Previous to the introduction of the plan of completely inclosing the temperature-measuring fluid in an air-exhausted tube, — the work of the Florentine Academicians, it was impossible to obtain reliable data as to the relative distribution of heat and the winter and summer variations of temperature upon different parts of the earth's surface. At present, thanks to the numerous and systematic observations which have been made at all points generally accessible to civilized observers, the laws by which this distribution is governed have been in a great degree ascertained. Nor does this apply to air-currents alone. By the aid of the thermometer the Gulf Stream and the other great oceanic currents have been discovered and mapped out, and light has been thrown upon their origin, and the effects which they produce in modifying the climate of extensive regions of the globe, and influencing the characters of their flora and fauna.

Since the days of Dr. Franklin, who by its aid first positively determined the existence of the Gulf Stream, this little instrument has become of great importance to the mariner, who may frequently, by the decreased temperature of the water, ascertain his proximity to land and to icebergs or other dangers, when it cannot be detected readily by other means.

On an average, the thermometer falls about 1° for each 300 feet of elevation above the surface of the sea. Were it not for the great fluctuations in its indications, due to various causes, this might be availed of as a rough method of determining vertical hights. The determination of the boiling-point of water, which depends upon the absolute density of the atmosphere and not upon the temperature, falling 1° for each 450 feet of elevation, affords a much more accurate means of approximately determining hights above the sea-level. With a simple apparatus specially contrived for this purpose and a good thermometer, a degree of accuracy approaching that of the barometer may be attained. See HYPSOMETER.

In making thermometers, tubes are selected having as nearly as possible a uniform bore throughout. A column of mercury an inch or less in length is then introduced, and the tube connected to a flexible india-rubber bag at each end.

By means of screws, one bag is compressed while the other is expanded, and the mercury is thus gradually forced from one end of the tube to the other, the space which it occupies at each part of the tube is noted, and, in graduating, the degrees at each portion of its length are made longer or shorter in proportion to the length occupied at that part by this short column of mercury; this preliminary process is called *calibration*.

The required dimensions of the bulb are found approximately by weighing a measured length of the mercurial column, and computing the capacity of the bulb from the known expansion of mercury and its specific gravity.

The bulb may be formed upon the tube previous to calibration, or attached afterward. This is done by heating one end of the tube in the blow-pipe and forcing in dry air from an india-rubber bag.

For putting in the mercury, a small reservoir of paper or glass

containing mercury is fixed upon the upper end of the tube. Heat is then applied to the bulb, which, driving out the air, forces the mercury to descend by atmospheric pressure. The upper end of the tube is next heated and drawn out, ready to be hermetically sealed. The mercury is then boiled in the tube, its vapor driving out all traces of air, and, while in a state of ebullition, the tube is sealed by directing the flame of a blow-pipe against its upper end, which fuses the glass and closes the aperture.

Another mode of filling is to heat the bulb and immerse the open end of the tube in a reservoir containing mercury.

The freezing-point is determined by placing the bulb in finely pounded ice, from which the water drains away as it melts. This temperature is fixed and invariable under all circumstances.

The boiling-point is obtained by placing the bulb in steam having the same elasticity as that of the atmosphere: a peculiar apparatus, devised by Regnault, being generally employed for the purpose. As the temperature of boiling water varies with different barometric pressures, it is necessary that a uniform standard should be assumed; this is taken at 30 inches in this country and England, or 760 millimetres in France; and should the hight of the barometer vary from this at the time, a correction of the apparent boiling-point on the tube is necessary to give the true hight of that point.

At the Tower Manufacturing Company's establishment, Chester, Pa., the tubes, which are received in lengths of about one yard, are nicked and broken off to the proper length. The bores are then examined with a lens, and the tubes assorted into ten sizes, and then passed to the glass-blowers. Each of these is provided with an oil lamp and a pair of foot-bellows. Melting the glass at one end, he blows it into a bulb proportionate in size to the bore of the tube by forcing in air from an india-rubber ball applied to the other extremity, and while yet hot he immerses this end in mercury, which, as the bulb cools, rises and partially fills it. The tube is then withdrawn, and a short india-rubber tube attached to the open end; into this mercury is poured, and that in the bulb is boiled to expel the air, which rises through the mercury in the rubber tube, leaving the upper part of the bulb and glass tube filled with mercurial vapor; as this condenses, the mercury in the rubber tube descends and takes its place; this tube is now removed, the bulb heated, and the open end of the tube is hermetically sealed. The bulb and lower part of the tube are then immersed in the water from melting ice, and afterward in baths at 62° and 92° Fah., and the hight of the mercury marked. The lengths of these spaces are carefully measured, and if they are equal the bore of the tube is assumed to be so, and the length of each degree laid upon the brass scale is the same; if otherwise, by means of a peculiar dividing-engine, they are lengthened or shortened to correspond with the variation of the bore. The figures and letters are next punched, and the plate is passed laterally between rollers to remove the bur left by the tools. It is then silvered and lacquered, the tube attached, and the whole inserted in its japanned case.

As to graduation, the Florentine Academicians took the cold of ice and snow for their zero, and the greatest summer heat of Florence for the upper limit of graduation. These being variable were inefficient.

Boyle suggested a fixed point obtained by thawing oil of aniseseed, as it was, unlike ice, always procurable.

Hooke suggested freezing water as one point.

Halley proposed spirit boiling as another point.

Newton suggested the boiling point of oil, as the range would be so much increased. He next suggested melting ice and boiling water as two points; the interval to be divided into an arbitrary number of degrees which were to be continued up and down. These standards obtained general acceptance.

The use of mercury in the tube was suggested by Halley, about 1697. This fluid is very convenient for the purpose, as having a range of over 700° Fah. between its freezing and boiling points, and expanding very nearly uniformly with equal increments of heat.

Fahrenheit, a native of Dantzic, established as an instrument-maker at Amsterdam, first practically carried out Halley's suggestion. He divided the space between the freezing and boiling points of water into 180°, and commenced the graduation of his scale at the point to which the mercury fell when the bulb was plunged into a mixture of pounded ice and salt; this, producing the greatest degree of cold known to him, he termed zero; and as it corresponded to 32 of the 180 equal spaces between the boiling and freezing points of water, the latter was marked 32°.

Reaumur, about 1730, using spirits of wine, adopted the freezing and boiling points as the two standard points of his scale; the space between these was divided into 80°, and the former was assumed as the zero from which the graduations were extended in each direction. De Luc introduced mercury instead of the spirits of wine.

This thermometer was in use in France until the revolution of 1789, but is now generally superseded by the Centigrade.

Celsius, a Swedish astronomer, in 1742 divided the space between the freezing and boiling points into 100°; this thermometer, known in the North of Europe by his name, and elsewhere as the Centigrade, is that in common use on the Continent of Europe, and is very generally employed in scientific investigations elsewhere.

Fahrenheit's is almost wholly confined to the United States, Holland, and to Great Britain and her colonies.

Delisle's thermometer, used to some extent in Russia, has its zero at the boiling-point, and is graduated downwardly, the freezing-point being at 150°.

To find the degrees Fahrenheit corresponding to a given number of degrees Centigrade, multiply by 9, divide by 5, and add 32 to the quotient; thus, 100 C. $\times 9 \div 5 = 180$; $180 + 32 = 212$. By a reversal of the process, that is, by subtracting 32 from Fahrenheit degrees, multiplying by 5, and dividing by 9, we find degrees Centigrade corresponding to those of Fahrenheit; thus, $212 - 32 = 180$; $180 \times 5 \div 9 = 100$. The same rule, using 4 instead of 5, serves to change degrees of Fahrenheit into those of Reaumur and vice versa.

Among the varieties of thermometers may be cited the

Air-thermometer; that of Santorio and Boyle. See *ante*, page 53, Fig 116.

Balance-thermometer; an invention of Kewley, by which mercury inclosed in a balanced tube is caused to make one or the other of its ends preponderate, in order to open and close a window or damper. See page 216.

Barometrical thermometer: a form of boiling-point apparatus for measuring hights, invented by Dr. F. Wollaston. See HYPSOMETER, Fig 2531, page 1160.

Chemical thermometer; one so contrived that its scale is kept out of contact with coloring or corrosive liquids when these are being tested.

Clinical thermometer: one used for detecting the heat of the person. It is conveniently constructed to be applied to the surface of the skin, to the axilla, or in the mouth. See *infra;* also page 567.

Differential thermometer; records differences, say the maximum and minimum during the period of exposure. See Fig. 1650, page 701.

Electrical thermometer; an air-thermometer, designed to show the expansion of air when an electric spark is passed through it.

Marine thermometer; one in which the lower part of the tube is protected by curved bars or otherwise, to prevent its being readily broken by rough handling. See Fig. 3064, page 1393.

Maximum thermometer; one for recording the highest point attained during an observation. See *infra;* also page 1412.

Mercurial thermometer; the common thermometer, in which mercury is the measuring liquid.

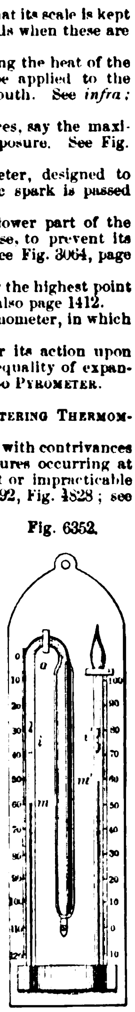
Metalline thermometer; one depending for its action upon the expansibility of a single metal, or the inequality of expansion of different metals, as Breguet's. See also PYROMETER.

Minimum thermometer. See *infra*.

Registering thermometer. See SELF-REGISTERING THERMOMETER.

The *self-registering* thermometer is provided with contrivances for indicating the highest or lowest temperatures occurring at times or in situations where it is inconvenient or impracticable to observe them directly. See also page 2092, Fig. 1828; see also THERMOGRAPH; THERMETOGRAPH.

Fig. 6352.



Six's Register-Thermometer.

Six's *self-registering* thermometer was invented in 1782, but has since been modified. It registers the maximum and minimum temperature that may occur between observations.

a is a long bent tube having a bulb filled with alcohol which reaches to m; from this point mercury reaches to m', above which is a second body of alcohol, which expands into an exhausted and hermetically sealed bulb. $i\ i'$ are two indexes of steel, covered with glass, and having pellets of enamel at their ends. A bristle is wound around each index, so as to enable it to hold its place in the tube unless in adjusting it for an observation, which is done by a magnet.

In operation, each index is brought down by a magnet, so as to rest upon the surface of the mercury in its own leg of the tube. An increase of temperature after the adjustment will expand the alcohol and raise the index i'; should the temperature afterward fall, the index will retain its place, the mercury falling away from it. Should the temperature fall, and the alcohol in bulb a contract, the mercury will raise the index i, which will cling to the side of the tube, the alcohol flowing past it. Graduations are attached to each leg.

Brookes's *self-registering* thermometer is used in the Greenwich Observatory, England, and consists of a zinc case around the shaft, and a float on the surface of the mercury. On an arm attached to this float is thrown a ray of prepared light, which is thence directed upon a piece of sensitive photographic paper. The paper travels by clock-work, and upon it are shown the variations of temperature, the cross lines on the paper indicating time, as the motion is regular and the rate is known.

A *solid* thermometer, to indicate temperatures higher than

the boiling-point of mercury under one atmosphere (676° Fah.), is called a PYROMETER (which see).

Spirit-thermometer; one in which spirit is employed instead of mercury.

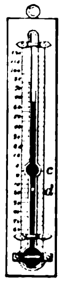
Statical thermometer; a kind of air-thermometer arranged to open and close a window or ventilator by the expansion and contraction of its contained air. See THERMOSTAT.

For Rutherford's instrument, see THERMETOGRAPH.

For Beck's instrument, see THERMOGRAPH.

In Phillips's *maximum* thermometer, about ½ inch of mercury at the end of the column is separated from the rest by a minute particle of air. This index is pushed along the tube as the mercury expands, and remains in the same position, when the mercury contracts, thus showing the greatest degree of heat to which the instrument has been exposed. The separated portion is returned to its place by a jerking motion imparted to the thermometer. The instrument, for use, is laid or suspended in a horizontal position.

Fig. 6353.



Twining's Thermometer.

Twining's maximum thermometer is a spirit-thermometer, having about ⅓ of the way up the tube a bulbous enlargement in which a globule of mercury is lodged. This permits the spirit to flow past it in expanding, but when it again begins to fall, the globule is carried down with it, becoming elongated in the narrower bore of the tube; this is graduated each way from the bulbous enlargement; the number of degrees indicated by the mercury on the lower scale, added to the temperature shown by the spirit in the upper part of the tube, gives the greatest heat reached.

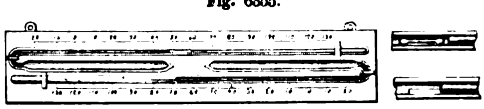
A recent form of automatic *registering* and *printing* thermometer consists of a glass tube bent in the form of a siphon, the closed leg of which is filled with alcohol and the open one with mercury. On the surface of the mercury in the open end there rests an ivory float suspended from a delicate balance, having platinum wire attached to each end of the lever. When the column of mercury in the thermometer tube rises or falls from the effect of temperature, the platinum wires dip in small mercury cups underneath them, thereby causing a current of electricity to pass through one of two electro-magnets operating mechanism for giving motion to a fine micrometer screw. The motion of this screw elevates or lowers the balance, thereby breaking the circuit. Whenever a change of temperature equal to one tenth of a degree Fahrenheit occurs, the magnetic circuit is completed, and the screw is moved a space equivalent to the change in the hight of the mercury in the thermometer. At the same time the clock-work moves the type-wheels indicating the temperature, which is printed at the end of each hour on a slip of paper moving in front of them. A pencil held against a revolving drum also records a continuous curve, exhibiting at a glance the hight of the thermometer.

Fig. 6354.

Maximum Thermometer.

In Negretti and Zambra's *maximum* thermometer (Fig. 6354) the tube is contracted near the bulb, so that the mercury is not withdrawn into the bulb by contraction, but remains at the maximum indication of temperature reached during its exposure.

Fig. 6355.



Self-Registering Thermometer.

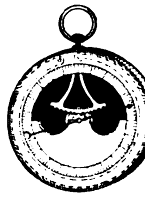
Rutherford's *self-registering* thermometer (Fig. 6355) has a maximum and a minimum tube on the same plate. The first carries a small piece of iron at the end of its mercurial column, pushed forward by expansion, but remaining stationary after the mercury begins to contract; the latter contains spirit, in which is a small index of glass or enamel, shaped like a dumb-bell. This retreats as the fluid contracts, until the lowest temperature is reached, at which point it remains, but permits the fluid to flow past it during expansion.

Fig. 6356.

Breguet's Thermometer.

Breguet's thermometer (Fig. 6356) consists of a helix formed by soldering together three strips, — silver, gold, and platinum. The silver, which is most expansible, is placed on the interior, and the platinum, as being least expansible, on the exterior. When the temperature rises the helix unwinds, and as it falls it contracts again, either movement causing an attached needle at the lower end to traverse a graduated arc.

Fig. 6357.



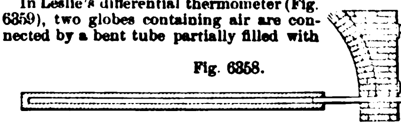
Dial-Thermometer.

Fig. 6357 is a dial-thermometer. The case contains a double circularly bent strip of steel and brass, fixed at one end, and having at the other a lever whose longer arm carries a toothed sector working into a pinion, to which a pointer is attached. The unequal expansion of the two metals under changes of temperature causes the pointer to traverse back and forth upon the arc.

Fig. 6358 is Brogniart's *pyrometer*, consisting of an iron bar lying in a groove in a porcelain slab; one end of the slab rests against the bottom of the groove, and the other moves an indicator outside of the furnace. The expansion of the iron by heat is considerable, compared with that of the porcelain, and their difference measures the temperature.

In Leslie's differential thermometer (Fig. 6359), two globes containing air are connected by a bent tube partially filled with liquid. When both globes are at the same temperature, the liquid stands at equal hights in each branch of the tube; but if their temperature be unequal, the greater expansion of the air in the more heated globe causes the liquid in the opposite leg to stand at a higher level.

Fig. 6358.



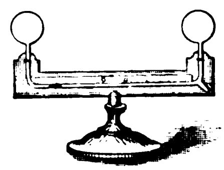
Pyrometer.

Fig. 6359.

Leslie's Differential Thermometer.

Rumford's thermoscope (Fig. 6360) is analogous to the foregoing, the vertical branches of the tube being shortened. An alcohol index remains at the center or zero of the horizontal tube when the bulbs are of equal temperature, but is pushed toward one or the other end when they differ.

Fig. 6360.

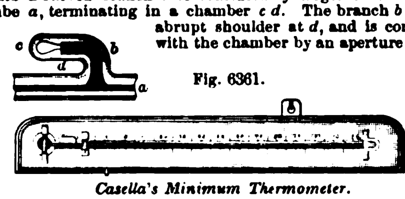


Rumford's Thermoscope.

The two latter thermometers do not measure the absolute temperatures, but serve to show the relative differences of heat between two objects in close proximity to each other.

Casella's *minimum* thermometer (Fig. 6361) has near the bulb a curved branch *b* of considerably larger bore than the tube *a*, terminating in a chamber *c d*. The branch *b* has an abrupt shoulder at *d*, and is connected with the chamber by an aperture having a diameter exceeding that of tube *a*. The instrument is adjusted for use by tilting it so as to expel all mercury from the chamber, and suspending it in a horizontal position. The hight of the mercurial column in tube *a* then indicates the temperature of the surrounding air. When the temperature falls, the mercury contracts in the direction of least resistance, along the main tube *a*, the resistance offered by the shoulder *d* preventing its passage into the chamber; but when again expanded by increase of heat, the orifice connecting the tube *b* and the chamber, being larger than the bore of the main tube, offers less resistance than the latter to the passage of the fluid, which consequently flows into the chamber, remaining stationary in the main tube, and indicating the lowest temperature to which the instrument has been exposed.

Fig. 6361.



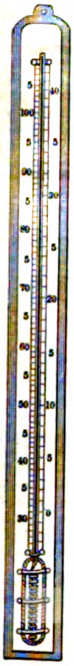
Casella's Minimum Thermometer.

A very sensitive thermometer is formed by substituting for the ordinary bulb a tube coiled in spiral form, either flat or elongated, thus exposing a large surface of mercury in proportion to its mass to the influence of the external heat.

At the Paris Exhibition of 1862 were exhibited a series of thermometers designed to show the relative absorbent powers

of different colors for radiant heat. These were filled with alcohol tinged of different colors, and when exposed side by side to a common radiant source, all differed from each other; but when removed from the light to an apartment of uniform temperature, their indications exactly coincided.

Fig. 6362.



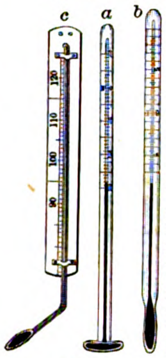
Coil-Chamber Thermometer.

Thermometers specially designed for *clinical* purposes have very thin bulbs, in order to render them more sensitive.

a b are the *surface* and *fever* thermometers of Dr. Seguin. The former has a flat bulb, and is designed to be applied to the surface of the skin; while the latter may be placed in the axilla or other suitable place, or in one of the natural cavities of the body. The natural temperature of the body is assumed as the zero point of the scale, and the graduations read in each direction from this point.

c is Casella's maximum clinical thermometer. It has a globule of mercury serving as an indicator, separated from the mercurial column by an air-space.

Fig. 6363.



Clinical Thermometers.

Cripp's continuous self-registering thermometer has a glass bulb, rather more than an inch in diameter, blown on a tube 12 inches long, and having a bore of $\frac{1}{8}$ inch. The tube is then coiled round the bulb in a close spiral, and two needle-pointed pivots are fixed to the bulb. When these pivots are placed in proper upright supports, the thermometer swings freely, like a delicately balanced wheel. Enough spirit is now placed in the thermometer to fill the bulb, and about 4 inches of the tube at 60° Fah. Mercury is introduced until 4 inches of the tube, above the spirit, is filled with it. The spirit is then heated to 120° Fah., which sends the mercury to within one quarter-inch of the extremity, and the tube is then closed, containing of course a minute quantity of air. The whole apparatus is placed in its supports. If the temperature falls and the spirit contracts, the mercury follows it, and the center of gravity is immediately altered. The thermometer accommodates itself to the change by a partial revolution upon its axis, the direction being opposite to that in which the mercury moves. By the simple operation of the two forces heat and gravity, a positive mechanical motion is produced which is transmitted to a minute endless chain placed vertically and carrying a pencil. Facing the pencil is a vertical cylinder moved by clock-work and revolving once in 24 hours. This cylinder carries a strip of paper ruled with one hundred lines one twentieth of an inch apart, and each representing 1° Fah. Across these are twenty-four dark lines for the hours, and lighter ones for the quarters. To prevent friction from the movement of the pencil over the paper, the former is kept constantly one tenth of an inch from the paper, and a small striker taps it every five minutes, or oftener, driving its point against the paper. The movement of the coiled thermometers, and therefore the temperature, is registered by a series of dots.

A registering thermometer, designed to measure and register the temperature of ocean depths, of deep borings, or other inaccessible places, or of any locality at any desired time, is composed of a mercurial thermometer, curved in inverted V-shape, and fixed on a scale graduated to Fahrenheit degrees. The cylindrical tube which contains the mercury is slightly bent at the zero point. The instrument is connected with a clock, on the lower portion of the dial of which is a supplementary hand pointing to the numbers 1 to 12. By placing this pointer at any determined number, when that hour is reached the clock-work causes the thermometer to revolve one revolution. The effect of this is to break the mercurial column at the bent portion at 0°, and turn it into the other leg of the tube, where it remains, its hight indicating the temperature at the time for which the dial was previously set.

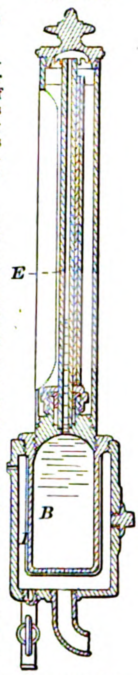
Ther′mo-met′ric A-larm′. An instrument to release an alarm when a dangerous heat is reached in an apartment. A form of *fire-alarm.*

A bent glass tube with a bulb at each end, one of which with a part of the stem contains ether; the other with a part of the stem containing mercury and open to the external air. The tube is poised on its center by gravity. Should the temperature be raised by the presence of fire, the ether would be expanded, the mercury driven into the bulb, the instrument tipped over on its axis, and the alarm sounded. See THERMAL ALARM; THERMO-ELECTRIC ALARM; THERMOSCOPE; THERMOSTATIC ALARM.

Ther′mo-met′ric Steam-gage. A steam-gage which indicates the amount of pressure in a boiler by the amount of expansion of a fluid at the temperature due to the pressure.

In the example, the reservoir *B*, containing mercury, is inclosed in a steam-chamber *I* connected directly with the steam-space of the boiler. The mercury rises in the glass tube *E*, which has a scale directly indicating the pressure in pounds. The reservoir *B* is coated with copper or other suitable material, to prevent steam from penetrating its walls and condensing inside.

Fig. 6364.



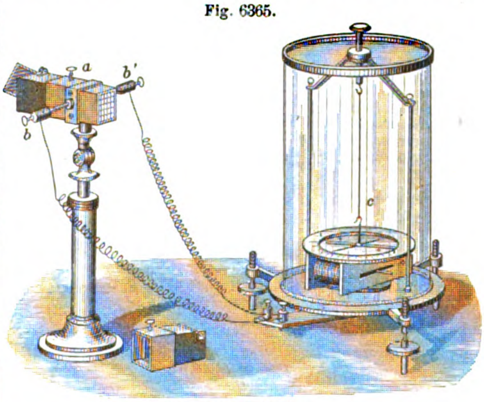
Thermometric Steam-Gage.

Ther′mo-met′ric Ven′ti-la-tor. A modification of Arnott's chimney-valve. It consists of a circular disk, like the throttle-valve of a steam-engine, accurately balanced on a spindle. On one side of the disk is an inverted siphon, with a bulb at one end and open at the other. The lower portion of the siphon-tube contains mercury and the bulb contains air. Any increase of temperature expands the air in the bulb, depresses the mercury, and disturbs the balance of the valve, which opens and allows air to pass. The reverse action takes place when the temperature falls.

Ther′mo-mul′ti-pli-er. An instrument invented by Nobili for measuring small variations of temperature due to radiant heat. Its action depends on the fact that thermo-electric currents are developed by two metals whose opposite junctions are exposed to different degrees of heat. The pile employed consists of alternate plates of bismuth and antimony.

As improved by Melloni, these are arranged side by side so as to form a square bundle, the ends of which are the alternate junctions of the elements. These are contained in a copper case *a*, having covers at each end, which may be removed to expose that part to heat. The terminals of the pile are connected by metallic rods *b b′*, with wires leading to a galvanometer *c*. When a beam of radiant heat strikes the pile, an electric current is produced, the amount of which is determined by the galvanometer.

Fig. 6365.



Thermo-Multiplier.

Ther′mo-scope. An instrument for indicating relative differences of temperature. The term was applied by Count Rumford to an instrument invented

by him, and similar in principle to the differential thermometer of Professor Leslie. See DIFFERENTIAL THERMOMETER. See also Fig. 6360.

Any instrument which shows variations of temperature, whether or not it indicates the actual differences, is sometimes called by this name, including the thermometer. Such were those of Galileo, who in 1593 constructed thermoscopes, which were dependent concurrently on changes of temperature and on variations in the pressure of the external air. These were probably similar to the aërometers of the Spanish Saracens. See AËROMETER.

As early as 1641 observations of temperature were made at regular intervals with spirit-thermometers similar to our own.

Barker and Mayer's thermoscope, August 26, 1873, is designed to indicate in a manner to be readily discernible to the eye the existence of excessive heat in journal-bearings, etc., and also the proper degree of heat to be employed in various processes in the arts. For this purpose two compounds are used. The first is produced by adding a solution of copper sulphate, mixed with sulphurous acid, to a clear solution of hydrargyro-iodide of potassium; the resulting red precipitate is washed, dried, and, by means of suitable varnish or other agent, applied directly or mediately to the object. It changes color at about 160° Fah., but resumes its natural color when the temperature is reduced.

The second is a bright yellow silver precipitate, produced by adding a solution of silver nitrate to the hydrargyro-iodide solution above.

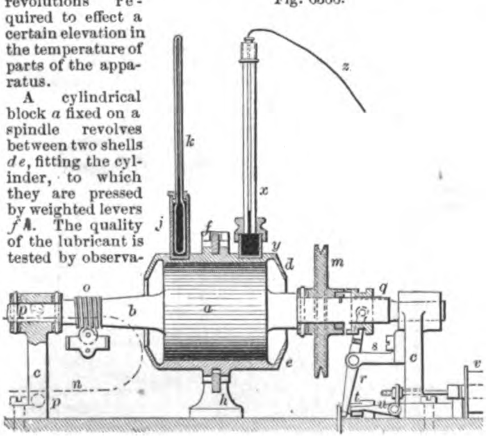
For many purposes the compounds may be applied to cardboard, leather, or thin metal, and by this means attached to the object.

Marcy's thermoscope consists of a thin copper tube of very small bore, and having a bulb at one end. This is inserted within a glass tube, fixed on the periphery of a wheel to which it corresponds in curvature. The tube is hermetically sealed at one end, and in it is poured a certain amount of mercury, which assumes the lowest position in the tube. The axis of the wheel carries a hand which serves as a pointer on a graduated index, and the wheel is balanced on knife-edges. The instrument is particularly designed for experiments on animal heat; the bulb of the copper tube being applied to any part of the body, the contained air expands, displacing the mercury and causing a movement of the index. On being applied to a cooler part, or being cooled by water, the index is caused to move in a reverse direction.

Figs. 6366, 6367, are Stapfer's apparatus for testing lubricants by the number of revolutions required to effect a certain elevation in the temperature of parts of the apparatus.

A cylindrical block *a* fixed on a spindle revolves between two shells *d e*, fitting the cylinder, to which they are pressed by weighted levers *f h*. The quality of the lubricant is tested by observa-

Fig. 6366.



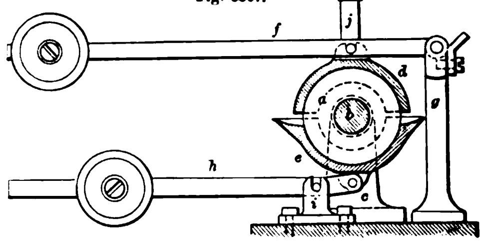
Stapfer's Apparatus for Testing Lubricants. (*Side Elevation and Partial Section.*)

tion of the heat generated by the friction of the opposing surfaces. The upper shell *d* is held down by the weighted lever *f*, which is jointed to the upper end of the standard *g*, the lower shell *e* being pressed upward by the weighted lever *h* that rests upon a fulcrum at *i*. The shells are prevented from revolving with the cylinder by pins in the levers engaging in slots formed in lugs on the shells. A metallic cistern *j* containing mercury is attached to the upper shell, and the bulb of a thermometer *k*, being immersed therein, indicates the temperature to which it has attained.

A band-wheel *m* is mounted on the spindle, and the worm *o* formed on the spindle drives a train in the counter *n*, which registers the number of revolutions. The counter is attached to the standard *c* by two screws, indicated at *p p*.

In another application of the machine, the band-wheel is fitted to revolve loosely on the spindle, and through its engagement with the sliding-clutch *q*, imparts motion thereto. The clutch is changed in and out of gear with the band-wheel by the fork-lever *r*, which is mounted on a stud carried by the bracket *s*, and is acted upon by a spring *t* that tends to throw the clutch out of gear. The clutch is

Fig. 6367.



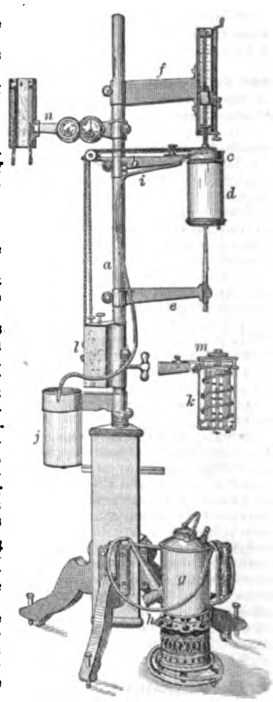
Stapfer's Lubricant-Tester. (*Vertical Transverse Section.*)

retained in gear by a catch on one arm of the bell-crank lever *u*, where it engages with a projection on the lever *r*. The other arm of the bell-crank lever is connected with the armature of an electro-magnet *v* in such a manner that so long as the armature is not attracted by the magnet, the clutch remains in gear, and the cylinder *a* consequently continues to revolve. A battery is connected with the magnet and with the upper end of a thermometer *x*, and the glass tube thereof forms a break in the circuit.

The mercury of the thermometer contained in the metallic cistern *y* fixed to the shell *d* rises with the increased temperature of the shell, caused by the loss of the lubricating properties of the oil, until it touches the end of the wire *z* that projects into the tube.

The mercury then serves to make the circuit, and the armature is attracted, raising the catch from the projection of the lever *r*, and the spring *t* forcing back the said lever, the clutch is thereby disengaged, and the rotation of the cylinder ceases. See also THERMO-ELECTRIC ALARM.

Fig. 6368.



Osborne's Esthermoscope.

Fig. 6368 is a thermoscope of peculiar construction, for meteorological purposes, the invention of J. W. Osborne of Washington. The object of this instrument is to give expression to the aggregate of all the climatic influences which tend at any time and place to affect the normal temperature of the body, or to modify the demand on it for the physiological production of animal heat. As warm-blooded animals, we are constantly losing just as much heat as we make, and therefore in estimating weather or climate, we speak of it as cold or hot in proportion as it cools us rapidly or slowly, irrespective of the nature of the several causes which determine that cooling. The three great factors which affect us thermically are the actual temperature, the moisture of the air, and its motion as wind over our bodies. The first of these alone is all but universally accepted as indicating relative temperatures affecting animal life. A little reflection will show that it does not do so in reality, playing often quite a subordinate part in determining the sensible heat or cold which we experience. A so-called temperate climate, for instance, will, if windy, cool us faster than a cold and frosty one when perfectly still; and a summer temperature of 90° is fresh and pleasant if dry and breezy, while it is almost unendurable if thoroughly moist and free from wind.

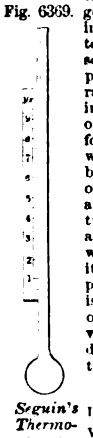
This instrument, shown at Fig. 6368, consists of an upright standard of heavy brass tubing *a*, about six feet high, from which several horizontal brackets extend. One of these *b* carries a ring *c*, from which hangs a cylinder of "bond," or bank-note paper *d*, 100 millimetres diameter, and 150 long (about 4 × 6 inches). The lower end of this is closed by a very thin brass disk, the paper being attached to it and to the ring above by strong rubber bands, or very thin clamping-rings of brass. The arm *e* with the upright wooden pin is used to steady the cylinder when exposed to the wind, or while moving the instrument. The bracket *f* carries a thermometer, the bulb of which is about the center of the cylinder. This cylinder is usually full of cold water, but when an observation is to be made, its temperature is raised to blood heat, or higher, if desired, in the following manner: the copper vessel *g*, being partly filled with hot water, is then elevated above the cylinder, so that the hot water flows in by pipe *h*, and the cold water flows off by the tube *i* into the receptacle *j*. In this way, by simple displacement, any desired temperature can be reached with facility. The cylinder is shown in section at *k*. To maintain the water at an equable temperature throughout, an agitator, consisting of a spiral ribbon, is made to rotate by means of the horizontal pulley *m*, driven by the clock-work *l*, while from the disk below three stationary blades rise perpendicularly, which serve to hold the water from revolving, and force a current to descend the sides and rise in the center against the bulb of the thermometer.

The temperature of the water having been raised to blood heat, or any other point fixed upon, the time in seconds which each degree takes to fall is noted by means of the spring-back stop-watches, on the arm *n* (which also carries the ordinary wet and dry bulb thermometers). These watches are so connected that the movement required to stop one starts the other; whereby a series of intervals can be measured and recorded, each from zero, with perfect accuracy. We thus get the rate of cooling of the mass of water (weighing nearly three pounds) for a series of six or eight degrees, from which a single expression can be calculated.

It will be seen that the cylinder is subjected to influences similar to those which act upon the human body. The paper of which it is made is quite porous, enough to admit of evaporation analogous to that from the skin and lungs. It is cooled by this, and by radiation and convection, as the body is cooled. The rate at which it cools furnishes therefore an expression of the intensity of the aggregate thermal effect, comparable with that experienced by the human body, and proportional for the same or similar instruments at different times and places. The very obvious necessity for the information sought when once pointed out, and the difficulty of obtaining it, give to this invention a peculiar interest.

Fig. 6369 is an instrument devised by Dr. Seguin of New York, to be used in diagnosis. It is intended to detect variations of temperature of the body and the rate of radiation going on therefrom. It consists of a glass tube seven inches long, with a minute bore open at one end, and terminating at the other in a bulb. An adjustable scale is attached to the outside of the tube. To prepare it for use, immerse the bulb in hot water, which rarefies the air inside. The open end is then plunged into cold water and quickly withdrawn, when a drop or two will be found to have entered the tube. This forms a *water index*, which should become stationary within an inch or two of the bulb. If it falls into the bulb, or does not approach it sufficiently, too much or too little heat was applied in the first instance, and it will be necessary to jar the water from the tube and try again. When the index is provided, adjust the scale, bringing its lowest figure on a level with the top of the column of water in the tube, and it is then ready for use. It may be applied to any part of the surface where disturbance of temperature is suspected. It is said to give, by contact, indications of the volume of heat escaping by radiation, and the velocity of loss; and by blowing on the bulb, to indicate the degree of combustion that takes place in the lungs.

Fig. 6369.



Seguin's Thermoscope.

Ther'mo-si'phon. A siphon attachment to hot-water heating-apparatus, invented by two engineers, — Kewley of London, and Fowler of Devonshire, England. They found that the circulation of the water was greatly increased by passing it through the two legs of a siphon, especially when the tubes were irregular in point of horizontal direction, and both above and below the level of the boiler. See Loudon's "Encyclopædia of Gardening," London, 1834, page 597.

Ther'mo-stat. A self-acting apparatus for regulating temperatures.

The balance-thermometer is poised horizontally on an axis, and so arranged that as the mercury contracts or expands in the tube on either side of the mean temperature for which it is adjusted, one end or the other of the thermometer will tip up and actuate a device whereby the heat of an apartment or greenhouse is increased or diminished, as the case may be.

One form was invented by Dr. Cummings of Chester, England, and used to open and shut the windows of hot-houses. A balance-thermometer, patented in England in 1816 by Kewley, was employed to open and shut doors.

An electrical thermostat consists of an ordinary mercurial thermometer, provided with a platinum wire connecting with the mercury in the bulb. Through the other end of the tube is inserted another platinum wire capable of being elevated or depressed. These two wires are in connection with the poles of a battery, and in the circuit is an electro-magnet whose armature controls the opening or closing of a valve for the admission of hot air. If it be desirable that the temperature of the air should not rise above a certain temperature, say 60° Fah., the free end of the movable wire is brought to the required number on the tube. When the heat is such as to cause the mercury to rise to that degree, the electric circuit is completed, the armature closes the hot-air valve until the temperature is diminished, when the circuit is broken, and the valve again opened.

Other forms of thermostat are adapted to open and close the draft openings of furnaces to regulate the admission of fresh air to the fire, and insure a uniformity of combustion.

Dr. Ure, about 1830, contrived a thermostat, the action of which depended on the unequal expansion of two metals by heat, for regulating the safety-valves of steam-engines.

A self-acting statical damper or heat-regulator was invented by Dr. Cummings many years since, and was designed as a mode of opening windows and ventilators in apartments by the variations in the temperature of the included air.

The sash is hung upon centers, so as to oscillate readily, and a cord passes from it to an areometer tube, which is partly charged with quicksilver, and has a body of included air in a bulb at top. The open lower end is plunged in a cup of quicksilver; and as air in the bulb is expanded or contracted by heat, the weight of the suspended tube and bulb becomes relatively less or greater by the variation in the quantity of quicksilver contained, causing the tube to rise or fall, and so operate the sash or valve.

The name *thermostat* was first applied by Dr. Ure to an instrument patented by him in 1831, in which the bending of a spring composed of two unequally expansible metals, as steel and brass, was made to control a valve or damper.

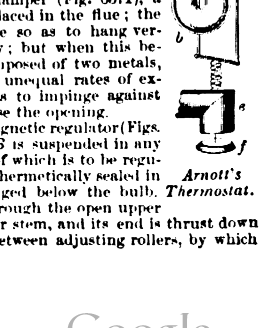
A thermostat was applied by Bonnemain of Paris, in 1777, to his calorifère, by which he heated buildings. The heater consisted of a boiler with an ascending hot-water pipe, which coursed through the stories or apartments of the house, and then descended again to the boiler with its contents comparatively cooled. He heated an incubator in this manner. The variation of temperature seldom exceeded ¼° R. See B, Fig. 2666, page 1178.

The thermostat was inserted in the boiler, and acted upon the door of the ash-pit so as to regulate the admission of air to the fire.

It depended upon the unequal dilation of different metals by heat. It was formed of a bar of iron screwed to one of brass, inclosed in a leaden tube terminating in a ring of brass and plunged into the boiler. The dilation of the leaden tube had the effect of drawing upon the rod and bringing the ring in contact with a claw at the short end of a bent lever communicating by a wire with the ash-pit door, which acted as a damper.

Fig. 6370 shows a form applied by Dr. Arnott to his stove. *a b* is a curved tube containing mercury in the bend *b*: the end *a* is inserted in the combustion-chamber, and as the contained air is expanded by heat, the mercury rises in the outer leg of the tube, carrying with it the float *c*, connected by a rod to the frame *d*, from which is suspended a wire carrying the valve *f*, which closes the opening of the pipe *e* by which air is supplied to the combustion-chamber. A fall of temperature produces the reverse effect. In a simpler form, the lower end of the tube *e* is brought into proximity to a funnel-shaped reservoir of mercury, which on expanding by heat closes its mouth.

Fig. 6370.



Arnott's Thermostat.

In Tamkin's automatic damper (Fig. 6371), a disk turning on an axis is placed in the flue; the disk is weighted on one side so as to hang vertically when the heat is low; but when this becomes excessive, a spring composed of two metals, as copper and iron, having unequal rates of expansion, becomes bent, so as to impinge against the damper and partially close the opening.

In Dr. Sternberg's electro-magnetic regulator (Figs. 6372, 6373), a thermometer *E* is suspended in any apartment the temperature of which is to be regulated. A platinum wire *a* is hermetically sealed in a portion of the tube prolonged below the bulb. An adjustable wire *b* slips through the open upper extremity of the thermometer stem, and its end is thrust down the tube. The wire passes between adjusting rollers, by which

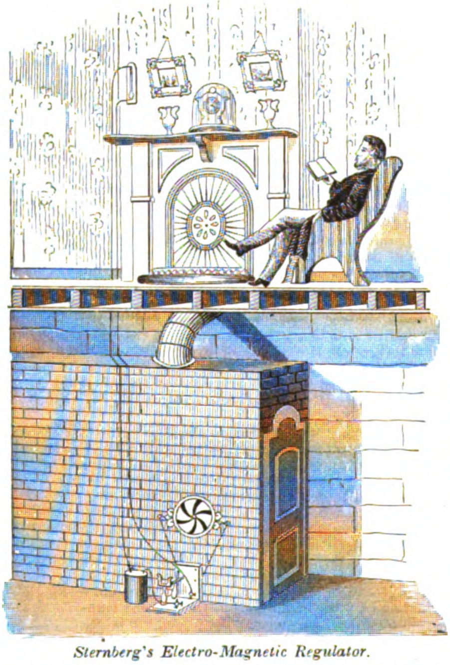
Fig. 6371.

Tamkin's Automatic Damper.

it is raised or lowered until its end stands at any desired degree of the scale. By means of binding-screws, the wires a b have electric communication with the wires c d, which pass to the furnace or heating-apparatus, and are there connected with the apparatus by which the valve or damper is operated. A battery-cup is interposed in the circuit at any convenient locality. When the heat of the room in which the thermometer hangs causes the mercury to rise and meet the point of the adjustable wire, an electric circuit is completed, passing through the helix of a temporary magnet, causing its armature to be attracted, moving a lever by which the valve or damper is closed. This diminishes the heat of the room, and causes the mercury to fall below the point of the wire. The circuit being thus broken, a spring withdraws the armature from the electro-magnet and opens the damper.

Pressure of steam may be regulated by making the steam-gage act as a regulator, the electric circuit being made and broken by the needle of the steam-gage dipping in a cup of mercury. This may be arranged either to govern the supply of air admitted to the furnace or a valve by which steam escapes from the boiler. A modification

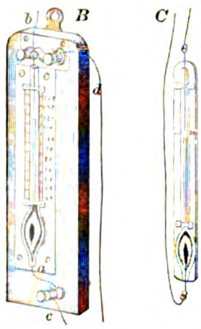
Fig. 6372.



Sternberg's Electro-Magnetic Regulator.

of the apparatus, in which the rising and falling of a float opens and closes the circuit, may be employed as a means of controlling the supply-pipe valve of a reservoir.

Fig. 6373.



Sternberg's Thermometer.

A thermometer (C) in which the upper wire is fixed to a certain graduation in the tube is used for immersion into liquids or gases which are to be maintained at a given temperature.

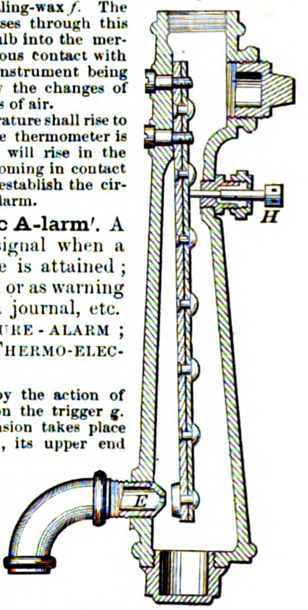
Wilson's thermostat for steam-heaters (Fig. 6374) has a compound plate made of two metals, say of brass and steel, which bends by the unequal expansion of the two metals by increment of heat, and thus stops the steam induction-aperture E. H is adjusting stop-valve screw.

Watkins combines a compound metallic strip a with a closed tubular case m by means of an insulating base b and a metallic conducting-cap i and indicator set-screws n n, whereby, by the expansion or contraction of the compound metallic strip, a galvanic circuit may be closed or opened at any required degree of heat to operate a fire-alarm telegraph-instrument.

In Guest's electrical thermostat (Fig. 6376), the circuit is closed by the rising of a column of mercury in a tube, so as to touch the upper wire d. The instrument has a bulb a with an expansion-tube b, surrounded by an outer vessel c, which is closed hermetically by a cork and sealing-wax f. The end of the wire e passes through this outer vessel and the bulb into the mercury, being in continuous contact with it, the action of the instrument being thus not disturbed by the changes of temperature and access of air.

Whenever the temperature shall rise to the degree to which the thermometer is adjusted, the mercury will rise in the expansion-tube, and, coming in contact with the wire therein, establish the circuit and produce the alarm.

Fig. 6374.

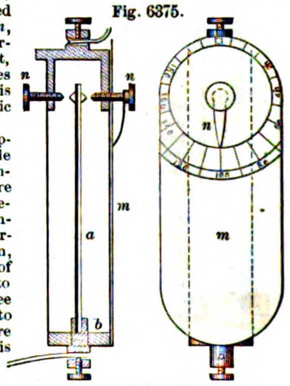


Wilson's Thermostat.

Ther′mo-stat′ic A-larm′. A device to give a signal when a certain temperature is attained; used as a fire-alarm or as warning of the heating of a journal, etc. See TEMPERATURE-ALARM; THERMOSCOPE; THERMO-ELECTRIC ALARM; etc.

Fig. 6377 operates by the action of the thermal bar a upon the trigger g. Whenever lineal expansion takes place in the thermal bar a, its upper end being rigidly fixed to d by the screw-threaded shank, such expansion acts directly and entirely upon the lever e, and through it upon f, causing them to assume the position shown in dotted lines, and releasing g. g may be the trigger or detent of any suitable alarm-apparatus, releasing a wound-up signal-apparatus, or winding up a signal-apparatus by its movement; or it may be simply a circuit, closing or breaking, serving to separate or bring together the two springs i and k attached to insulating-blocks m m, which springs form the terminals of a battery-circuit, as represented by the wires p n, in which circuit is placed any suitable electric apparatus.

Fig. 6375.

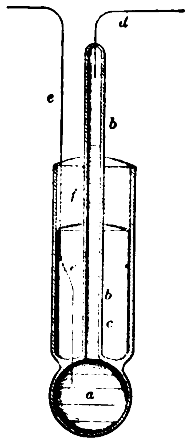


Watkins's Electrical Thermostat.

Fig. 6378 shows the application to a portable thermometer of an alarm-bell operated by the closure of an electrical circuit derived from a battery concealed in the base, the circuit being normally open, but closed by the rising of the mercurial column to any predetermined degree of the scale, according to the degree of temperature required. The operation is as follows: the wire h is represented as extending down the stem of the thermometer to the point on the scale marked 25°. The mercury in the stem stands at about 15°. While this remains the case the circuit is open, and the armature m is not in contact with the poles of the electro-magnet. But when, by reason of increased temperature, the mercury in the stem rises to the point marked 25°, it comes into contact with the end of wire h and closes the circuit, which causes the armature m to be drawn into contact with the electro-magnet l and an alarm to be sounded upon the bell q by the hammer p. When the temperature falls below 25° the circuit is again broken and the armature is drawn away from the magnet by the spring-arms n n. A second hammer, attached to the armature, may be arranged to strike the bell when that fall of temperature occurs. A continuous alarm, if preferred, can be arranged to be operated by the closed current in any of the well-known methods. By sliding the plate d up or down, the end of the wire h may be made to coincide with any desired point on the scale, and the alarm will be sounded when the temperature reaches that degree.

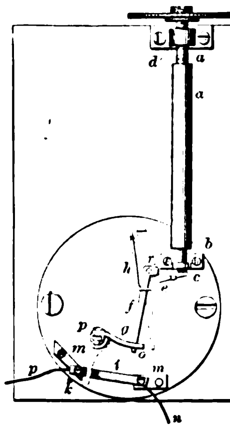
Ther′mo-type. An impression (as of a slice of

Fig. 6376.



Guest's Electrical Thermostat.

Fig. 6377.



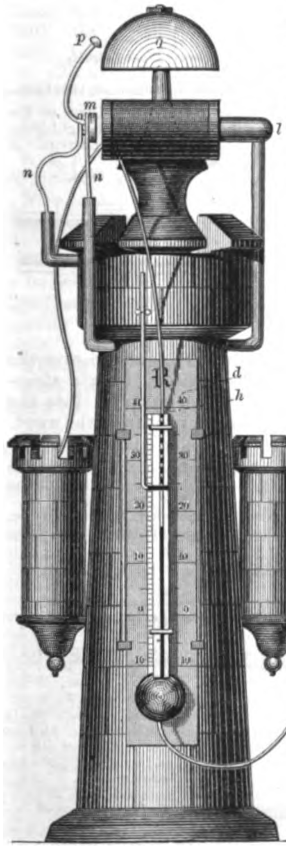
Guest's Thermostatic Alarm.

wood) taken by means of wetting with dilute acid, pressing on the object, and subsequently heating the impression.

Thi'baude. (*Fabric.*) (Fr.) Cloth made from cow-hair.

Thib'et-cloth. (*Fabric.*) A camlet made from goat's hair.

Fig. 6378.



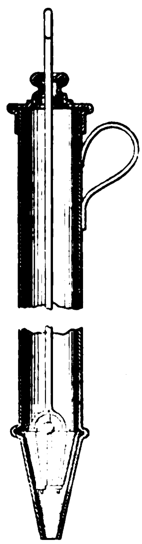
Snow's Electrical Thermostatic Alarm.

Thi'ble. A skimmer or slice. (Old English.)

Thick-and-thin Block. (*Nautical.*) A block having two sheaves of unequal size, in the same plane. A *fiddle-block*.

Thick'en-ing. (*Calico-printing.*) Paste which contains the mordant or dye, in some cases, and forming a vehicle therefor.

Fig. 6379.



Thief-Tube.

Thick'ness. (*Foundry.*) That application of loam in loam-molding which represents the metal, and which is afterward knocked away to leave space for the same.

Thick'ness-ing. (*Wood-working.*) Reducing boards or pieces to an even thickness ready for dressing to shape.

Thick-set. 1. (*Fabric.*) A stout, twilled, napped cotton cloth. A kind of fustian.

2. (*Husbandry.*) Thorn-bushes used in hedging, in England. The thorn does not succeed so well here. One or two of the American thorns are better here than the English hawthorn, but are far from satisfactory.

Thick-stuff. (*Shipbuilding.*) All plank above four inches in thickness.

Thief-tube. A tube for withdrawing samples of liquids from casks, etc. A *sampling-tube*; a *velinche*. Some *burettes*, *pipettes* (see Fig. 3750), and *dropping-tubes* are made on this principle.

Thill. 1. (*Vehicle.*) A *shaft*. One of the two side pieces by which one horse is hitched to a vehicle.

2. (*Mining.*) The floor of the mine.

Thill-coup'ling. A device for fastening the shafts to the fore-axle.

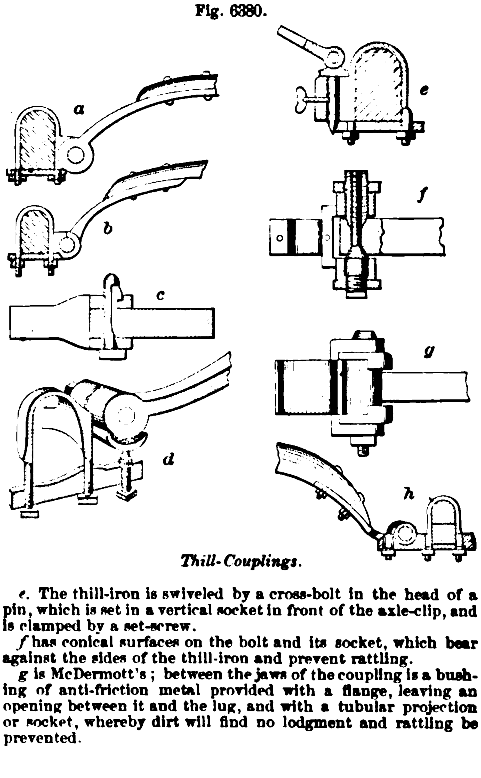
The ordinary mode of coupling (*a*) is by means of a screw-bolt to a clip on the fore-axle. This wears loose and rattles: hence inventions have been brought forward to improve the mode of coupling.

Many patented contrivances, as *b*, depend upon the insertion of a plug behind the pin of the thill, forcing it forward into the hook which is attached to the clip.

***c* consists of a key and spring-latch as a substitute for the screw-bolt, and occupying a similar position, without special adaptation of the other parts.**

***d* is Bridget's coupling. The set-screw beneath the socket-plate and elastic pad raises the thill-iron against its pivotal pin and prevents rattling.**

Fig. 6380.



Thill-Couplings.

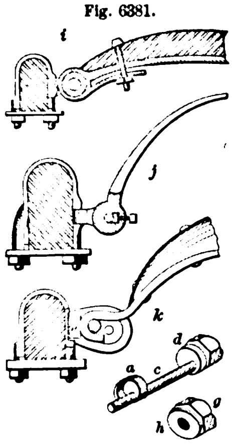
***e*. The thill-iron is swiveled by a cross-bolt in the head of a pin, which is set in a vertical socket in front of the axle-clip, and is clamped by a set-screw.**

***f* has conical surfaces on the bolt and its socket, which bear against the sides of the thill-iron and prevent rattling.**

***g* is McDermott's; between the jaws of the coupling is a bushing of anti-friction metal provided with a flange, leaving an opening between it and the lug, and with a tubular projection or socket, whereby dirt will find no lodgment and rattling be prevented.**

h. The clamp-hook or convex-headed cap is situated between the branches of the forked thill-iron, and forms part of a bolt which is secured in the jack by a nut.

Fig. 6381.



Thill-Couplings.

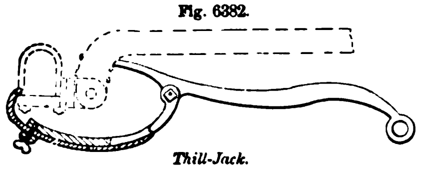
i. An open ring bushing is placed around the bolt, and the loop of the thill-iron is bent around the bushing, which may be of raw hide. The end of the iron is bent around and traversed by a temper bolt.

j. The head of the thill-iron has a recess opening into the hole through which the bolt passes; in this recess is a friction-plate, which is pressed against the bolt by a set-screw to prevent rattling.

k. The thill-hook is placed in the clip, and the bolt inserted. The bolt, being turned half a revolution, brings the eccentric pin *c* against the thill-hook, and forces the latter against an elastic pad *e* in front of the clip The working faces *a a'* of the bolt turn in the eyes of the clip, as does also the collar *h* of the nut *g*, which prevents the return motion of the bolt.

Thill-jack. A tool for attaching the thills of a carriage to the clips of the axle. By means of the lever clamp the rubber, which is placed in contact

Fig. 6382.



Thill-Jack.

with the thills to prevent rattling, is compressed, so that the thills may be easily attached. A *shaft-coupling jack.*

Thill-tug. A leathern loop depending from the harness saddle to hold the shaft of a carriage.

Thim'ble. 1. A frusto-conical metallic sheath used to protect the end of the finger in sewing. Seamstresses use a thimble having a rounded end with numerous small pits or indentations. Those used by tailors, upholsterers, and needle-men generally are open at the end.

The name is said to have been derived from *thum-bell*, having been first worn on the thumb, as the sailor's thimble still is. It was introduced into England from Holland in 1605, by John Lofting, who manufactured them at Islington.

Thimbles of bronze, exactly like the modern, have been found at Herculaneum.

The thimble is sometimes utilized as a tool-holder. The *extension thimble* of the dentist is a prong on the end of the thimble, used to reach into the mouth to hold the foil or a compress, while operating on the teeth

The bur thimble has an open ring for the index or middle finger, and a socket attached, in which rests the end of the drill handle.

The *hand-shield* used by sail-makers and saddlers is called a *palm*.

Silver thimbles are made from coin-silver, cast into ingots, and rolled into sheets, from which circular disks are cut by stamping; these are then placed over a circular opening and subjected to the action of a plunger. The end, side, and rim are turned in a lathe, where they are also polished by a round steel rod dipped in oil.

The ornament near the rim is impressed by means of a rapidly revolving steel wheel; a second wheel forms the ornament near the middle. A third wheel provided with points makes the indentations on the side and end. The inside is then polished in a similar way to that employed for the outside. The thimbles are finally boiled in soapsuds to remove the oil, and then brushed.

Iron thimbles for sewing are *raised* by stamping with five or six blows, between as many pairs of conical dies, which are successively more and more salient. The metal is annealed between each operation.

In Paris they are made from strips of thin sheet-iron, which is punched into disks about two inches in diameter; these are heated red-hot, struck up to the required depth, then placed in the lathe, where the interior is polished, the outside turned off, the pits indented with a kind of milling tool, and a groove formed on the outside to receive the gilding. After being annealed and brightened, the inside is also gilt with a strip of gold-leaf applied by the pressure of a mandrel. A fillet of gold-leaf is similarly secured in the exterior groove.

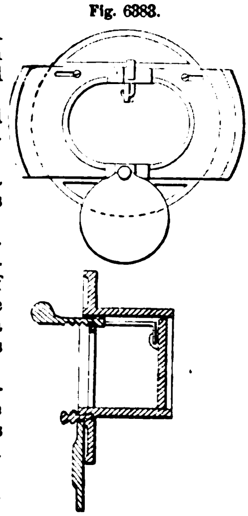
2. (*Nautical.*) An iron ring having an exterior groove worked into a rope or sail, for the purpose of receiving another rope or a lanyard. A large eyelet.

3. (*Machinery.*) *a.* A sleeve or tube through which a bolt passes, and which may act as a stay.

b. A ferrule to expand a tube; specifically, a ferrule for boiler-tubes.

4. A sleeve around a stove-pipe when it passes through a wall or ceiling. In Fig. 6383, the sliding-jaws in the face are capable of embracing pipes of varying sizes, and the opening is closed by a shutter; a damper is placed in the rear end.

Fig. 6383.



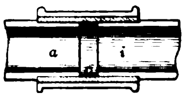
Stove-Pipe Thimble.

Thim'ble-eye. (*Nautical.*) An eye in a plate through which a rope is rove without a sheave. A *dead-eye.*

Thim'ble-joint. A sleeve-joint, with an interior packing to keep the joints of pipes tight during expansion and contraction.

The adjoining ends of the pipes *a i* are turned true on the outside, and have a thimble, or short cylinder of wrought-iron, to inclose them, leaving only a small space for the current. A piece of tin *c*, or inner thimble, is interposed, and made to fit well to the turned parts of the pipes, which, under the influence of heat or cold, work forward or backward, like a piston in a cylinder. In a range of pipes 120 feet in length, there is a motion from expansion of three quarters of an inch; but the usual allowance for the expansion of cast-iron pipes is one eighth of an inch in 10 feet, or $\frac{1}{960}$ of their length.

Fig. 6384.



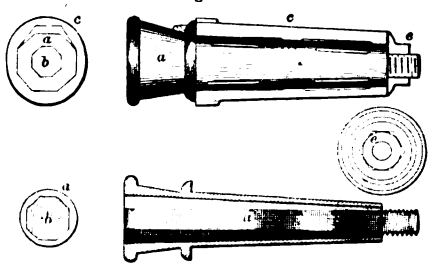
Thimble-Joint.

Thim'ble-skein. (*Vehicle.*) A sleeve over the arm of a wagon-axle; distinguished from a *strap-skein*, which is simply a flat iron strip let into the wood of the axle-arm to take the wear from the wood. See also Axle.

In Fig. 6385, *a* shows a thimble-skein; *b*, the wood of the axle-arm, over which the skein is slipped; *c*, the box of the hub; *e*, the nut on the screw at the end of the skein.

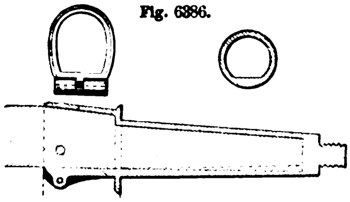
The thimble-skein (Fig. 6386), at its lower bearing surface, has a flat straight seat for the under side of the wooden axle,

Fig. 6385.



Thimble-Skein.

Fig. 6386.



Snyder's Thimble-Skein.

and has a gradual taper from its front to its rear end to facilitate fitting to the axle.

Thirl'ing. (*Mining.*) A worked space connecting the *rooms* of a mine. The *rooms* are galleries proceeding regularly — in coal-mines — from the *dip-head* or *main-level*, and the unworked space forms a *wall*. By cutting gaps in this *wall* at regular intervals, the *wall* becomes a row of *pillars*, the said connecting workings are *thirlings*.

Thir'ty-two. (*Printing.*) A sheet of paper which folds up into 32 leaves or 64 pages. Usually written 32mo.

This'tle-dig'ger. A long narrow spade for cutting the roots of thistles below the crown of the root, and lifting them from the ground. See Fig. 5334, page 2251.

Thole. 1. (*Nautical.*) A pin inserted in the gunwale of a boat to serve as a fulcrum for the oar in rowing. They are arranged in pairs, the space between forming one kind of rowlock. Tholes are shown on the gunwales of ancient Assyrian boats. (Rawlinson's "Five Great Empires," Vol. I. page 550.) Called also *thowls*, *thole-pins*. See ROWLOCK; also Fig. 3360, page 1542.

2. (*Husbandry.*) The *nib*, pin, or handle of a scythe-snath.

3. (*Architecture.*) *a.* The scutcheon or knot at the center of a timber-vault.

b. A place in temples where votive offerings were suspended.

Tho'lo-bate. (*Architecture.*) A cupola, and a base; that part of a building on which a cupola is placed.

Tho'lus. (*Architecture.*) An appellation given to buildings of a circular form. Vitruvius uses it to signify the roof of a circular building. Now frequently applied to the *lantern* which surmounts a dome.

Thong. A leathern strap or lash.

Tho'ra-co-sco'pi-um. (*Surgical.*) A STETHOSCOPE (which see).

Tho'ri-um. A heavy gray metal which burns when heated in the air.

Thor'ough-bolt. (*Shipbuilding.*) A bolt going through from side to side.

Thor'ough-brace. (*Vehicle.*) A strong band or thong extending from the front to the back C-spring and supporting the body.

Thowl. See THOLE.

Thrash'ing-ma-chine'. (*Husbandry.*) One for beating out grain from the heads. The normal form operates upon wheat, barley, oats, rye, and timothy. Some modifications have been made for flax and clover-seed.

In Egypt, the ancient modes of thrashing have been maintained till modern times. (See Fig. 4196.) Their wheat was bearded.

"For the fitches are not thrashed with a thrashing instrument, neither is a cart-wheel turned about upon the cummin; but the fitches are beaten out with a staff, and the cummin with a rod. Bread-corn is bruised; because he will not ever be thrashing it, nor break it with the wheel of his cart, nor bruise it with his horsemen." — Isaiah xxviii. 27, 28.

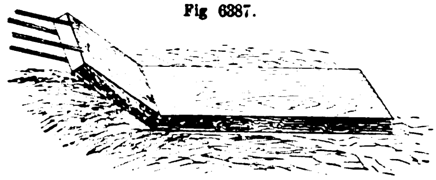
We learn from Amos that the sheaves were carted to the floor. Four instruments of thrashing are mentioned in this passage, — the *flail*, the *drag*, the *wain*, and *treading by cattle*. Another, not mentioned, was the *ripple*; doura, sorghum, or flax was thrashed by drawing across a comb-like instrument. See Fig. 4341.

The practice was, and is, to gather the grain to a spot which is exposed to the wind, and there lay floors of sheaves about a foot thick. As the grain in the sheaf is thrashed, it is heaped in the center of the circular track on which the operation is performed, awaiting a favorable day for winnowing.

Barley harvest preceded that of wheat in Egypt and Palestine, and Boaz winnowed barley at his thrashing-floor when Ruth waited upon him.

1. The thrashing by flails was adopted for the more tender kinds of grain.

Fig 6387.

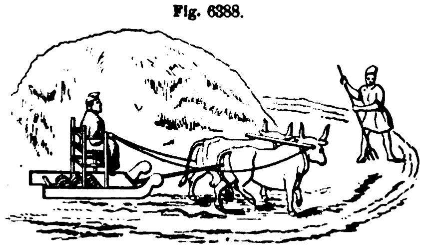


Syrian Mowrej.

2. The drag was a frame of wood shod with iron (or sharp pieces of lava in Palestine); it was sometimes toothed, making it "a new, sharp thrashing instrument, having teeth." (Isaiah xli. 15.) This may have resembled the Roman tribulum, which was a sled drawn by oxen. The driver rode upon it.

3. The *wain* was a frame with a number of axles on which were placed gangs of wheels. It was drawn by oxen around the track on which the sheaves were laid. A man attended with a

Fig. 6388.



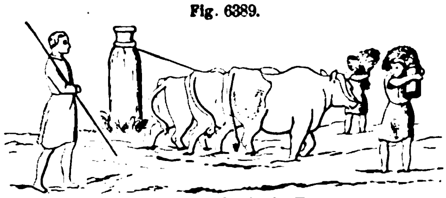
Egyptian Mowrej.

fork to throw in the unthrashed straws and keep a full thickness on the floor beneath the thrasher. Niebuhr and Thompson have described the process at length. It is as it has always been since the first record of such things.

Varro (150 B. C.) describes a Carthaginian machine which traveled on rollers studded with iron knobs and having a seat for the driver.

4. The tramping by cattle needs no particular description. The Hebrew law forbade the muzzling of the mouth of oxen while trampling out the corn.

Fig. 6389.



Tramping out Grain in Egypt.

Dr. Thompson considers the thrasher made of a slab, studded beneath, to be the common form of machine, and states that it grinds the straw up into chaff; the latter makes the winter feed of the animals, who know not hay. The arrangements were similar when Gideon thrashed wheat by the wine-press under the oak in Ophrah, 1249 B. C.; and when the plague was stayed at the thrashing-floor of Ornan the Jebusite (1017 B. C.), at the elevated spot afterward known as the hill of Zion, and which was purchased by David for 600 shekels of gold as a site for the temple his son Solomon was to build.

Among the Romans thrashing was carried on in similar ways: —

1. The ears or the grain in the straw, as it came from the field, was thrashed by the *flail*;

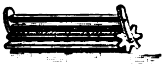
2. Or trodden out by men or horses;

3. Thrashed by a *tribulum*, a loaded board shod with iron bars and drawn by oxen;

4. Thrashed by a *Punic wain*, a frame supporting a rider and running on toothed rollers.

Virgil recommends that the thrashing-floors be spaded up and rammed down with chalk and cow-dung. Pliny advises lime slacked with the amurca of the olive to make a cement floor. Cow-dung and the marc of olives are still used in France for preparing thrashing-floors.

Fig. 6390.



Roller for Thrashing.

Thrashing in Lombardy is generally performed by means of a fluted roller (Fig. 6390) drawn around in a circular track.

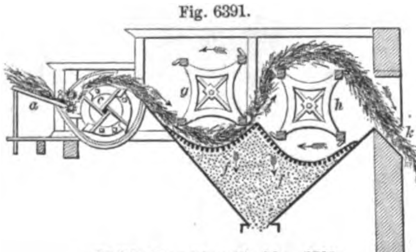
Hohlfield of Hermerndorf, in Saxony, 1711-1771, invented a thrashing-machine while working on the estate of Gusow, in the service of the Prussian minister, Count de Podervils. We are not informed as to its construction; it seems to have given satisfaction. He also invented a straw-chopper and many other machines.

Menzies made a machine in Scotland in 1732, and Stirling of Dumblane another in 1758, but they do not seem to have been successes.

Meikle, of Tyningham, East Lothian, Scotland, invented a machine in 1786, which is the type of modern thrashers. Menzies's had a series of revolving flails, and Stirling's had a cylinder with arms upon a vertical shaft running at high velocity. Meikle invented the drum with beaters acting upon the grain in the sheaf, which was fed between rollers. The English improvement was to make the beating drum work in a concave known as the *breasting*, the grain and straw being scutched and rubbed between the two and carried to the shaker, which removed the straw from the grain and chaff, a large amount of grain also falling through the bars of the concave.

Fig. 6391 shows the Meikle machine, in which the grain in the straw is fed from the board *a* between two fluted rollers to the beater-cylinder *c*; thence passes to another beating-cylinder *g*, which operates above a concave grating; a third cylinder *h*

Fig. 6391.



Meikle Thrashing-Machine, 1786.

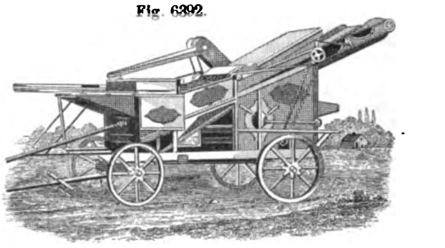
raises and loosens the straw, which parts with its grain *f* through the concaves, and the straw is delivered at *k*. The circular rakes *g* and *h* were added in 1789 by Chillingham. In 1800, the fanning-mill was added.

The American improvement upon this consists mainly — besides numerous details which secure speed, lightness, and effectiveness — in having, upon the drum, spikes or teeth which pass between fixed spikes on the concave; the grain in the straw being subjected to a severe beating and rubbing action as it passes in a zigzag course between the two, being carried by the teeth of the drum. The latter is now usually a skeleton cylinder of iron bars with sword-shaped spikes secured by threaded tangs and nuts. The front edges of the spikes are rounded and smooth, to prevent breaking of the grain; the spikes of the concave have smooth edges presented toward the coming grain for a similar reason. The English still adhere to the flat beaters, like narrow wings or slats, placed longitudinally, and with edges projecting outwardly from the drum. The Americans adhere to the spiked cylinder. A fair trial between the two was had on the farm of Mr. Mechi, Tiptree Hall, Kelvedon, England, in 1853. The American machine was operated by the two persons who had shipped it from the United States; one of them was the present writer. The trial was conclusive. The American machine was driven by a portable engine of six horse-power, and averaged 64 bushels of wheat per hour; 448 bushels of barley were thrashed in six hours, nearly treble the work of the English competing machines, and the grain in much cleaner condition.

The editor of the London "Times," Mr. Mowbray Morris, himself witnessed the operation, and wrote as follows in an editorial of the following day, November 1, 1853: —

"The machine, which is portable, weighs only fourteen hundred-weight, thrashes easily, and without waste, at the rate of one bushel in forty seconds, and turns out the grain perfectly clean and ready for market. It is therefore about twice as light in draught as the lightest of our machines of the same description; does as much if not more work than the best of them, and, with much less power, dresses the grain, which they do not, and can be profitably disposed of at less money than our implement-makers charge. . . . We build thrashing-machines strong and dear enough, and tremendously heavy either to work or to draw. The American farmer demands and gets a machine which does not ruin him to buy or his horse to pull about, which runs on coach and not wagon wheels, and which, without breaking the heart of the power that drives it, yields the largest and most satisfactory results. Nothing, therefore, can better illustrate the difference in mechanical genius in the two countries than this grain-separator as compared with its British rivals."

Fig. 6392.



American Thrashing-Machine.

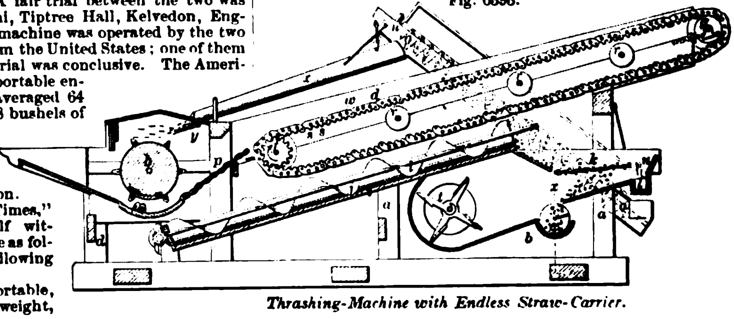
It may be mentioned that the apparent perversity with which the British retain flat beaters instead of the teeth is that in many parts of Britain there is a profitable market for trussed straw; the straw is less broken by the beaters than by the teeth, is in more unbroken lengths, and trusses more readily and handsomely.

The American thrashing-machine has some characteristics common to nearly all its machines. An inclined chute furnishes the sheaf, heads foremost, to the action of the radial teeth that are attached to the skeleton cylinder, and are opposed to the teeth in the concave plates beneath. A straw-carrier elevates and discharges the straw, shaking out the grain, which falls into the well. A lifting screw elevates and forwards the grain and chaff from the well to the vibrating shoe that carries the dividing screens, which, with the aid of the blast from the fan in its rear, separates the grain from its accompanying refuse. The clean grain then falls into a forwarding screw that discharges through a spout into a measure or bag.

An elevator returns the tailings and unthrashed heads to the cylinder to be worked over. An endless belt furnished with transverse slats, and sometimes covered with an apron, takes the straw from the machine. Some machines are also provided with a straw-carrier that elevates and forwards the straw, commonly discharging it on the stack, as seen in Fig. 2570, page 1126. See also STRAW-CARRIER.

The machine (Fig. 6393) has a thrashing-cylinder *b*, a grating *p*, a slatted straw-carrier *w d*, which has cogs *s s* beneath it to shake it as it passes over the rollers *r r*. The straw-carrier is driven by a pinion *f* from the side gearing, and the carrier is

Fig. 6393.



Thrashing-Machine with Endless Straw-Carrier.

tightened by the shiftable roller *g*. Grain is lifted from the well by the conveyor *i j* and discharged on to the screen *k*, where the blast from the fan *t* meets it and blows the chaff over the end of the shoe, the grain falling into the concave *b*, whence it is removed by the screw conveyor *x*, which is axled on *c*. Heavy tailings fall inside the board *u*, and are caught in the tray *l*, discharged into the box *o*, raised by the conveyor *n*, and discharged by the spout *x y* into the cylinder case. *a a* are the stanchions of the machine.

In Fig. 6394, the features are similar in most respects, but differ in the shape somewhat. It also has a beating-cylinder to lighten up the straw as it comes from the thrashing-cylinder, to allow the grain to fall out. The straw-carrier consists of suspended oscillating frames with teeth; these move in two gangs, one set alternating with the other, and shoving the straw forward step by step.

The English thrashing-machines are driven by engines of from 4 to 6 horse-power. The feeding-rollers are $3\frac{1}{2}$ inches in diameter, and make 35 revolutions per minute. The straw-rakes have the same diameter, and make 30 revolutions per minute. The drum has beaters, formed by slats on the ends of radial arms, differing in that respect from the American thrashing-machines, which usually have skeleton-cylinders armed with radial teeth. The mode of feeding in the English machines also differs from ours. The sheaf, with us, after cutting the band, is spread upon the inclined feed-chute by the person who is feeding, and passed gradually into the throat of the machine, head ends first. In some of the English machines, the straw is fed in broadside on, to prevent the breaking of the straw; by this means, only a part of each beater acts upon the ears. Other machines, as above remarked, have rollers which carry the grain in the straw from the feed-board to the thrashing-cylinder.

The diameter of the English drum is $3\frac{1}{2}$ feet, and it makes 300 revolutions per minute. While it has nearly double the diameter of our thrashing-cylinder, it has only about one fourth of the number of revolutions. The space, therefore, is about the same. The American thrasher is more expeditious than the English, does its work as thoroughly, and cleans the grain as well. It is lighter, cheaper, and requires less power for a given amount of work performed.

Fig. 6396 is a longitudinal sectional view of an English form of thrashing-machine in which the opened sheaves are fed between a beater-cylinder and concave; delivered on to an elevator consisting of a number of narrow belts with spikes; thence to a second elevator, the grain and chaff meanwhile falling in a shower upon the shaking shoe beneath, where, by means of riddles and blast, they are separated. The straw is delivered at the rear of the machine to a fan and spout, which carry it away and deliver it on to a stack. The shoe delivers the grain into sacks at *a*, the tailings fall into a pile at *b*, and the chaff at *c*.

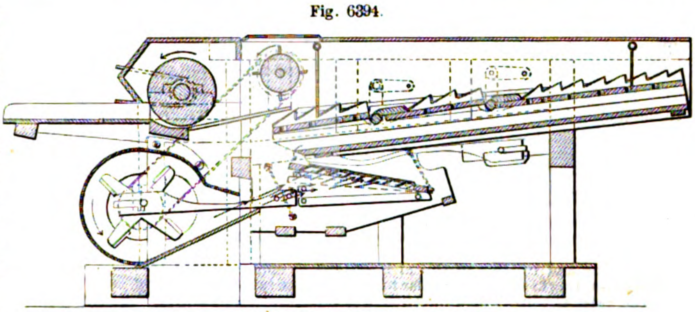
The thrashing-machine of Sir W. W. Wynne, at Wynnstay, Britain, is perhaps one of the most complete of which we have any account. An elaborate description of it, illustrated by cuts, is given in the supplement to Loudon's "Cyclopædia of Agriculture," London.

It separates the grain from the straw, and delivers each into its proper place without any other attention than feeding. The barn is on a declivity, and has three stories. The sheaves are carried into the upper one, where the thrasher is situated. On the second floor is the first winnower and chaff-house, communicating with the straw-house and cattle-yard. On the lower floor is the second winnower and the foot of the elevators, which raise the grain for distribution to the granaries, to the bruisers, which fit it for feed.

It is driven by an overshot water-wheel 18 feet in diameter, 4 feet wide.

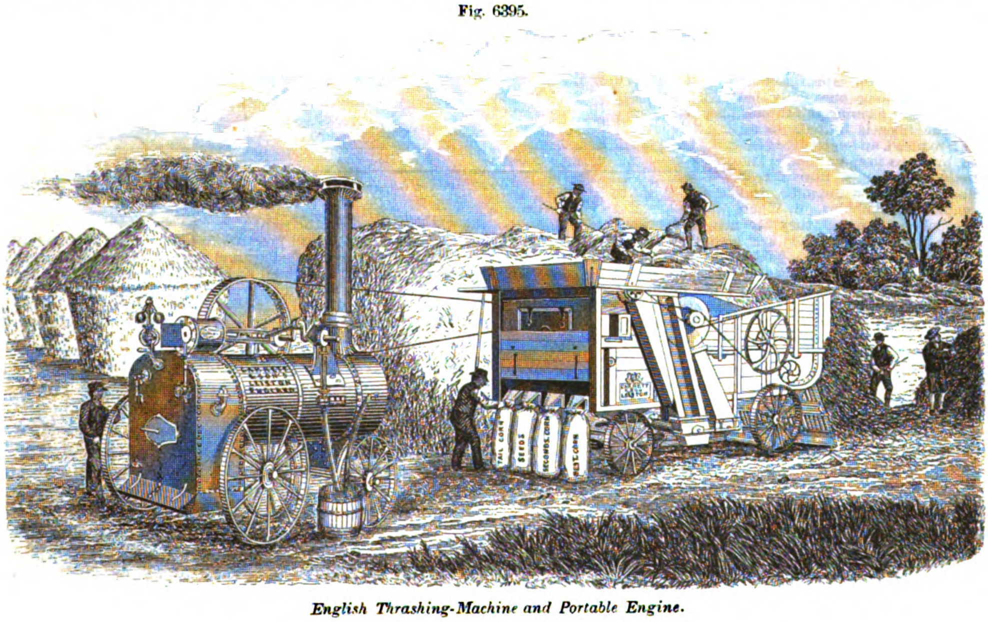
Cresy gives the quantity of wheat thrashed and cleaned by the English machines as from 12 to 24 bushels per hour. This is not over one third of the work performed by an American

Fig. 6394.



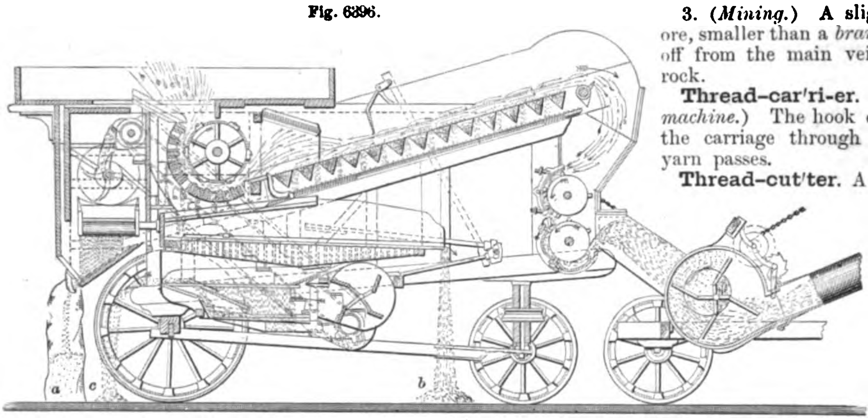
Thrashing-Machine with Oscillating Straw-Carrier.

Fig. 6395.



English Thrashing-Machine and Portable Engine.

Fig. 6396.



Ransome's English Thrashing-Machine (Vienna Exposition).

machine of good quality, on reasonably good wheat. Perhaps Cresy's figures are not up to the present mark.

Thread. 1. In the manufacturer's language, thread is a compound cord consisting of two or more single yarns, doubled and twisted.

In the trade it is divided into

Lace thread.
Stocking thread.
Sewing thread.

Lace thread consists of two yarns, Nos. 140 to 350, twisted together.

Stocking thread varies in the number of its yarns.

Sewing thread consists of three or more yarns united and intertwisted.

The doubling and twisting of thread is effected by spindles and flyers operating in a manner similar to the THROSTLE (which see). The twist is usually in a direction the reverse of that given to the individual yarns.

Thread of fine quality was imported into England from Holland and Flanders for many centuries. The thread for making the Honiton (Devonshire, England) lace was imported from Antwerp.

Long-fibered cotton, as "Sea Island," or Egyptian, is best adapted for making thread. Sewing-thread undergoes the following operations in the process of manufacture: —

1. It is passed through a picker, which separates and arranges the fibers. 2. The carding-machine straightens the fibers and coils the roving or sliver into a can. 3. The combing-machine separates the short fibers, the long ones only being used in forming the thread. 4. The fiber is united, drawn out, reduced, and partially twisted, previous to spinning. 5. The rovings are spun into a very fine thread upon the mule, and wound upon bobbins. 6. When the bobbins are full, they are transferred to the winding-machine, where the threads are wound off, two together, on to other bobbins. 7. These bobbins are taken to the twisting-machine, where the two threads are twisted tightly together and wound upon bobbins again. 8. Three of these doubled threads are wound off as before. 9. They are twisted together, forming a compound thread consisting of six strands or yarns.

The thread thus made is reeled off, tied up into hanks or bunches, and taken to the bleachery, where it passes through the processes of boiling, bleaching, washing, soaping, bluing, and drying; or to the dye-house, where it is thoroughly boiled and prepared, and colored by various dyes. After bleaching or dyeing, the hanks are again returned to the mill and wound upon large bobbins, from whence the thread is wound on the small spools for market.

The spooling-machines automatically wind the thread on the spool, cut the nick, insert and fasten the end of the thread, cut it off, draw the spool off the spindle, drop it into a hopper, replace it by another spool, and continue the winding. Each machine winds eight spools at a time, at the rate of 300 dozen per day.

The thread and gauze manufacture was begun at Paisley, in Scotland, 1759.

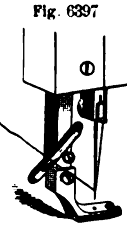
2. The spiral projecting rib on the shaft of a screw.

3. (*Mining.*) A slight vein of ore, smaller than a *branch*, passing off from the main vein into the rock.

Thread-car'ri-er. (*Knitting-machine.*) The hook or eyelet on the carriage through which the yarn passes.

Thread-cut'ter. A small blade attached to a thimble, to a thread-stand, or to a sewing-machine, to cut off a sewing-thread; a substitute for breaking it, or for a pair of scissors. See list, page 2112, SEWING-MACHINE, Class F, section 26.

Fig. 6397



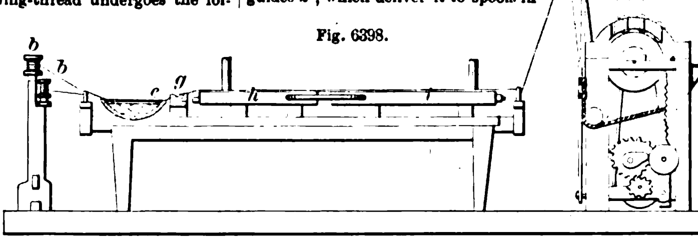
Thread-Cutter.

Thread'er. A device for guiding the thread into the eye of a needle. See NEEDLE-THREADER, Figs. 3312, 3314, page 1520; also list under SEWING-MACHINE, Class F, section 8, page 2111.

Thread-fin'ish-er. A machine in which thread is treated to give it a smooth and polished surface. It usually consists of a sizing and drying operation, which smooths down the fluff of the fiber and imparts a hard, glossy surface.

In the example (Fig. 6398), the thread is shown as going from left to right; from the bobbins *b b* to the size-bath *e*, the wipers *g*, steam-chests *h i*, to the guides *k'*, which deliver it to spools in the winding-frame on the right.

Fig. 6398.



Thread-Finishing Machine.

In Fig. 6399, the thread proceeds from the spools on stand *W* by a guide *j*, thence is coiled around the rollers *d d*, which are in a frame having a horizontal reciprocating motion to rub the threads, in order to harden and round and at the same time rub the fluff from the thread. It then passes by a reciprocating guide-bar *p* to the receiving-spool *N*. See also THREAD-FRAME; THREAD-POLISHER.

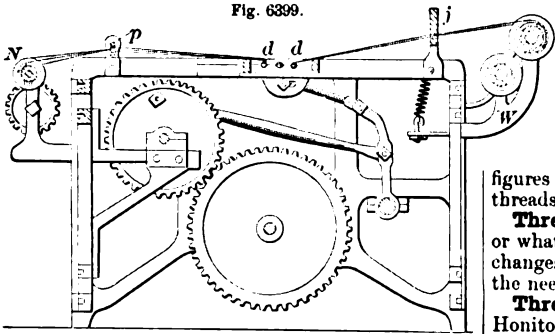
Thread-frame. The doubling and twisting mill by which two or more yarns are combined to form a thread. The yarns as they are unwound from the bobbins or cops are passed beneath the surface of a solution of gum or starch in a trough *a* (Fig. 6400); the wetting enables them to be condensed into a more solid thread; they then pass between rollers *b*, by which they are laid parallel, or nearly so, and are thence conducted to the flyer *c*, by which they are twisted together, and to the bobbin, on which they are wound.

Fig. 6401 shows a machine similar to the throstle, by which

doubling and twisting cotton or linen yarn to form thread is performed.

The view is a transverse section of the machine. *a* is the cast-iron frame; *b*, the *creel* on which the bobbins *c c* are loosely

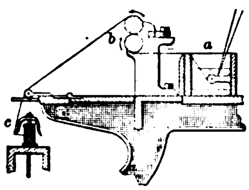
Fig. 6399.



Thread-Finishing Machine.

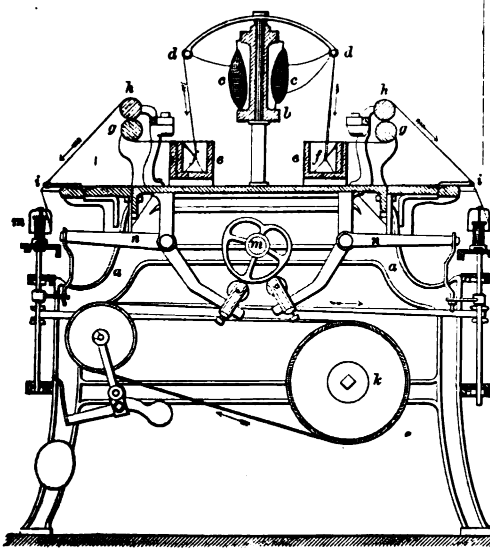
supported along the whole line of the machine, their lower ends turning in oiled steps, and their upper ends in wire eyes. *d d* are glass rods over which the yarn winds as it is unrolled; *e e*, oblong narrow troughs, lined with lead and filled with water, through which the thread passes to moisten it, being drawn through eyes at the bottoms of the forks *f f*, which may be lifted out of the trough. *g g* are smooth rollers of iron, and *h h* rollers of boxwood, between which the thread is pressed. The thread passes from the bobbins *c c* over the rods *d d*, thence downward beneath the forks *f f*, under the rollers *g g*, and upward between them and the rollers *h h*, thence downwardly through eyes *i i* to the bobbins *m m*, by which it is twisted and on which it is wound. The rollers *g* are turned by gearing, and turn the rollers *h* by friction. The spindles are driven from the drum *k* by a band passing over the pulley *l*, weighted to keep the pulleys tense. The bobbins are traversed vertically to wind the thread evenly upon them by a gear on the end of one of the lower roller-shafts, which turns a carrier-wheel engaging a wheel on the shaft carrying the heart-cam *m*; this operates the levers *n n*, raising and lowering the bobbins. See also THREAD-POLISHER.

Fig. 6400.



Thread-Frame.

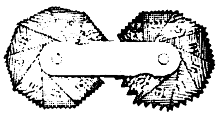
Fig. 6401.



Thread-Frame.

Thread-gage. A gage for determining the number of threads to the inch on screws and taps. It consists of a number of toothed plates turning on a common pivot, so that the serrated edge of each may be applied to the screw until one is found which corresponds therewith. The figures stamped on the plate indicate the number of threads to the inch.

Fig. 6402.



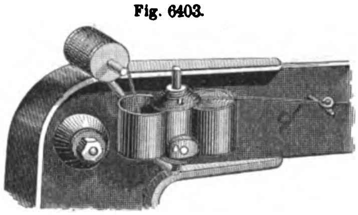
Thread-Gage.

Thread-guide. (*Sewing-machine.*) A loop, eye, or what not, to form a guide for the thread when it changes its direction at points between the spool and the needle eye.

Thread-lace. Lace of linen thread; such as Honiton, and many other kinds.

Thread-oil'er. To lubricate the thread and facilitate its passage through the goods or leather. It

Fig. 6403.



Thread-Oiler.

is placed upon the spool-wire of the machine, and secured by tightening the set-screw *c* in the oiler, which has a wire attached to support the screw, as shown in the cut. The button *a* has a notch at its lower end, by which the thread is conducted through the cup.

Thread-pol'ish-ing Ma-chine'. A machine for imparting the final gloss to thread preparatory to spooling. This is usually effected by passing it between rubbers or rollers.

In Fig. 6404, the thread is conducted from the bobbins *f* over pins *g*, and thence through size-bowls *a* and eyes to the rubber carriages *a' a' a' a'*; these have each a series of projecting pins, between which the thread passes, and are connected with blocks *u' z* caused to reciprocate in vertical guides *w* by cranks on the shaft *b* of the roller which rotates the bobbins. The upper and lower carriages simultaneously move in opposite directions toward and from the center *c'*, and each pair may be disconnected without interference with others in case of breakage of the thread, which is wound upon the reels *l l*.

In the machine (Fig. 6405), the thread, after passing between a pair of sizing-rollers *G H*, is conducted through a guide *d* to a pair of rotary disks connected by a series of parallel bars *F*, which exert a rubbing action; thence through a second guide *e* to another pair of rotary disks connected by similar rubbing-bars, and finally, after passing through a pair of pressing-rollers *I I*, is wound upon reels. *J* is a brush for removing size from the bars *F*. Rollers or rotary brushes may be substituted for these bars. See also THREAD-FRAME.

Thread-wax'er. A bowl of heated shoemaker's wax, through which the thread is conducted in sewing-machines for boots, shoes, and leather.

In the example (Fig. 6406), the thread enters the side of the semicircular trough through the tension-aperture under the depressor, thence passes over the shaft and between the two elastic expressor-disks. The trough is heated by a lamp beneath.

See list under SEWING-MACHINE, Class C, section 2, pages 2108, 2109.

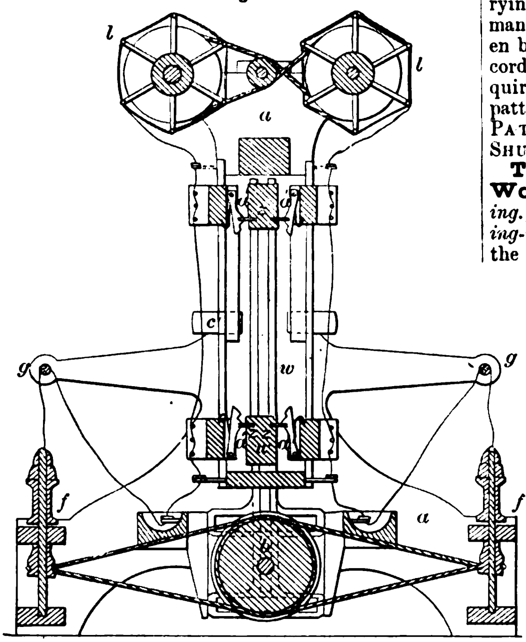
Thread-wind'er. A machine for spooling thread, etc.

In that shown (Fig. 6407), a friction-wheel *C* imparts motion to a small wheel on the axis carrying the spool. The

thread-guide *F L* has an adjustable pivot, by which it is adapted to different sizes of spools and thread, and is traversed, to lay the thread evenly on the spool, by a cam-wheel *R* rotated by a screw-thread on the shaft *B*.

Fig. 6408 is a machine for laying the exterior layers of button-hole twist, etc., on the spool, so as to form various patterns. The spool is placed on a spindle upon the pulley *M*, and part of

Fig. 6404.

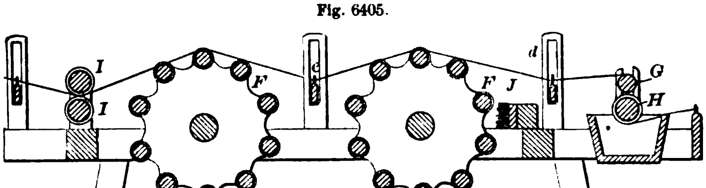


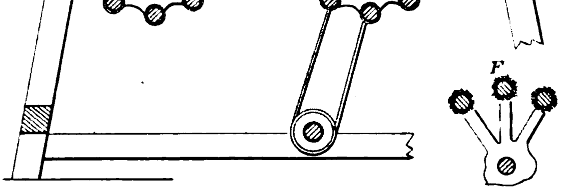
Thread-Polishing Machine.

the thread unwound and passed through the eye of the flyer *F* and the axis of the flyer and its pulley. It is then rewound upon the spool, the pattern formed upon the surface depending upon the angular adjustment of the arm carrying the pulley *M* and the velocity given to the pulley and flyer.

Fig. 6409 is a machine for winding thread for making fancy cassimeres. As the central thread or cord is spun or twisted and wound, the lapping thread of any other color is guided to it by slots in a tube through which the cord is conducted; a sectional pinion on the driving-shaft causes the delivery of the cord to be intermitted as desired, or the cord may be drawn

Fig. 6405.





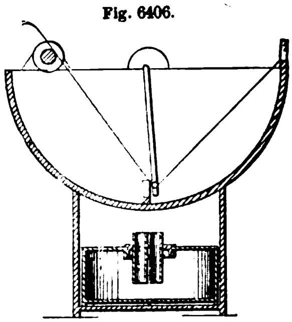
Machine for Polishing and Dressing Thread.

back a short distance from time to time, or the thread-guide may be reciprocated.

Thread-wind'ing Guide. A handle containing a holder for a spool, and having suitable tension-devices, and at one end an eye through which the thread is guided upon a bobbin.

Three-box Loom. (*Weaving.*) One having three shuttle-boxes, from which shuttles carrying yarns of as many colors are driven by the *picker*, according to the requirements of the pattern. See LOOM; PATTERN-CHAIN; SHUTTLE-BOX; etc.

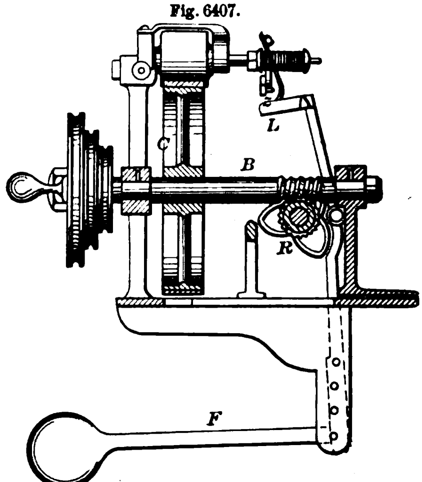
Fig. 6406.



Thread-Waxer for Sewing-Machines.

Three-coat Work. (*Plastering.*) The first is called *pricking-up* on lath; *roughing-in* on brick. The second coat is called *floating;* the third, *set* or *finishing-coat.*

Fig. 6407.



Thread-Winding Machine.

Three-cyl'in-der En'gine. An arrangement of three cylinders working on a common crank-shaft, to overcome the dead-center without a fly-wheel. The eccentrics and valves are so set that steam is admitted to the cylinders in succession, and not simultaneously, by which means the pistons are always in different thirds of their stroke, and two cylinders are always acting effectively.

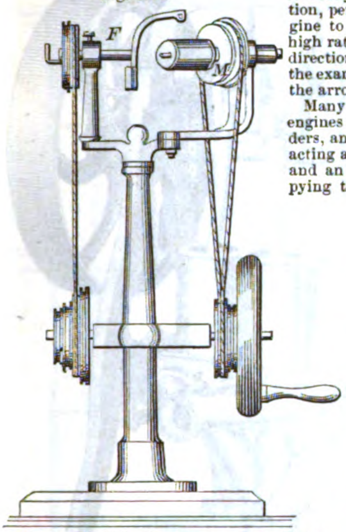
In the drawing (Fig. 6412), the piston in the upper cylinder is at the outboard end, the one at the left at one third of the inboard stroke, and the one on the right at two thirds of the outboard end and exhausting.

Brotherhood's engine (Fig. 6413) has three connected cylinders *a b c* at angles of 120° to each other. Each has a deep but light piston connected to a crank *d*, common to all. One of the connecting-rods has a single eye at the crank end, while the other two are forked at that end, one straddling the other, so that their centers are in the same line. Steam is admitted into the central space *g* through the induction-opening *e*, and exhausted through the opening *f* in line with the crank-shaft. The supply and exhaust are effected by a revolving slide-valve carried around by the crank-shaft. The steam-pressure in the central chamber always exceeds that on the outer end of each

piston, but varies in amount, so that the strain on the connecting-rods and joints is always in one direction, permitting the engine to be run at very high rates of speed. The direction of motion in the example is shown by the arrow.

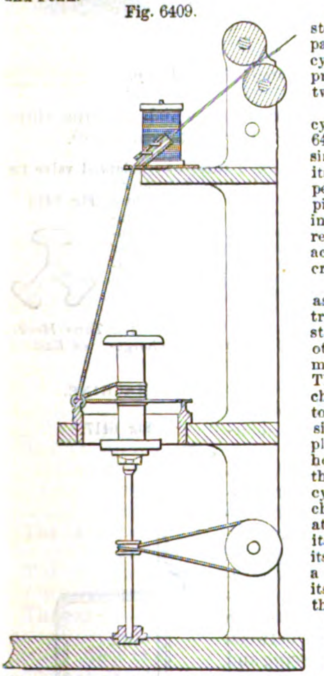
Many marine and river engines have three cylinders, and some have two acting at angles of 120°, and an air-pump occupying the position of a third steam-cylinder. A favorite arrangement with Maudslay and Penn.

Fig. 6408.



Machine for Winding Button-Hole Twist.

Fig. 6409.



Machine for Producing Variegated Thread.

The Baxter canal steam-engine has a pair of high-pressure cylinders and a lower-pressure cylinder between the other two.

In Willans's three-cylinder engine (Fig. 6414), each cylinder is single-acting, receiving its steam upon the upper side only of the piston. The connecting-rods attached directly to the pistons actuate a three-throw crank-shaft.

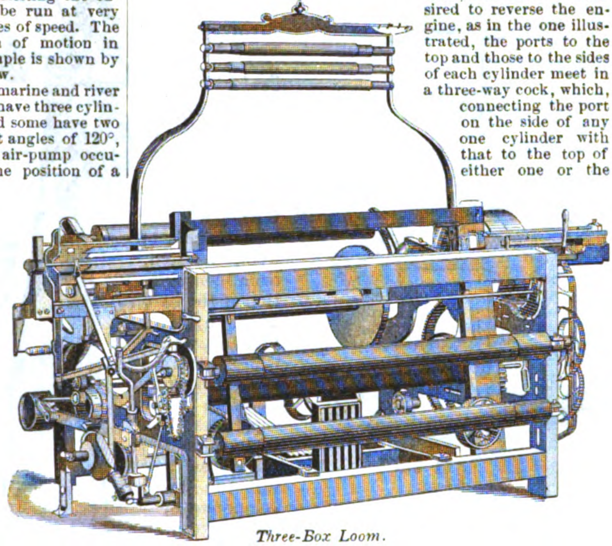
Each piston serves as a steam-valve controlling the supply of steam to one or the other of the two remaining cylinders There is a steam-chamber in each piston and a port in its side. Steam is supplied by means of a hollow rod passing through the top of the cylinder into a steam-chest. When the piston attains three fourths of its downward stroke, its steam-port overlaps a port in the side of its cylinder, and steam then passes to the top of another of the cylinders. When the piston has reached about one half its return stroke, uncovering the port in the side of its cylinder, it allows the steam to escape from the cylinder into which it was previously admitted, into a casing round the crank-shaft, from which the exhaust-steam is taken either to a condenser or to the air, as the case may be.

Fig. 6410.

Thread-Winding Guide.

In an engine which is required to run only one way round, the port in the side of each cylinder passes direct to the top of one of the other cylinders; but where it is desired to reverse the engine, as in the one illustrated, the ports to the top and those to the sides of each cylinder meet in a three-way cock, which, connecting the port on the side of any one cylinder with that to the top of either one or the other of the other cylinders, reverses the engine.

Fig. 6411.



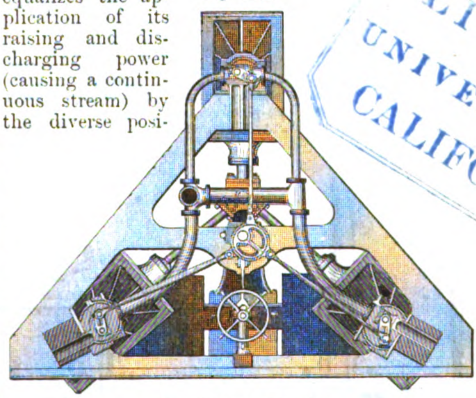
Three-Box Loom.

The equilibrium of the power is maintained by its threefold action.

The lubrication is done through a steam-lubricator on the steam-chest, and the waste oil passing down to the bottom of the casing lubricates the lower ends of the connecting-rods as they pass round.

Three-cyl'in-der Pump. Haskell's three-cylinder pump, having one inlet and outlet common to all the cylinders, equalizes the application of its raising and discharging power (causing a continuous stream) by the diverse position of the three-throw crank to which the pistons are attached.

Fig. 6412.



Three-Cylinder Engine.

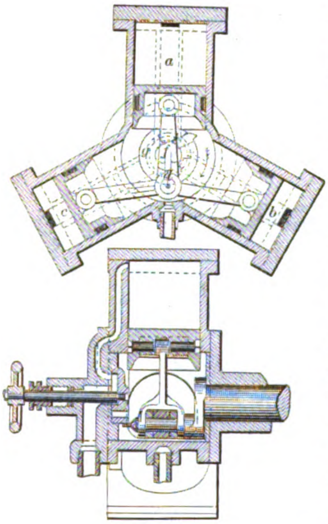
Three-deck'er. (*Nautical.*) A ship with three gun-decks.

Three-head'ed Rail. One having three treads united by webs, set at an angle of 120° with each other.

Three-high Roll. (*Metal-working.*) A rolling-apparatus in which three rollers are arranged in a vertical series, so that the metal may be passed through between the middle and lower roll, and then back between the middle and upper one; rolling it at each passage without changing the direction of motion of the rolls. See Fig. 4416, page 1969.

Three-part Flask. (*Founding.*) One containing a mold which comes off the pattern in three pieces. See *c d e*, Fig. 2010, page 877.

Fig. 6413.



Brotherhood's Three-Cylinder Engine.

Three-pile. (*Fabric.*) A costly thick pile velvet.

Three-ply Car′pet. A carpet made of wool, worsted, or a combination of the two, and having three webs whose warps are interchangeable, so as to allow such ones to be brought to the surface as may suit the development of the pattern. Also known as *triple-ingrain carpet*. See TWO-PLY CARPET.

Three-square File. The ordinary, tapering, hand-saw file of triangular cross section. *r*, Fig. 1965, page 840.

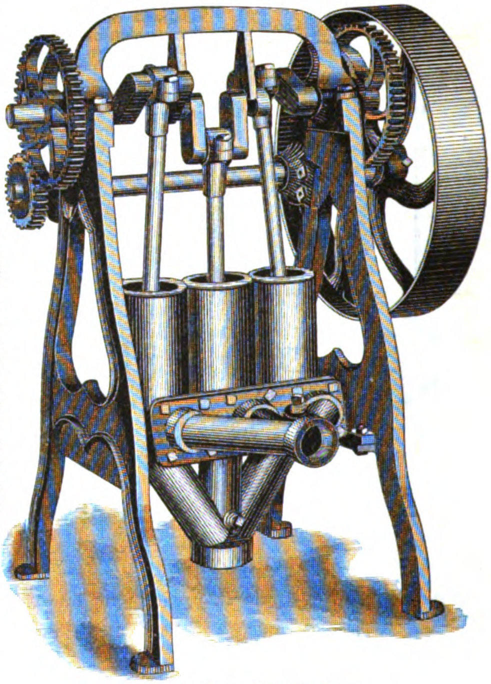
Three-stone Mill. A mill with one middle runner having two faces, which act against two lateral stones. See Fig. 2316, page 1021.

Three-way Cock. One having three positions, directing the fluid in either of three different channels.

In the illustration (Fig. 6417), the plug has a single transverse channel; when the direction of this is vertical, the flow is direct through the delivery-pipe, but when oblique or horizontal, the flow is into an auxiliary tube, which curves upward and then enters the delivery-pipe.

The *four-way cock* is an invention of James Watt. See Fig. 2091, page 912.

Fig. 6415.



Haskell's Three-Cylinder Pump.

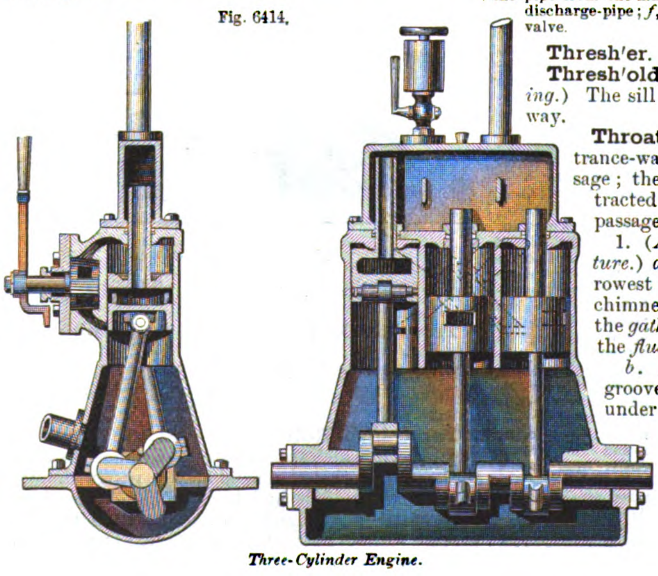
Three-way Valve. One which governs three openings, as a THREE-WAY COCK (which see).

Fig. 6418 is a view of Locke's three-way balanced valve for hydraulic elevators. 1 shows it supplying water; 2, closed; 3, slowly discharging: corresponding to, 1, lifting the cage; 2, holding the cage stationary; 3, allowing the cage to descend gradually. The indented positions at the lower end of the valve and of the tubular downward prolongation into the square chamber are for the purpose of making the openings and closings gradually, so as to make the first flow of water gradual. *a* is the pipe from the main; *c*, pipe to the hoist; *l*, discharge-pipe; *f*, supply-valve; *s*, discharge-valve.

Fig. 6416.

Three-Headed Rail.

Fig. 6414.



Three-Cylinder Engine.

Thresh′er. See THRASHING-MACHINE.

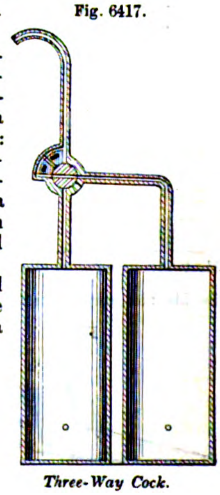
Thresh′old. (*Building.*) The sill of a doorway.

Throat. An entrance-way or passage; the more contracted part of a passage-way, as:

1. (*Architecture.*) *a.* The narrowest part of a chimney, between the *gathering* and the *flue*.

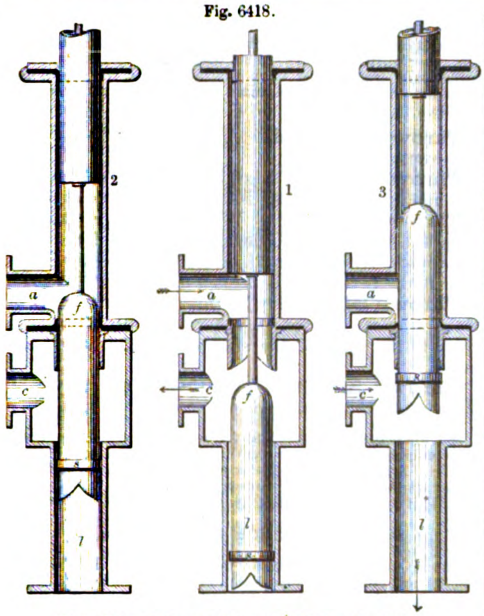
b. A small groove on the under side of a

Fig. 6417.



Three-Way Cock.

Fig. 6418.



Three-Way Balanced Valve for Hydraulic Hoists.

coping or projecting molding. A *gorge.* See GUTTER.

2. (*Shipwrighting.*) The interior angle at the bend of the arms of a knee or compass timber.

3. (*Nautical.*) *a.* The crotch of a gaff where it rests against the mast.

b. The upper front corner of a fore-and-aft sail. The *nock.*

c. The interior angle at the junction of the arm and shank of an anchor.

4. (*Agricultural.*) The entrance-way where grain in the straw passes from the feed-board to the cylinder of a thrashing-machine.

5. (*Wheelwrighting.*) That portion of a spoke just beyond the swell at the junction of the hub, where the spoke is thinner toward its outer side.

6. (*Puddling.*) The narrowed entrance to the neck of the furnace, where the area of flue passage is regulated.

7. The opening in a plane stock through which the shavings pass upward.

8. (*Fortification.*) The narrowed space between the flanks of a bastion at their junction with the curtain, or between the rear ends of the faces of a *redan.* A gorge. See REDAN; BASTION.

Throat-brails. (*Nautical.*) Brails which lead through blocks beneath the jaws of a gaff.

Throat-down'hauls. (*Nautical.*) Ropes for rousing down the throat of a gaff.

Throat-hal'yards. (*Nautical.*) A tackle for lifting the gaff at the throat. The *peak* halyards lifts the other end.

Throat-latch. (*Saddlery.*) The strap which passes under a horse's throat and assists in holding the bridle in place. *Throat-band.*

Throat-strap. (*Saddlery.*) The upper strap of a halter that encircles the horse's throat; also called *jaw* strap.

Throe. A tool for splitting balks of timber into shingles or clapboards. A *frow.*

Thros'tle. 1. (*Cotton.*) The *drawing-frame* of the cotton manufacture. The great invention which succeeded the *spinning-jenny* of Hargreaves. The *drawing-frame* is for attenuating *slivers* of fiber by passing them through consecutive pairs of rollers, each pair in the succession revolving at a higher speed than its predecessor. Leon Paul, by patent of 1738, claimed a mode of spinning by rollers, but the device did not come into use. (See SPINNING.) Richard Arkwright perfected the invention and patented it in 1769.

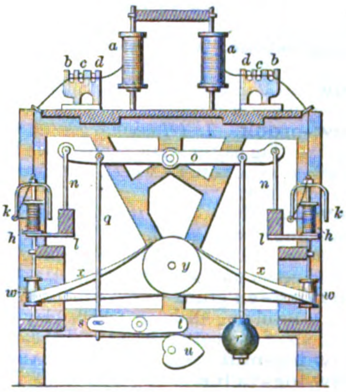
Arkwright's original spinning-frame was fed with rovings which passed between three pairs of rollers of successively increasing speed. The yarns were wound upon bobbins by means of flyers. It was the culmination of several attempts, and possesses the main features of the *throstle* and the *bobbin* and *fly-frame* in function, as well as in the relative positions of parts. See SPINNING, Fig. 5404, page 2271.

The *bobbin* and *fly-frame* is similar in principle to the throstle, and is adapted for giving a partial twist to the sliver as delivered from the carding-machine or the doubling-frame. The slivers in cans are fed to the *coarse* bobbin and fly-frame, where they are reduced and partially twisted so as to give them greater coherence, being elongated say 4½ times. The rovings thus produced are wound on bobbins which are placed on the *creel* of the *fine bobbin* and *fly-frame*, by which they are still farther reduced and twisted.

These rovings on their bobbins are then transferred to the throstle, a transverse vertical section of which is shown in Fig. 6419.

a a are two of the bobbins. The thread, as it is drawn off from these, passes through the drawing-rollers *b c d*, and then to the spindles. Here it is twisted and wound upon the bobbins. The bobbins *h* have no rotatory motion imparted to them,

Fig. 6419.



Throstle.

but simply rest upon the trays *l*, and are dragged round by the thread as it twists itself round them, as the fork or fly *k* revolves much more rapidly than the thread is given out from the drawing-rollers. The up-and-down motion of the bobbins is effected in the following manner: —

The lever *o* turns at its center on a spindle fixed to the framework. At its ends it is connected by the rods *n n* to the trays *l l*, upon which the bobbins rest, and receives an oscillating motion from the heart-shaped cam *u* through the lever *s t* and rod *q*. The cam depresses the one side of the lever, which is pulled down on the other side by the weight *r* as the cam recedes. By this means the trays, and therefore also the bobbins, are moved up and down. The spindles receive their motion from the drum *y* and the belts *x x* passing round the small pulleys *w w*. The speed of the rollers and spindles is proportioned to the required fineness of the yarn. For example, the drum *y* making 600 revolutions per minute, the spindles, whose pulleys are $^1/_6$ of the diameter of the drum, make 3,600 revolutions. There are usually from 75 to 150 spindles on each side of the throstle, and they are set about 3 inches apart, all being driven from the drum *y*, which extends the whole length of the machine.

The specific difference between the action of the *throstle* and the *mule* is that the former has a continuous action, *drawing*, *twisting*, and *winding*; while the *mule* has an alternate action, *drawing* and *twisting*, and then *winding*.

It is thus stated by Tomlinson: —

"The *mule* having made a definite length of yarn, the operation of spinning is suspended while the yarn is being wound up

on bobbins or spindles. In the throstle the yarn is both spun and wound at the same time. The throstle-yarn is smooth and wiry, while the mule-yarn is soft and downy. *Throstle-yarn* is employed for warps of heavy goods, and for making sewing-thread; *mule*-yarn is used for the weft of heavy goods, and for the warp and weft of soft and fine goods." See BOBBIN and FLY-FRAME; DRAWING-FRAME; ROVING; MULE; DOUBLING; JENNY.

The throstle derived its name from the singing or humming which it occasioned. It was also called the *water-frame* from the fact that the machinery in Arkwright's mill, where it was first used, was driven by a water-wheel.

2. A spindle for wool.

Throt'tle. (*Steam.*) A name for the THROTTLE-VALVE (which see).

Throt'tle-le'ver. The handle of the throttle-valve.

Throt'tle-valve. (*Steam-engine.*) A valve which regulates the supply of steam to the cylinder. In the Watt engine it is a disk turning on an axis and occupying in its transverse position the bore of the main steam-pipe.

It is frequently an ordinary conical valve with a stem operated by a screw.

In land engines it is generally connected with the governor.

Through-bolt. (*Machinery.*) A bolt passing entirely through and fastened on opposite sides of the object or objects secured by it, as in 1, 3, 4, 5, Fig. 768.

Through-bridge. One in which the track rests on the lower stringer (Fig. 2702, page 1201) in contradistinction to a *deck*-bridge (*a*, Fig. 3775, page 172), in which the track occupies the upper stringer, the top of the truss.

Through-stone. A bond-stone, extending across the thickness of the wall. A *perbend.*

Throw. (*Machinery.*) The radial reach of a crank, eccentric, or cam.

Throw-crook. 1. (*Husbandry.*) A tool like a brace for twisting hay or straw bands. See Fig. 2448.

2. (*Pottery.*) A potter's wheel. A *thrower.* See THROWING-TABLE.

Throw'ing. 1. A third process in the spinning and combining of silk thread. See THROWN SINGLES.

2. (*Pottery.*) The operation of forming a mass of clay into a vessel on the potter's wheel.

Throw'ing-en'gine. (*Pottery.*) A potter's wheel. A revolving disk on which clay is formed by the hands of the potter, into the shape of a vessel.

Throw'ing-mill. See THROWING-TABLE.

Throw'ing-ta'ble. A revolving, horizontal table on which earthen vessels are shaped by the potter.

Clay ware is *thrown*, *pressed*, or *cast*. In some cases, after being partially dried, it is *turned* to give it smoothness.

The throwing-table consists of a horizontally rotating disk, turned by the foot, an assistant, or by machinery.

Fig. 6420.

Throwing-Table.

A lump of clay prepared by an assistant, called a *baller*, is handed to the *thrower*, who dashes it upon the center of the wheel, and then, with wet hands, commences to work the mass. Pressing it upward, he raises it into a cone, and then flattens it so as to express bubbles. Then, with skillful motions of the hand inside and out, aided by a piece of horn, bone, or porcelain, and called a *rib*, he gives it the shape shown in the figure. The outer surface is worked by a *templet*, and gages projecting horizontally from a post upon the table assist the eye of the workman in giving the required hight to the shoulder and the lip.

Throw'ing-wheel. A potter's wheel. See THROWING-TABLE.

Throw-lathe. A small lathe which is driven by one hand, while the tool is managed by the other.

Thrown. (*Mining.*) When a lode is intersected by a slide, if the undiscovered portion of the lode has apparently been lengthened, it is said to be *thrown up*: if the reverse, it is *thrown down.*

Thrown Silk. A silk thread made of two or more *singles*, twisted together in a direction contrary to the twist of the *singles* of which it is composed.

Thrown Sin'gles. Silk thread, the result of three separate spinning operations.

Silk filaments are twisted to form *singles*. Several of these are combined and twisted together (doubling), forming *dumb singles*. A number of the latter are associated and twisted together (*throwing*), forming *thrown singles.*

This, if single-twisted, is *tram*; if double-twisted, is *organzine*.

If the gum be left in it, it is *hard silk*; if the gum be removed, *soft silk.*

The operation is as follows: the filaments of silk from the bobbin are twisted in one direction, and the *single* thus obtained is wound on a second bobbin. A number of bobbins containing singles are placed in a frame, and their ends, being united, the combined bunch of singles is wound on a bobbin, and from thence on to a reel. From this the bunch of singles is conducted to a rotating flyer, which twists it and delivers it as *thrown* silk on to a bobbin. See DOUBLING.

Thrum. 1. (*Nautical.*) *a.* Coarse untwisted rope, used for mops and for mat-making.

b. A wad of such yarns or a sail passed overboard and hauled into the vicinity of a leak, so as to be drawn thereinto.

c. To insert tufts of hemp or coir in the meshes in making a rope-mat.

2. (*Weaving.*) The ends of the warp or weft threads.

Thrust. 1. (*Mining Engineering.*) The breaking downward of the roof of a gallery, owing to the weight of the superincumbent strata. Opposed to *creep*, which is an upheaval of the gallery floor.

2. (*Husbandry.*) The white whey which last leaves the curd in pressing.

Thrust'ing-screw. The screw of a screw-press; of a cheese-press, for instance.

Thumb-cleat. (*Nautical.*) A small cleat forming a leader to carry the bight of a rope.

Fig. 6421.

Thumb-Nut.

Thumb-nut. One having wings by which it is turned by the thumb and finger to tighten upon its bolt.

Thumb-screw. 1. A screw with a flat-sided head, adapted to be turned by the finger and thumb.

2. An old instrument of torture to break the thumb-joint. A *thumb-kin.*

Thumb-stall. 1. (*Ordnance.*) A stall of buckskin stuffed with hair, which a cannoneer wears on his thumb to cover the vent while the piece is being sponged and loaded.

2. A sailor's thimble used in sail-making.

Thun'der-rod. An old-time name for the lightning-rod, designed to make their houses

"Secure of thunder's crack." — TITUS ANDRONICUS.

Thurl. (*Mining.*) *a.* A short communication between *adits.*

b. A long adit in a coal-pit.

c. To make a breach into former workings or gate-roads.

Thurst. (*Mining.*) The ruins of the incumbent strata after the *pillars* and *stalls* are wrought out.

Thwack'ing-frame. (*Tile-making.*) A table with a curved top, upon which a half-dried pantile is bent to form. The tool by which the upper side is beaten has the shape of the segment of a cylinder, and is called the *thwacker.*

Thwart. (*Nautical.*) One of the transverse planks which keep the sides of a boat asunder, like the beams of a ship, and serve as seats for the rowers. They are spaced about 2 feet 10 inches apart, from center to center, in single-banked boats, and 3 feet in double-banked boats.

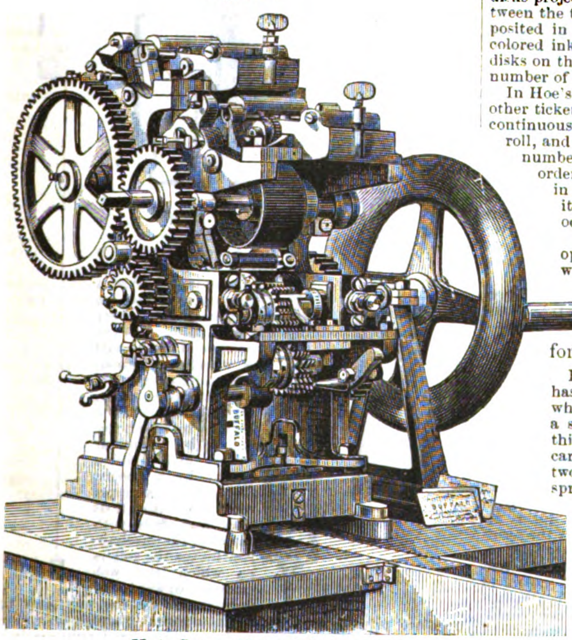
Tib'i-a. (*Music.*) Formerly, a flute; as made of the leg bone of an animal.

Tick. (*Fabric.*) A woven fabric for holding the filling of mattresses and beds. *Ticking; ticken.*

Tick'et. A piece of card, bone, ivory, metal, or what not, printed, impressed, or plain, the equivalent of a sum of money paid for a ride, admission to a concert or other entertainment, etc. One meaning of the Latin *tesseræ.*

Pericles founded the practice of paying for places at theaters; and at Pompeii have been found bone tickets of admission, one side representing the theater, and the reverse having words and figures, some with the place in the theater to which they gave admission engraved upon them. See farther in Fosbroke's "Ency. Antiq.," I. 386, 387.

Fig. 6422.



Hoe's Rotary Ticket-Printing Machine.

Tick'et-hold'er. 1. A device to hold a railway ticket in the hat or to the lappel of the coat; or a tag to a bale or package. See TAG.

2. A contrivance to attach a card or check to a trunk or parcel. See BAGGAGE-CHECK, Fig. 524, page 210.

Tick'et Print'ing and Num'ber-ing Ma-chine'. A machine for printing and consecutively numbering tickets. The first machine of this kind was invented by Edmondson, in England, about 1840, and was designed to remedy the troublesome practice then in use on railways of stamping and tearing each ticket from a book previous to its delivery to the purchaser. This machine imprinted the date and consecutively numbered the tickets, but was imperfect in its inking arrangements, frequently rendering the tickets illegible.

Church and Goddard's machine, introduced subsequently, printed, numbered, cut, counted, and packed the tickets. Pasteboard, cut into strips, is placed in a feed-trough and brought under the prongs of a fork working with an intermittent movement, and passes successively between four pairs of horizontal carrying-rollers, by which it is intermittingly moved forward over a bed carrying the type and the numbering-rollers. At each stop, during the forward progress of the strip, the bed is caused to rise by means of a cam-movement, and print first the denomination of the ticket, and secondly the number; as it falls after each upward movement a self-acting apparatus inks the type. The completed ticket is then severed between a fixed knife and a reciprocating knife attached to the bed, and is delivered into a box provided with a piston by which the tickets are packed.

A counting-apparatus connected with the working parts of the machine is caused to ring a bell when a certain number of tickets (say 100) is completed. The numbering disks are operated in a manner analogous to those employed for paging books.

In another machine the types and numbering-disks are fixed in a metallic frame, which also carries the numbering-disks. The frame is mounted on a rock-shaft, and is rocked by means of a handle to bring the types down on the card and produce an impression; as it is raised again, the unit disk is advanced one figure, and the types are inked by a roller receiving its supply from an inking-table which forms the top of the frame.

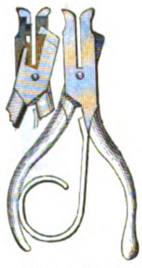
Baranowski's machine (French) has a horizontal shaft, having near each end a disk, carrying a metallic frame of similar curvature to the disk, and on which the type and numbering-disks are arranged radially to the shaft. The type-frame has a slot or opening through which the peripheries of three numbering-disks project. The tickets are automatically fed one by one between the type-frame and a press-roller of india-rubber and deposited in a box. The arrangements are such that different colored inks may be used upon the same ticket. Registering-disks on the same shaft with the numbering-disks indicate the number of tickets printed.

In Hoe's machine for printing and numbering railway and other tickets, the forms are placed on a cylinder which has a continuous rotary movement. The tickets are worked from a roll, and are printed at the rate of 10,000 to 12,000 an hour, numbered, cut, and deposited in a receptacle in regular order, at a single operation. The number may be printed in a different color from the body of the ticket, and it can be changed with great facility. The machine occupies a space of about two feet square.

The Rand and Avery machine is very rapid. It is operated with closed doors, and though shown to the writer, it may not be their wish to have a description published.

Tick'et-punch. A punch used by railway and street car conductors for perforating tickets.

Fig. 6423.



Ticket-Punch.

In the example, the fixed jaw has one longitudinal slot, into which the ticket is inserted, and a second slot at right angles to this, in which the movable jaw carrying the punch works. The two jaws are kept apart by a spring when not in use.

The alarm and registering ticket-punch, now used on street-cars and elsewhere, cuts off and saves a piece of a ticket or a trip slip, and gives an audible notice of the punching. The pieces and the register (if there be one) are the records of the number of passengers, and the bell-alarm calls the attention of the payer to the fact of the punching, enlisting his attention in the service of the company.

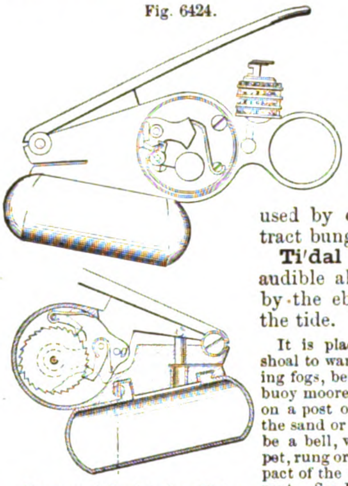
Tick'ing. (*Fabric.*) A closely woven, striped linen or cotton cloth to hold feathers, husks, or other filling for beds or mattresses. It is usually twilled.

Tick'len-burgh. (*Fabric.*) A coarse, mixed linen fabric.

Tick'ler. 1. A book or case containing memoranda.

The memorandum-book of the Middle Ages was the volume which was most read by the owner. Petrarch had a MS. Virgil, with the commentary of Servius. It contains marginal notes in his own hand, and an account of the death of Laura, on a distinct leaf of paper pasted on the wood of the binding.

Fig. 6424.



Alarm and Registering Ticket-Punch.

2. A prong used by coopers to extract bungs from casks.

Ti′dal A-larm′. An audible alarm operated by the ebb and flow of the tide.

It is placed on a spit or shoal to warn off vessels during fogs, being on a vessel or buoy moored to the spot, or on a post or pile driven into the sand or shingle. It may be a bell, whistle, or trumpet, rung or blown by the impact of the passing tidal current. See FOG-ALARM.

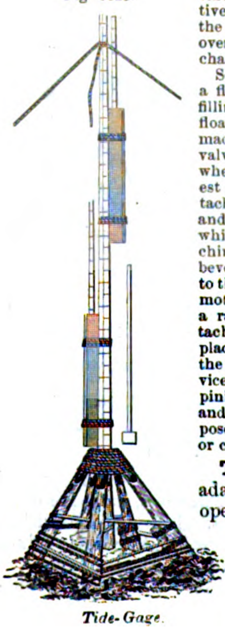
Ti′dal Ba′sin. A dock filled at high tide.

Ti′dal Mo′tor. An arrangement by which the ebb and flow of the tide is utilized as a source of power to move machinery, etc. The idea is not new, and various devices have been invented for accomplishing the object.

A common mode is to place gates at the mouths of inlets which are opened during the flood and closed at the commencement of ebb tide; the head of water thus obtained is used to turn a mill-wheel. Signor Thomassi has proposed to use the rise of the tide as a means of compressing air in a chamber or reservoir, from which the air thus compressed may be conducted to any number of stationary engines, the effective power thus obtained being proportional to the excess of its tension over that of the atmospheric pressure; this may be greater or less in proportion to the relative contents of the chamber into which the water is admitted, and that in which the air is condensed.

By an additional chamber, in which a partial vacuum is produced by the reflux of the tide, a continuous motor is produced, the effective force in this case being equal to the excess of atmospheric pressure over that of the rarefied air in the chamber. See also SLUICE.

Fig. 6425.



Tide-Gage.

Scharit's tidal motor consists of a float, with a screw and valves for filling the float with water. The float consists of a rectangular box made water-tight, and provided with valves for the admission of water when the float has reached its highest point. To the float a nut is attached, which works upon the screw and imparts thereto a rotary motion, which is communicated to the machinery to be driven by means of bevel-gears, one of which is attached to the top of the screw. A continuous motion in one direction is secured by a ratchet and pawl, which are attached to the horizontal shaft that is placed directly over the center of the screw. Modifications of this device have double racks working in pinions for communicating power, and a single rack for the same purpose; another modification has ropes or chains working on pulleys.

Ti′dal Valve. A valve adapted to sluice-ways, which opens to the pressure of the land water when the tide falls, and closes as the tide rises, to prevent the flooding of the land by sea-water. See SLUICE.

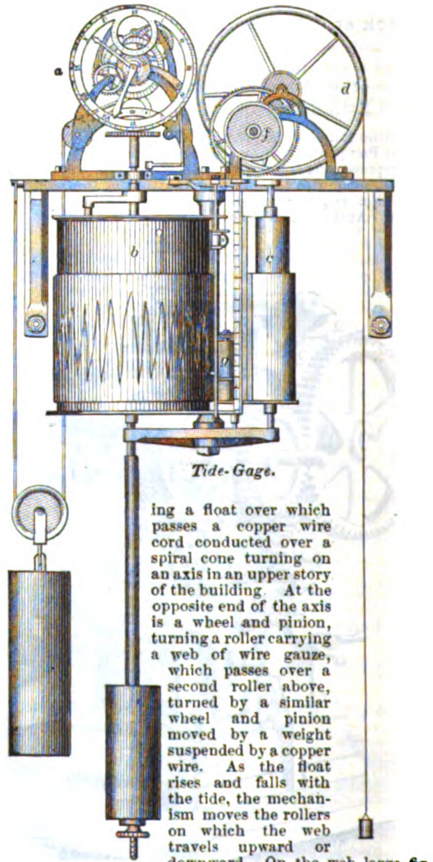
Tide-di′al. See TIDE-GAGE.

Tide-gage. Used in harbors to measure the rise and fall of the tides. A common form consists of a graduated spar, 24 feet long, and having boxes at the side, in which is a float with an elevated stem. The spar is secured to a pier or quay, or is anchored in a frame and secured by guys. The rod is $\frac{3}{4}$ inch in diameter, and is supported by a cork of 3 inches cube. The stem is guided by staples in the spar.

The tide-gage at Sunderland, England, invented by Mr. Meik, engineer of that harbor, is self-registering, and shows to mariners the depth of water on the bar at all stages of the water.

A well is sunk beneath the building containing the apparatus, its bottom being on a level with that of the entrance to the channel. This contains a pipe, open to the water, and containing a float over which passes a copper wire cord conducted over a spiral cone turning on an axis in an upper story of the building. At the opposite end of the axis is a wheel and pinion, turning a roller carrying a web of wire gauze, which passes over a second roller above, turned by a similar wheel and pinion moved by a weight suspended by a copper wire. As the float rises and falls with the tide, the mechanism moves the rollers on which the web travels upward or downward. On the web large figures are painted in a white, transparent varnish on a dark ground, and as it moves up and down, two fixed pointers indicate in feet and half-feet the depth of water on the bar at that time. The figures are visible to a considerable distance at sea, and are strongly illuminated at night.

Fig. 6426.



Tide-Gage.

The self-registering gage is also actuated by a float in a well, which, by means of a cord passing over a wheel, moves a rack carrying a pencil, which traces on a ruled web of paper passing over a drum turned by clock-work a line corresponding to the fluctuations in the hight of the water. The web of paper is of sufficient length to receive the automatic record for fourteen days.

Fig. 6426 illustrates Sir William Thomson's self-registering tide-gage. It consists of a clock a supported on a stand, and which, besides keeping time, actuates the drum b which winds upon itself with a uniform movement a continuous web of paper from the cylinder c. A cord or fine wire passing over the pulley d carries at one end a counterbalanced float-weight e which rises and falls with the tide. A pinion on the end of the shaft of the pulley d engages a gear-wheel on the shaft of the pulley f, from which is suspended a weighted ink-bottle g carrying a

pen. These rise and fall with the movement of the float *f*, though their motion is less in the proportion of the respective diameters of the wheel and pinion. The pen traces a continuous record on the paper in the form of a zigzag line, the angles of which correspond with the hights of high and low water, the horizontal distance between each two angles answering to the intervals of time between two high or low tides.

Tide-gate. The lock-gate of a tidal basin. See SLUICE.

Tide-lock. One situate between the tide-water of a harbor or river and an inclosed basin when their levels vary. It has two pairs of gates. A *guard-lock*.

Tide-me'ter. See TIDE-GAGE.

Tide-mill. A mill driven by a wheel set in motion by the tide.

Mills of this kind were used in Venice as early as 1078, and they were employed in London in 1772.

Generally the water is admitted as the tide rises, through a sluice over which the mill is placed, into a reservoir, turning the wheel in its passage through the sluice. At high tide the sluice-gates are shut until the tide has fallen sufficiently, when they are again opened, and the water again turns the wheel during its outward passage.

The mill may float on the surface of the water, rising and falling with the tide. The flood-gate in this case is arranged to have a simultaneous and equal rise and fall, so as to maintain a uniform head of water.

Dr. Gregory enumerates four different arrangements of tide-mills: —

1. The water-wheel may turn one way when the tide flows, and the other way when it ebbs.
2. The wheel may turn in a constant direction, in either course of the tide.
3. The water-wheel may rise and fall, as the tide ebbs and flows.
4. The axle of the wheel may be fixed, the wheel receiving the influx and efflux of the water, being more or less submerged according to the state of the tide. The former is the preferable arrangement. See also TIDE-WHEEL.

Tide-wheel. A wheel turned by the ebb and flow of the tide, and employed as a motor for driving machinery, etc.

The most remarkable variations in the tide are at Chepstow, where the rise of spring tides is about 60 feet; at Bristol it is 40 feet; in Mount St. Michael's Bay it is 46 feet; in the Bay of Fundy and on the coast of Nova Scotia it is about 60 feet; whilst in the Northern Atlantic it is on the average from 10 to 12 feet; at St. Helena only 3 feet; and on the shores of the islands of the Pacific it is barely perceptible.

Where the rise is so extreme, it is produced by the contraction of the sides of the river or estuary, as the Bristol Channel, for instance, or a convergence to one point of wide stretches of coast, as at the Bay of Fundy.

In some cases the phenomenon of the *bore* is produced, which is defined by Colonel Emery as being a peculiar undulation, which announces the arrival of the flood tide in many rivers. It consists of two, three, or sometimes four waves, very short, and succeeding one another rapidly, which bar the whole river, and ascend it to a great distance; they often break upon the crown, and upset everything they meet in their course, and are accompanied by a fearful noise. In the Severn, the bore is stated to be of almost daily occurrence, and sometimes even to attain a hight of 9 feet; in the Dordogne it rises from 5 to 6 feet, and travels at the rate of about 5 miles in 34 minutes; in the Seine it does not exceed 3 feet; in the Thames it only exists in a rudimentary state; whilst in the Hoogly, at Calcutta, it rises about 5 feet, and is transmitted at the rate of about 17½ miles per hour; and in the Menga the rise is said to be 12 feet.

The tide-wheel at East Greenwich on the Thames is, or was, a breast-wheel raised and lowered with the tide, so as to always have a submergence of four feet water. The buckets are divided into four steps, so as to prevent any jerking or irregular motion. The wheel turns both with the flowing and ebbing of the tide, having a sluice-gate and tail-gate on each side, one pair being opened when the other pair is closed.

Dryden's is an undershot-wheel, each float being set at an equal angle with the radius drawn from it to the center. The bottoms of the buckets have narrow openings to admit air as they rise from the water, so that they may not have to overcome atmospheric pressure.

A species of wheel like the sails of a windmill may be employed, having a vane or float so arranged that it will always turn the same face toward the current, and its axis always rotate in the same direction. See CURRENT-WHEEL.

The turbine is also employed, but is adapted to work with one flow only.

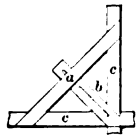
Gwynne's double-acting balanced pressure-wheel is intended to produce a continuous movement both with the ebb and flow; the buckets are arranged to present a direct surface to the passage of the water in either direction, and the wheel turns on a vertical spindle in a casing through which the water flows

Tie. 1. (*Architecture.*) A beam or rod which secures parts together and is subjected to a tensile strain; as a *tie-beam*, which forms the base of the triangle in a roof-truss and withstands the outward thrust of the rafters. See ROOF; TRUSS; KING-POST; QUEEN-POST; TIE-BEAM; RAFTER; etc.

It is the opposite of a *strut* or *straining-piece*, which acts to keep objects apart, and is subject to a compressing force; such as a COLLAR-BEAM, or STRAINING-BEAM (which see).

An angle tie or brace is a framing on the inner side of an angle, for the purpose of tying the work together. Fig. 6427 represents the framing of the external angle of a building.

Fig. 6427.



Angle-Tie.

a, angle or diagonal tie.
b, dragon-piece.
c c, wall-plates.

2. (*Railway Engineering.*) A piece of timber laid transversely of the track and held down by *ballasting*, serving to retain in place the rails, which are spiked to it.

3. (*Nautical.*) *a.* A mooring-bridle.

b. A *lashing.*

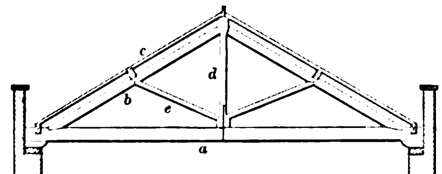
4. A band-fastening for bale-straps. See BALE-TIE, Fig. 540, page 218.

5. (*Mining.*) A support for the roof, attached to a rib.

Tie-beam. (*Carpentry.*) A horizontal timber in a frame connecting posts, and secured to them by a joint, or by mortise, tenon, and pin.

In a roof-truss the king or queen posts are planted upon it, and are strapped thereto. The feet of the *principal rafters* are stepped into the tie-beam which withstands the outward thrust. In dwellings the tie-beams support the ceiling of the room below.

Fig. 6428.



Tie-Beam, etc.

a, tie-beam. *b*, principal rafter. *c*, common rafter. *d*, king-post. *e*, strut.

Tier. 1. (*Nautical.*) *a.* A range of *fakes* of a cable or hawser. A *fake* is a single coil in a tier.

b. Cable tier. A place below decks where the cable is coiled.

c. A row or rank, as of vessels alongside a wharf, or moored alongside each other in a stream.

2. (*Music.*) A row of pipes in an organ.

Tie-rod. A rod acting as a tie in a truss or other structure.

Tier-saw. One for cutting curved faces to bricks for arches and round pillars.

Tier-shot. Grape-shot in regular tiers divided by disks.

Tie-strap. (*Saddlery.*) A long strap having a buckle and chape on one end, used as an extra strap to a bridle for tying.

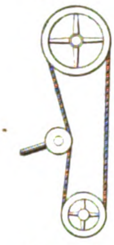
Tie-wall. A transverse wall in the hollow spandril of an arch, at right angles to the spandril wall.

Tif'fa-ny. A thin silk gauze.

Tige. (Fr. *tige.*) A stem or stalk. A pin at the base of the breech in the Thouvenin system of fire-arms, for expanding the base of the ball; an anvil or support for the cap or primer in a central-fire cartridge.

Ti'ger. (*Sugar.*) A tank having a perforated bottom, through which the molasses escapes.

Fig. 6429.



Tightening-Pulley.

Tight'en-ing-pul'ley. One which rests against the band in order to tighten it, to increase its frictional adhesion to the pulleys over which it runs.

Til'bur-y. An open carriage on two wheels. A form of *gig.*

Tile. 1. A thin slab of baked clay.

It was used in great quantity in ancient Mesopotamia among that wonderful people that has passed utterly away, leaving mural remains indicating that it was the most densely populated region of antiquity.

In that country the common mode of keeping records of national and historical events was by stamping inscriptions upon tiles of clay, which were baked after the impression was made Mr Layard, in the course of his excavations at Nineveh, found a large number of these records, some of which were written with such minute characters that a microscope was required to decipher them. He believed that they were read by a magnifying lens, one of which, made of rock crystal, he found among the ruins of the palace of Nimroud.

These tiles are stored away in such order that they were evidently records, but a commoner description of tile furnished the material for many of their structures, sometimes in conjunction or alternation with brick, from which it differed more in form and proportions than in any essential respect.

The tiles of Assyria and China lead the way, so far as the history of this art is concerned, for the Egyptian system was not favorable to the existence of tiles, even in rainless Upper Egypt. While the bricks of Babylon were some burnt and some adobes, the bricks of Egypt were universally adobes, or merely sun-dried, and this does not suit a thin tile, however well it may answer for a thick brick. The references to tiles in Holy Writ are not infrequent. We read of tiles in Ezekiel and in the Gospel of Luke, where the sick man was let down through the tiles. Tiles were also common in Rome at that day.

The art of glazing tiles came from China, and before the introduction westward of this Chinese art, neither bricks, tiles, nor earthenware was glazed, but in cases where it was necessary to render their earthen vessels water-proof, they were daubed with pitch, wax, tallow, or other resistant. See POTTERY.

The vitreous glazes passed from China to India, and spread from thence after the conquest of the latter country by Mahmoud of Ghuzna, the bogy of the warrior episode, in Moore's "Paradise and the Peri." His conquest, wherein, as Moore says, he

> "Choked up with the glittering wrecks
> Of golden shrines the sacred waters,"

occurred A. D. 1000, about the time that Gerbert of Auvergne, the schoolmaster of Rheims, was introducing the civilization of the Spanish Saracens into France and Italy.

The passion for glazed tiles extended from India and Ispahan to Spain, from the thirteenth to the sixteenth centuries.

The palace of the Alhambra at Granada, the residence of the Moorish kings, was built in 1280, and many of the rooms are ornamented with glazed tiles.

The tomb of Sultan Mohammed Khoda-Bendeh, at Sultanich in Persia, was also built in the thirteenth century, and is ornamented on the cupola and minarets with a green glazed tile, and on the architrave with a dark blue tile.

The painted mosque of Gour, in India, now in ruins, was built in 1475, and derives its name from the profusion of glazed tiles which adorned it.

In Ispahan, the domes and mosques are covered with green and blue tiles; and the caravanserai at Mayar, near Ispahan, built in 1580 by the mother of Shah Abbas, is inlaid with green tiles.

The art of glazing tiles passed from Spain to Italy, which soon became celebrated for the taste and execution of its works in that line. Raffaello himself made designs for the paintings in *terra invitriata.*

The art spread to Holland, and long abode there. Delft was its headquarters; and the Dutch tiles, which some of us can recollect as lining the capacious fireplaces of old mansions, have been studied by many thousands besides the excellent Doddridge, who there learned Scripture history.

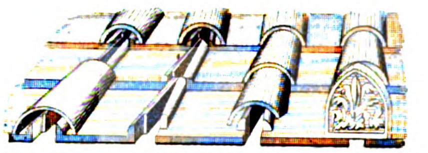
The glazing of delft-ware is given under POTTERY (which see). Under the same caption will also be found a description of the mode of making porcelain, which is closely allied to our present subject.

Rome was originally roofed with shingles; tiles of baked clay were introduced about the time of the war with Pyrrhus.

Tiles of marble were used in Greece about the time of Pausanias, 620 B. C. The temples of Jupiter at Olympias, of Athenæ at Athens (the Parthenon), were thus covered.

Tiles of bronze, gilt, were also used in some cases. The lower edges of the joint tiles were protected and ornamented by *frontons.* The edges of the flat tiles were turned up and covered by semi-cylindrical joint tiles, termed *imbrices.*

Fig. 6430.

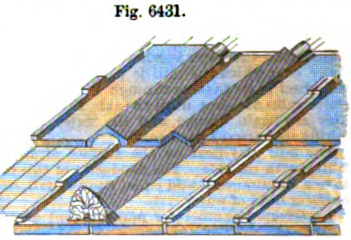


Roman Tiles.

The Greek and Roman tiles were made of marble, and have been imitated in clay.

Flat tiles with raised edges extend from rafter to rafter, the upper end having a rib that enters a groove formed on the under side of the tile placed above it. After these are laid, the joints above the rafters are covered with other tiles, each formed like the half of the frustum of a hollow cone, so that they are able to lap upon each other, their edges lying snugly to flat tiles of the roof. The end of these ridge-tiles was terminated by an ornament.

Fig. 6431.



Greek Tiles.

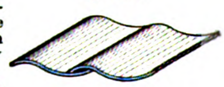
Tiles, both flat and curved, were in great demand in Roman architecture. Roofs were covered with the flat and curved tiles alternating. Tiles two feet square with a foot at each angle were used to line the thermæ, so that an air space between them and the wall should prevent the absorption of the water by the latter.

Tiles are extensively used in Europe for various purposes,— roofs, gutters, pavements, drains, house siding, lining flues, and furnaces, etc. They assume many forms; some have a local character, others are made in imitation of the antique.

Plain tiles are usually made ⅝ inch in thickness, 10½ inches long, 6¼ wide. They weigh from 2 to 2½ pounds each, and expose about one half to the weather. 740 tiles cover 100 superficial feet. They are hung upon the lath by two oak pins, inserted into holes made by the molder.

Plain tiles are now made with grooves and fillets on the edges, so that they are laid without overlapping very far, the grooves leading the water. This is economical of tiles, and saves half of the weight, but is subject to leak in drifting rains, and to injury by hard frosts.

Fig. 6432.



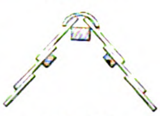
Pan-Tiles.

Pan-tiles, first used in Flanders, have a wavy surface, lapping under and being overlapped by the adjacent tiles of the same rank. They are made 14½×10½; expose 10 inches to the weather; weigh from 5 to 5¼ pounds each; 170 cover 100 superficial feet.

Crown, ridge, hip, and *valley* tiles are semi-cylindrical, or segments of cylinders used for the purposes indicated.

A *gutter*-tile has been introduced in England, forming the lower course, being nailed to the lower sheathing board or lath.

Fig 6433.



Ridge-Tile.

Fig. 6434.

Gutter-Tiles.

Siding-tiles are used as a substitute for weather boarding. Holes are made in them when molding, and they are secured to the lath by flat-headed nails. The *gage,* or exposed face, is sometimes indented, to represent courses of brick. Fine mortar is introduced between them when they rest upon each other.

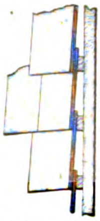
Siding-tiles are sometimes called *weather-tiles* and *mathematical tiles;* these names are derived from their exposure or markings. They are variously formed, having curved or crenated edges, and various ornaments either raised or encaustic.

Modifications of the pan-tile are shown in the examples *a b* (Fig. 6436), the edges being turned up and down respectively. *c d e* are modifications of the ridge-tile, in which the gutter and ridge are placed alternately.

f g show modes of securing. The former is molded with a

lug, which catches above the lath of the roof to hold itself in position. *g* shows a tile molded with two lugs, by which it engages the tiles of the courses above and below.

Fig. 6435.



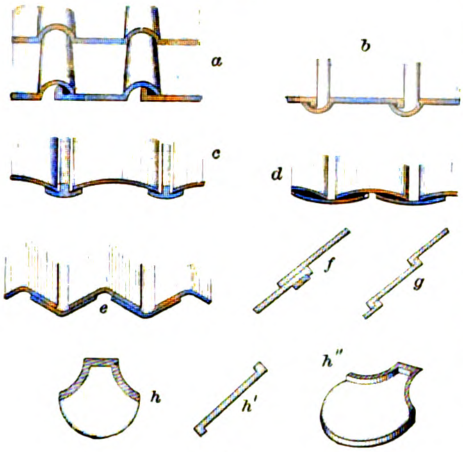
Siding-Tiles.

h h' h'' are elevation, section, and perspective views of a tile exposing a semicircular face to the weather. The semicircular portion has a drop-flange which catches over the re-entering curves of the upper part, these curves having upturned flanges for that purpose.

The glazed tiles are inferior to slate, as they imbibe about $1/7$ their weight of water, and tend to rot the lath on which they are laid. Good slate only imbibes $1/200$ part of its weight, and is nearly water-proof.

The *tile* is somewhat celebrated in an artistic sense, as forming the cover of the basket of keepsakes placed by a nurse upon the tomb of a Corinthian maiden. Being placed over an acanthus root, the basket became inclosed by the foliage, which turned gracefully over when it met the tile, and suggested to Callimachus the Corinthian capital. Such is the story, and it is pretty enough to believe upon a moderate amount of evidence.

Fig. 6436.



Tiles.

Encaustic tiles; ornamental tiles in which the colors are burned in. See page 801.

Galvanized iron tiles have been introduced in France. They are shaped like pan-tiles, so that each laps upon its neighbor in the course, as well as the lapping of each course upon the one beneath it.

The metal being thin, the tiles are easily cut to fit a sloping line of roof, corners, etc.; and they are fastened by a single nail of galvanized iron, with which is used a small leaden washer, to render the nail-hole perfectly tight.

2. (*Brass-founding.*) The cover of a brass furnace. Now made of iron, but formerly a flat tile. See BRASS-CASTING.

3. (*Metallurgy.*) A clay cover for a melting-pot.

Tile-creas'ing. (*Masonry.*) A row of tiles laid along the top of a wall, projecting beyond the face; or each face, if both are exposed. A row of bricks laid *header* fashion is laid above, and is called a *cope*. This is *plain* tile-creasing. A double row laid so as to break joint is double tile-creasing.

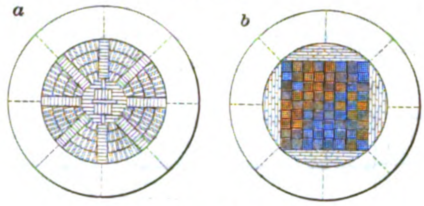
Tile-drain. One made of baked earthenware.

Til'er. A tile-kiln.

Tile-kiln. A form of kiln adapted to *burning* tiles.

A good form of tile-kiln, as used in Staffordshire, England, is shown in the accompanying figure. On the bottom of the oven are first placed 2,000 bricks, as shown at *a*, which is a plan of the oven as seen when eight courses of brick are laid edgewise. The eight rows, with twelve bricks in each, as seen in the plan, cover a space left in continuation of flues from the eight fire-holes. The bricks in the first seven courses are so placed as to leave a flue of an average width of 4 inches. The dotted lines show the position of the fire-holes. Upon these bricks are placed 7,000 tiles, forming a square, the spaces between the

Fig. 6437.



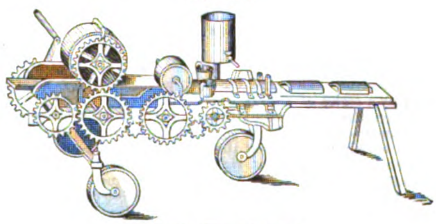
Tile-Kiln.

a, plan of brick courses. *b*, plan of tile courses.

tiles and the curved sides of the oven being filled up with bricks, as seen in the figure. *b* is a plan of the oven as seen when the first course of tiles are placed upon the bricks, seen in the figure *a*. The tiles are placed in bunches of twelve, and laid alternately cross and lengthwise; the nib on each tile spaces it from its neighbor and supports it in vertical position. The spacing of the bricks and tiles allows the circulation of the heat between them, and the circular oven is found well adapted to secure uniformity of heat.

The kiln is protected on the windward side, to prevent uneven urging of the fires. The oven being *set*, the doorway is bricked up and daubed, the fires kindled and kept burning, moderately at first, and then more freely. The usual time for firing is thirty-eight hours, and the consumption four tons of coal for a kiln of the size described. Three days are then allowed for cooling, and they are afterward taken out of the kiln. Those tiles which are to be made of a grayish color are thus treated. It having been ascertained that the tiles are burnt enough, and while still red-hot, a quantity of small fagots of green alder with the leaves on is introduced into each flue. The flue-holes are then well secured, and the holes in the roof each stopped with a paving tile, and the whole surface is covered with four or five inches of sand, on which a quantity of water is thrown, to prevent the smoke from escaping anywhere. It is this smoke which gives the gray color to the tiles, both internally and externally. The kiln is then left closed for a week, when the sand is taken off the top, the door and roof-holes are opened, as also the flue-holes, and the charcoal produced by the fagots taken out. Forty-eight hours after, the kiln is cool enough to allow of the tiles being taken out, and the kiln charged again. Whenever any of the tiles are to be glazed, they are varnished after they are *baked;* the glaze being put on, the tiles are put in a potter's oven till the composition begins to run. The glaze is generally made from what are called lead ashes, being lead melted and stirred with a ladle till it is reduced to ashes or dross, which is then sifted, and the refuse ground on a stone and resifted. This is mixed with pounded calcined flints. A glaze of manganese is also sometimes employed, which gives a smoke-brown color. Iron filings produce black; copper slag, green; smalt, blue. The tile being wetted, the composition is laid on from a sieve.

Fig. 6438.



Hunt's Tile-Machine.

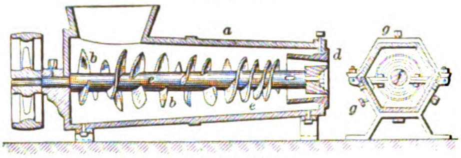
Tile-lay'ing Plow. A mole-plow invented by J. Fowler, Jr., England, about 1850, in which the mole was made to draw in a succession of drain-tiles strung upon a rope. See MOLE-PLOW, Fig. 3207, page 1469.

Tile-ma-chine'. Drain-tiles are either molded flat and bent around a former to the proper shape, or are made at once of a curved form by pressing the clay through a *dod* or mold of the required form. The latter plan is now usual.

Hunt's machine (Fig. 6438) has two iron cylinders, around which webs of cloth revolve, whereby the clay is pressed into a slab of proper thickness without adhering to the cylinders. It is then carried between two vertical rollers, which impart a

semi-cylindrical or other required shape, after which the tiles are polished and finished by passing through three iron molds of horseshoe form, being at the same time moistened by the dripping of water from a tank above, and finally conducted off upon an endless web.

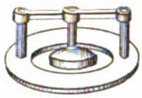
Fig. 6439.



Tile-Machine.

In more recent machines, the tiles are generally formed at one operation, by pressing. A charge of clay sufficient to form a number of tiles is placed in a cylinder and subjected to the action of a piston, which forces it out as a continuous tube through the *dod* (Fig. 6440), after which it is cut into lengths by a wire.

Fig. 6440.

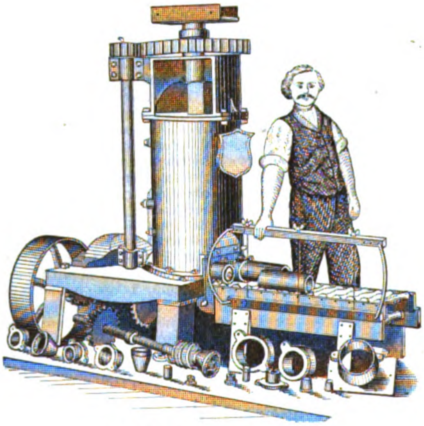


Dod.

The most modern machines generally employ a screw, which serves at the same time to mix the clay and force it through the mold; the process of feeding and molding is thus rendered continuous, no time being lost in charging the cylinder. See also Fig. 1746, page 741.

Tiffany's (Fig. 6441) consists of a vertical pug-mill containing rotary curved knives and a screw-follower for forcing the clay through the dies, an assortment of which are shown at the base of the apparatus.

Fig. 6441.



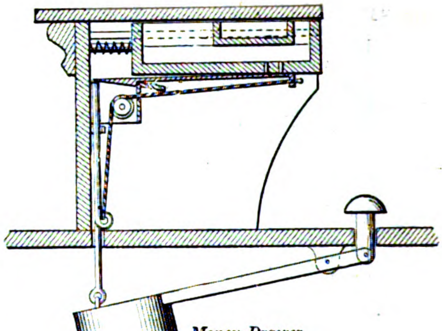
Tiffany's Tile-Machine.

The pipe, on issuing from the dies, is carried forward by a series of rollers having hollowed surfaces, and is cut into lengths by a rocking-frame provided with cross wires. In another machine, the clay is forced through the dies by two plungers working in boxes at the base of the pug-mill, and reciprocated by cranks set at right angles to each other on the same shaft; two sets of dies are employed; one plunger being retracted to allow its box to receive a supply of clay, while the other is engaged in forcing the clay through its die.

Till. A money-drawer in a counter or desk.

Fig. 6442 shows a shop-counter till, which is opened by pressure of the foot on a knob, which lifts a weighted lever and allows a spring to throw the door open. When the foot is withdrawn, the weight pulls the drawer shut.

Fig. 6442.



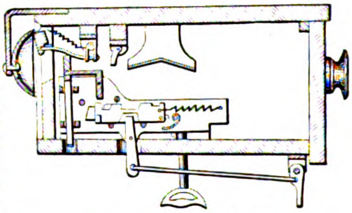
Money-Drawer.

Till-a-larm'. An attachment to drawers, especially to money or till drawers, to announce the surreptitious opening of the same. Some are simple, and are so attached as to strike an alarm whenever the drawer is opened, and consist of a bell and a spring hammer, the latter being tripped by the contact of a stud on the opening drawer. Other devices are more complicated, and only sound the alarm when the drawer is opened by one unacquainted with the specific devices which throw the alarm out of operation.

There are many patents on till-alarms, some of which have complicated locks and secret devices, which cannot be briefly explained within the limits assigned to this subject.

Fig. 6443 has a vertically sliding bolt, employed in connection with a series of notched tumblers, together with springs and catches, and with a catch-rod and plate, all so arranged that when the till is opened an alarm will be sounded upon the bell. By a secret trigger beneath the drawer, the bolt is withdrawn and the alarm-mechanism is undisturbed as the till is opened.

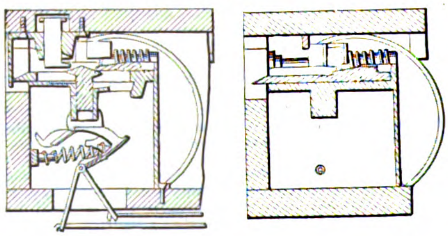
Fig. 6443.

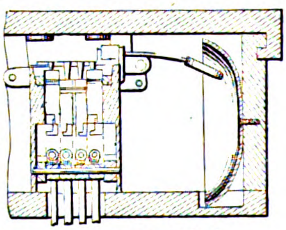


Purrington's Till-Alarm.

Fig. 6444 is a till-alarm and lock. When the till is closed, the outer bolts which rest on the tumblers are raised above the upper surface of the frame, while the central bolts which rest upon the other tumblers extend within the frame and in front of the cross-piece at the rear of the same. If, while the parts are in this position, an unauthorized person undertakes to open the till, the rear cross-piece is brought in contact with the central bolts, which will prevent its farther movement, while the drawer moves forward until the flange is brought against the lug, which prevents farther movement of the till. If the till be now moved back, the alarm is sounded. See also Fig. 129, page 57.

Fig. 6444.





Till Alarm and Lock.

Till'er. 1. A transverse handle at the upper end of a *pit* saw.

2. The handle of a cross-bow.

3. (*Nautical.*) The lever on the head of a rudder, and by which the latter is turned.

Rudders with tillers are shown in paintings of Edfou, Egypt.

Till'er-rope. (*Nautical.*) That connecting the head of the tiller with the drum of the steering-wheel.

Fig. 6445.

Tiller.

Till'er-wheel. More properly termed *steering*-wheel, as it does not always act upon the rudder through the intervention of a tiller, which is a bar or lever projecting

Fig. 6446.

Tiller.

from the rudder-head or rudder-post. See STEERING-WHEEL.

Sometimes called a "pilot" wheel, as that functionary has it in charge in the ordinary steamboating on our rivers.

Till-lock. One adapted to money-drawers of counters. See TILL-ALARM.

Tilt. 1. (*Vehicle.*) *a.* A wagon-cover, usually of canvas on wooden bows.

b. The temporary cover for an artillery-carriage, corresponding to our *paulin* or *tarpaulin*, is called a *tilt* in the British service.

2. (*Nautical.*) An awning over the stern sheets of an open boat, supported by stanchions on the gunwale.

3. (*Machinery.*) A TILT-HAMMER (which see).

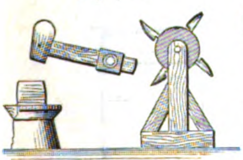
Tilt'ed Steel. Blistered steel heated in a furnace and subjected to the action of a tilt-hammer, which strikes about 700 blows per minute, and increases the solidity and tenacity of the metal.

Tilt-ham'mer. The word *tilt* is derived from a root which means a lifting or up-and-down motion, which is descriptive of the action of the hammer.

The hammer-stock is pivoted as a lever of the first or third order, and is acted upon by a *wiper-wheel*, whose cams or cogs tilt the hammer and then allow it to drop upon the bloom on the anvil.

Its particular use is in compacting the balls of iron as they come from the puddling-furnace, and driving out the dross with which the iron is associated when in the form of *pig*, and some of which is removed by the reverberating flames of

Fig. 6447.



Tilt-Hammer.

the furnace. It is also used in heavy forging.

In the first-mentioned use, the *squeezer* has to some extent superseded it; and in the latter line, the atmospheric and steam hammers — especially the latter — have entirely dispensed with the *tilt* motion when very heavy forgings are under treatment. See STEAM-HAMMER; STEEL-PRESS; FORGING.

A number of other power-hammers are reciprocated in vertical lines by other means than piston and cylinder. A list will be found under HAMMER.

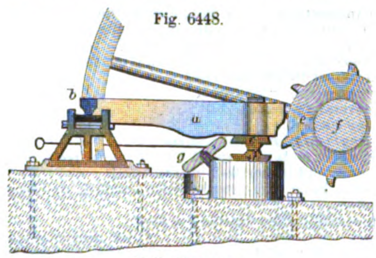
The ordinary tilt-hammer (Fig. 6448) has a cast-iron helve *a* supported at the end *b* on plummer-blocks, fixed upon wooden beams to ease the jar. The head *c* is of wrought-iron, faced with steel, passes through an eye in the helve, and is secured by a key. The base of the anvil is of cast-iron, and the *pane d* of wrought-iron, faced with steel. The head is raised by a series of cams upon a cast-iron collar *e*, called the *cam-ring bag*, fixed on the shaft *f*, which is provided with a heavy fly-wheel.

The hammer has usually a drop of 16 to 24 inches, and strikes 75 to 100 blows per minute. When not in use it is propped up by the support *g*. See TRIP-HAMMER; STRIKER; STEAM-HAMMER. See list under HAMMER.

The cushioned hammer shown in Fig. 6449 (Butterfield's patent) is made of iron, except the helve. The anvil and anvil-block are cast-iron, made separate and adjustable. The latter has a separate foundation, independent of that of the main bed.

The balanced helve swings upon two hardened adjustable steel centers, and is put in motion by the use of a broad adjustable steel eccentric operating in connection with the working-beam and rubber cushions, the length of stroke being governed by the adjustable eccentric; the force and power of the blow is greatly influenced by the reactive and united action of the cushions, which so far absorb the jar that a person holding his

Fig. 6448.



Tilt-Hammer.

hand upon the working parts, when under the most rapid and violent motion, cannot identify the strokes of the hammer.

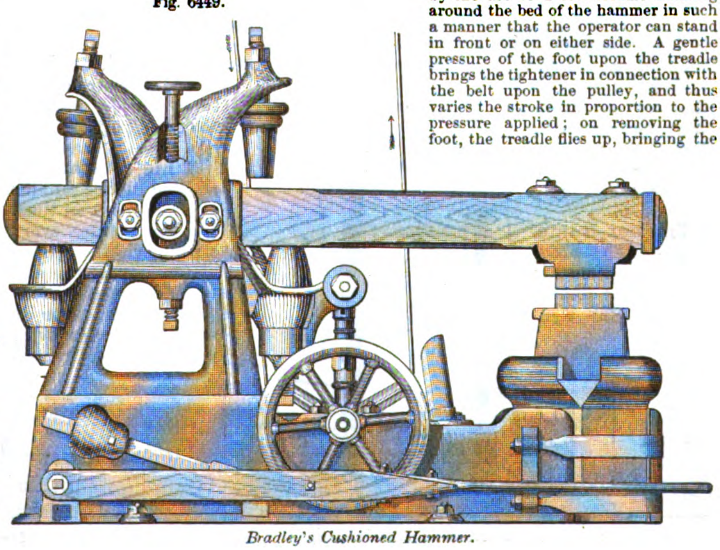
The cushions do the double work of relieving the frame from jar and giving force and power to the blow.

Tension can be given each cushion by raising or lowering the set-screws in the upper and lower sockets of the working-beam; the helve is placed in position and adjusted to any stroke or sized die by the use of set-screws where the same is attached to the frame; the husk is also adjusted to the helve in the same manner.

The object of raising or lowering the husk is to enable the operator to use different thicknesses of dies, or adjust it to the same dies after grinding, etc.

The power is applied and regulated by the use of a foot-treadle running around the bed of the hammer in such a manner that the operator can stand in front or on either side. A gentle pressure of the foot upon the treadle brings the tightener in connection with the belt upon the pulley, and thus varies the stroke in proportion to the pressure applied; on removing the foot, the treadle flies up, bringing the

Fig. 6449.



Bradley's Cushioned Hammer.

brake upon the balance-wheel, stopping it instantly, leaving the hammer up, as it cannot stop with the dies closed.

Tilt'ing-fil'let. (*Roofing.*) The strip, $2\frac{1}{2} \times \frac{3}{4}$ inch, and chamfered to an edge, laid down around the edge of a roof where the edges of the shingles or slates abut upon a wall. The object is to avoid leakage at the arris. An *arris-fillet.*

Tilt-mill. (*Metal.*) A building where a *tilt-hammer* is used.

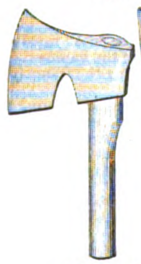
Tilt-roof. A round-topped roof, shaped like a *tilt* or wagon-cover.

Tim'ber. 1. (*Carpentry.*) A piece of wood in a frame. See BEAM; GIRDER; BRACE; TIE; JOIST; POST; PLATE; PURLIN; STRUT; etc. See list under CARPENTRY.

2. (*Shipbuilding.*) One of the curved frames which form the ribs of a ship. They are built up of several pieces: the *floor-timbers* are between the *keel* and *keelson*, and the outward and upward extension-pieces are *futtocks*, first, second, third, etc. The portions extending above the deck-level are the *top* timbers. See FRAME, Fig. 2093.

Cant timbers are placed obliquely on the keel.
Filling-timbers are to fill up between the frames.
Knuckle-timbers are the foremost in the bow.
Fashion-pieces, the hindmost in the quarter.
Each timber-frame comprises: —
The *cross-piece*, or half-floor.
The several *futtocks*.
The *top timber*.
The *lengthening-piece* (if necessary).
Their upper ends are capped by the *rough-tree rail*.
The lower end is mortised into the keel.
The *skin*, inner and outer, is bolted, nailed, or tree-nailed to the timbers.
Each course on the outside is a *strake*.
Thick *strakes* are *wales*.
To the channels (*chain-wales*) the *shrouds* and *back-stays* are connected.

Fig. 6450.



Timberer's Axe.

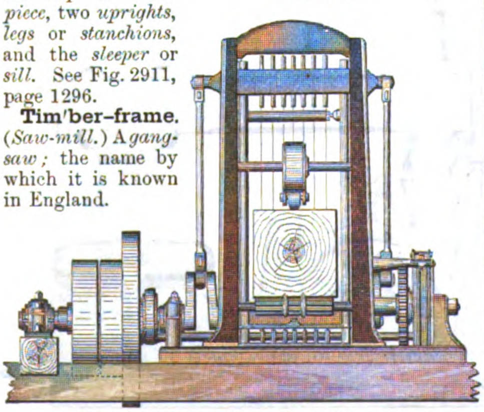
Tim'ber and Room. (*Shipbuilding.*) The width of a timber and a space. Also called *room* and *space*, or *berth* and *space*.

Tim'ber-bridge. See WOODEN BRIDGE; also list under BRIDGE.

Tim'ber-er's Axe. (*Mining.*) An axe or hatchet of the mine-carpenter, used in chopping to length and notching the timbers which support the roof and sides of the gallery or drift. A set of timbers consists of the *cap* or *head-piece*, two *uprights*, *legs* or *stanchions*, and the *sleeper* or *sill*. See Fig. 2911, page 1296.

Tim'ber-frame. (*Saw-mill.*) A *gang-saw*; the name by which it is known in England.

Fig. 6451.



Worssam's Timber-Frame (End Elevation).

Worssam's (Figs. 6451, 6452) comprises an iron sole-plate bolted to a timber framing and carrying upright standards. It has a swing-frame carrying a gang of saws and reciprocated by two connecting-rods, which vibrate outside of the main standards by the action of a double-throw crank-shaft. The timber is propelled to the saw on rollers, top-pressure rollers being provided to keep it well down. The ends of the timber are supported and guided by carriages running on rails back and front of the machine. See also Plate LIV., page 2042; Fig. 2157, page 942.

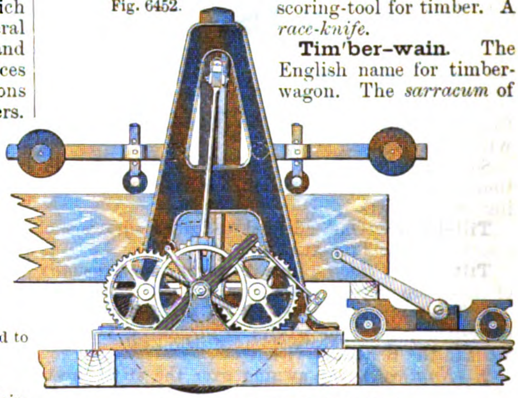
Tim'ber-head. (*Shipbuilding.*) So much of a frame-timber as rises above the deck.

Tim'ber-hitch. (*Nautical.*) The end of a rope is taken round a spar, led under and over the standing part, and passed two or three turns round its own part, making a jamming-eye.

Tim'ber-scribe. A scoring-tool for timber. A *race-knife*.

Tim'ber-wain. The English name for timber-wagon. The *sarracum* of Juvenal. Shown on the Trajan column.

Fig. 6452.



Timber-Frame (Side Elevation).

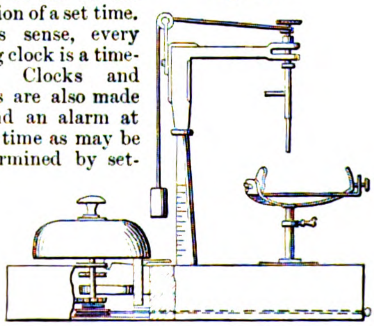
Tim'bre. Fr. (*Music.*) The *quality* of tone distinguishing voices, instruments, and stops, irrespective of *pitch* or intensity.

All the notes of a given stop of an organ have of necessity the same *timbre*, but in pitch they range throughout the extent of the chromatic scale. Corresponding notes, of *stops pitched in unison*, such as the *open diapason*, *dulciana*, *trumpet*, *bassoon*, *cremona*, *vox-humana*, have the same pitch, but each differs from the others in *timbre*; the *quality* of the tone is different. This difference is attained in various ways. Some of the pipes have wooden mouth-pieces, others metallic mouth-pieces, reed pipes, reeds of varying qualities, tubes of varying proportions and shapes, to imitate the peculiar sounds of the various instruments after which they are named, as *flute*, *trumpet*, *bassoon*, *oboe*, etc.

Tim'brel. A drum or tambourine used in ancient times. We read of it in Exodus and Job. Miriam sang, danced, and played on the timbrel when she took her part in the grand antiphonal by the Red Sea. See TAMBOURINE; TABRET.

Time-a-larm'. An audible notice at the expiration of a set time. In this sense, every striking clock is a time-alarm. Clocks and watches are also made to sound an alarm at such a time as may be predetermined by set-

Fig. 6453.



Time-Alarm.

ting the machinery therefor. (See ALARM-CLOCK.) The term is, however, specifically applied to a device to waken sleepers; in some cases it goes so far as to fire a pistol, strike a match, light a candle, and upset the bed, or empty a pitcher of water into the face of the sleeper. Strange how much trouble some people will take not to rest easy!

In Fig. 6453, the weight is elevated by coiling its supporting cord upon the shaft, and is raised so high that when the shaft is connected to the spindle of the minute-hand, the required time shall elapse before the weight descends sufficiently to depress the detent of the alarm. A scale on the post indicates the hight to raise the weight.

Time-ball. A ball on a pole, dropped by electricity at a prescribed instant of time. An *electric time-ball.* It is used especially in maritime cities to give time to the officers of the ships in port.

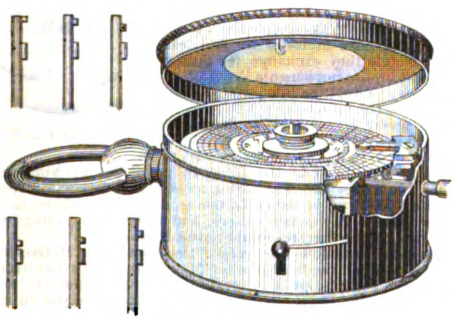
Time-can'dle. One in which the size and quality of the material and the wick are so regulated that a certain length will burn in a given time. Candles colored or indented at certain intervals so as to mark time were patented in England in 1859.

In Asser's Life of Alfred the Great it is stated that the king had for his daily use six tapers, each 12 inches long and containing 12 dwts. of wax, and divided into 12 parts or inches, of which three would burn in one hour. To prevent flaring and irregular consumption, he shielded the light by thin plates of horn, making a lantern. See LANTERN.

Time-de-tect'or. An instrument for recording the time at which a watchman may be present at different stations on his beat.

It is a kind of large strong watch, which is carried by the watchman, and is provided with several keys, differing some-

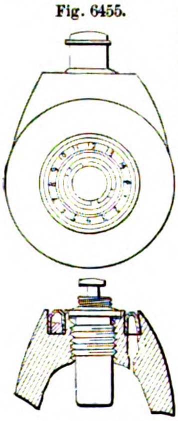
Fig. 6454.

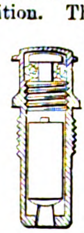


Time-Detector.

what from each other, and each adapted to operate a marker appropriate to itself alone, and which leaves an imprint on its own particular circle of the dial; one of these keys is secured at each station to be visited, and that one must be employed in order to leave the proper record, it not being accessible to the watchman at any other point.

Fig. 6455.





Time and Percussion Fuse for Explosive Shells.

Time-fuse. A fuse which can be so arranged as to explode a charge at a certain determinate interval after the time of its ignition. This is usually effected either by cutting out or off a portion of the fuse or by employing compositions of which given lengths burn at different rates.

Fig. 6455 shows a "Borman" fuse, which at the discharging point is in contact with a chamber containing quick powder, and communicating with the interior charge of the shell. See also FUSE, Fig. 2132, and pages 928, 929.

Time-keep'er. (*Horology.*) A watch or clock. See HOROLOGICAL INSTRUMENTS, list, pages 1123, 1124.

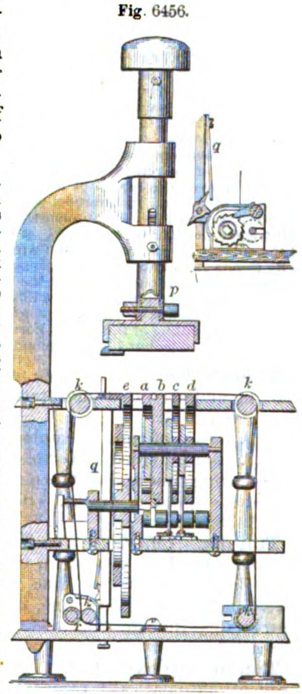
Time-lock. A lock having clock-work attached, which, when wound up, prevents the bolt being withdrawn when locked, until a certain interval of time has elapsed, even by means of the proper key. Various devices may be employed for this purpose; in one, a circular stop-plate rests against the end of the bolt and resists its withdrawal until pushed away by the movement of the train at the end of the time to which it was wound up. See ALARM-CLOCK, page 57.

Ti-men'o-guy. (*Nautical.*) A rope made fast to an anchor when stowed, to keep ropes from fouling on it.

Time'piece. An instrument for indicating time. See CLOCK; WATCH; CHRONOMETER; CLEPSYDRA; HOUR-GLASS; DIAL. See list under HOROLOGICAL INSTRUMENTS, page 1123.

Time-print'ing Ma-chine'. An apparatus for imprinting on a letter, dispatch, or other document the time at which it was sent, received, filed, etc. Adapted for use in telegraphic or other offices where numerous records of this kind have to be made.

Fig. 6456.



Hinchman's Time-Printing Apparatus.

Fig. 6456 is a stamping-apparatus which automatically records the time of each impression made upon it. It comprises a clock provided with a minute-wheel having 60 teeth, which, through the medium of a lever having at one end a spring nib which has a limited freedom of movement in one direction, acts upon a ratchet-wheel also having 60 teeth, and borne upon the same shaft with the plain wheel *e* on which the minutes are engraved. A pin on this wheel at the expiration of each hour strikes a pawl-lever, which rotates a wheel *a*, having the hours engraved on its periphery; to this is affixed a wheel *b* having 24 divisions, 12 marked A. M. and 12 marked P. M. *c* is a wheel numbered from 1 to 31, corresponding to days, and *d* a wheel having the months engraved on its circumference; these two wheels are adjusted by hand. An endless ribbon passes over the faces of the wheels *a b c d e* around rollers *k k k k*, and is inked by contact with the inking-roller *r*. Impressions are made by the hand-stamp *p*, which at the same time depresses a pawl-rod *q* that engages a ratchet-wheel *s*, causing the lower left-hand roller to rotate and feed the ribbon.
